The second master/slave device is the da Vinci robot (Intuitive Surgical, Sunnyvale, CA). This consists of a master console and a bedside slave. With this system, there are three or four arms (depending upon the model) mounted on a central surgical cart. These consist of one arm which manipulates a 3-D camera and two or three arms which contain and manipulate interchangeable instruments. All of these robotic arms are docked to the patient. Since the slave apparatus is separate from the bed, the bed position cannot be manipulated once the robotic arms are docked to the patient.

There are both advantages and limitations of currently available robotic systems. They are able to overcome constraints inherent to human surgery. For instance, offline robots allow for preprogrammed, accurately reproducible interventions. These systems can be highly precise. For instance, the MrBot, an MRI-compatible offline robot has been shown to place brachytherapy seeds to an accuracy of within 0.652 mm.23 Online robots avoid loss of dexterity caused by human fatigue and they have the capacity to filter out surgeon tremor by allowing the surgeon to set the scale of hand movement to instrument movement. For example, if the hand control is moved 1 cm, the robot can scale the instruments to move 1 cm, 5 mm, or a smaller fraction of that distance.

Another advantage is the dexterity afforded by the mechanical properties of the robotic surgical instruments. Da Vinci instruments are currently manufactured in 5 and 8 mm diameter and they allow manipulation with 7º of freedom. This contrasts with the Zeus system which allows 5º of freedom.22 Of great benefit is the fact that the distal ends of the instruments articulate and provide the instrument with the same motion as that of a human wrist. This enables the surgeon to articulate the instrument around corners in difficult-to-reach small spaces a long distance from the incision or port site. With regard to laparoscopic surgical procedures, this increases dexterity compared with traditional instruments because there are 7º of freedom as opposed to 4 with the traditional laparoscopic instruments. This accelerates the learning curve compared with traditional laparoscopic procedures since the instruments and the controls simulate the idea that the instruments are an extension of the surgeon’s hands. The console is constructed in such a manner so that the surgeon is able to operate from a seated position with the hand controls in an optimal ergonomic location.24,25

Figures 3 through 6 illustrate the da Vinci Surgical System. Pictured are the surgeon console (master), the bedside robotic device (slave) with attached robotic arms, and a wristed instrument with 7º of freedom. Visualization with online robotic systems is also advantageous. With the da Vinci surgical system, the camera is a high-resolution, 3-D system. This is made possible by having two cameras present in a single instrument. Feedback from these is routed through a binocular viewing screen present in the surgeon console. Additionally, the slave cart is constructed so that the camera is initially aligned in the center of the operative field so that proprioception regarding left/right and forward/backward is maintained. This allows the surgeon to have the operative field of view aligned directly with the instruments that are being manipulated.

Many surgical procedures have been accomplished using the da Vinci robot. Radical prostatectomies, nephrectomies, pyeloplasties, coronary artery bypass, uterine fibroid excisions, mitral valve replacement, gastric bypass, cholecystectomies, and even supraglottic partial laryngectomies have been performed (www.intuitivesurgical.com).20,24,26 Suturing with the da Vinci robot has a faster learning curve than with conventional laparoscopy.16 Most of these procedures have shorter convalescence periods when compared with the open surgical equivalent. Blood loss is also less with some da Vinci surgical procedures.

such as radical prostatectomies compared with traditional open surgical procedures.27–29

One of the original reasons why robotic surgery was developed was for telesurgery, where the surgeon is able to operate on a patient from a remote location. The intent at the time of the earliest research and development was for battle field applications so that injured soldiers could undergo emergent surgical intervention in an armored vehicle with the robotic instruments controlled by a surgeon at a more secure location.30 Multiple transcontinental telesurgical procedures have indeed been performed including

Figure 5 Da Vinci surgical system with the surgeon manipulating the robotic instruments at the slave cart by moving the hand and foot controls at the master console. (Reprinted with permission from Intuitive Surgical, Inc., Sunnyvale, CA.)

a laparoscopic cholecystectomy and obtaining percutaneous renal access for treatment of nephrolithiasis. This allows the potential for an experienced surgeon to mentor others or to prevent or repair surgical errors from a remote location. Also, robots allow surgeons to avoid or minimize exposure to radiation or other hazardous materials since they can often manipulate the robotic devices at a safe distance from the patient.21

There are several disadvantages of robotic surgery which bear discussion. Presently, the technology is expensive. The cost of the robot ranges from $1.12 to $1.65 million with an annual maintenance fee ranging from $109,000 to $165,000 depending upon the specific da Vinci model (Intuitive Surgical, February, 2007 price list). The instruments used have a limited number of uses, usually 10 uses before they need to be discarded. They generally cost from $200 to $320 per instrument per use (often five instruments per case are used). One likely contributing factor to the present high cost is the paucity of competition in the market place. Several competing companies are currently in the process of developing telerobotic systems, and it is possible that in the future this may lead to improved cost containment.

Extent of operating room time and space utilization are also potential considerations. Considering the different stages of procedures such as setting up the robot and docking it to the patient, operating room time increases. With master/slave robot systems, the setup time is substantial, and there is significant training involved for the operating room staff being able to set up the robot. Setup times and surgical times do, however, improve with experience. Also, one may need additional space in the operating room to accommodate the robotic system.

There are other logistical issues unique to robotic surgery that can add some adversity. For instance, the smallest instruments currently available for the da Vinci robot are 5 mm in diameter and additional miniaturization may be needed to facilitate microsurgical procedures within a confined space such as the oropharynx. A further disadvantage with the master/slave device is that the surgeon is not part of the sterile field and is therefore reliant upon the assistant to change instruments contained within the robotic arms. If there is a sudden and unexpected change within the operative field such as arterial bleeding which cannot be controlled robotically, the surgeon is dependent upon the assistant at the patient’s bedside until he or she is able to scrub in for portions of the surgery which may be safest performed without using the robotic slave component.

Although there are currently ongoing projects to improve this, robotic devices currently lack haptic feedback. Particularly with novice surgeons, it is possible to break sutures when tying knots or to crush or tear tissue because one must rely solely on visual cues to assess for how hard one is pulling on or pinching a suture or bit of tissue. With additional practice, surgeons are able to adapt to visual feedback as opposed to haptic feedback.

Robotic surgery may represent an ongoing paradigm shift in surgical practice. The available technology will continue to improve, making robotic surgery easier and likely more affordable in the future. This technology will continually broaden in its applicability. With respect to otorhinolaryngologic applications, progressive miniaturization will be advantageous for extirpative and reconstructive procedures which are presently difficult to accomplish with handheld instrumentation.

In this chapter, there are inherent advantages of robotic surgical technology including its tremendous 3-D visualization, the ability to finely scale instrument motion, its filtration of hand tremor, and the small and versatile end-effector instrumentation that allows one to operate in confined spaces in a manner similar to open surgery.

Transoral Robotic Surgery

The development and application of transoral robotic surgery (TORS) have followed transoral laser microsurgery which has gained limited popularity over the past 5 years. There are certain factors that may have hindered the widespread use of endoscopic laser microsurgery that may be overcome with TORS. One of the basic disadvantages is the well-recognized steep learning curve associated with transoral microsurgical procedures. The surgeon typically sits at arms length from the patient’s oropharynx and larynx while looking through the microscope. This operative configuration requires the use of long instruments that have an inherent fulcrum effect. This fulcrum effect results in the tip of the instrument moving in the opposite direction.
of the hand movements, and small movements of the surgeon’s hand translate into much larger movements at the instrument tip. In addition, small hand tremors are further magnified through the optics of the operating microscope. Also, the tips of the classic endoscopic oropharyngeal and laryngeal instruments are fixed, and this lack of rotation or wristed movement limits the actual surgery and does not allow more advanced techniques such as suturing. Overall, these disadvantages that are inherent to conventional transoral or endoscopic microsurgery are for the most part eliminated with the evolving robotic technology.

Pioneering work with TORS in preclinical and early human evaluation has established its feasibility for oropharynx and supraglottic procedures while providing principles for exposure and patient safety. While it is still early in the human clinical trial experience with TORS, for base of tongue cancers, O’Malley and Weinstein (unpublished data) are successfully resecting T1 to T3 cancers to negative margins with excellent postoperative healing and speech and swallowing results. The following sections will discuss some key operating room setup and technical principles for TORS procedures ranging from the larynx to nasopharynx.

**Basic Operating Room Setup.** For TORS, the operating suite configuration and robot position varies significantly as compared to the typical abdominal and pelvic robotic procedures where the patient’s head is situated toward the anesthesiologist and the robot is aligned perpendicular to the long axis of the patient. For transoral work, this setup would not allow access and robotic arm alignment. In TORS, the patient’s head is rotated 180° away from the anesthesiologist and the robot is introduced at approximately 30 to 45° angle to the long axis of the patient (Figure 8). The operating console is placed in the corner of the operating suite with a clear path for the surgeon to reach the patient’s head should this be required.

**Surgical Exposure.** The surgical exposure for TORS differs from conventional endoscopic microsurgery of the larynx and pharynx in that the robotic instruments are not introduced through a standard closed tube or even a bivalved laryngoscope. Standard closed tube or even bivalved laryngoscopes do not provide sufficient space anterior to posterior and lateral to introduce the high-magnification, 3-D endoscopic camera and the two or even three end-effector robotic instruments. For TORS, either the standard Crowe-Davis retractor (Figure 9) or the FK retractor (Figure 10) are used to provide access to the tonsil, base of tongue, supraglottis, glottis, and even the pyriform sinus. For the majority of procedures, once the Crowe-Davis or FK retractor is placed, further repositioning is not required. Upon adequate retractor positioning and exposure, a 0° or 30° endoscope can be used for excellent visualization depending on the particular operative site. A key advantage of the 30° endoscope is the ability to rotate the endoscope 360° to get angular exposure which significantly aids in anterior and lateral visualization of the anatomy and reduces the need for frequent retractor manipulation that may be required to gain visualization in conventional transoral endoscopic procedures.

**Maintaining Hemostasis and Managing Secretions.** An important principle to any surgical procedure, but in particular endoscopic procedures, is the maintenance of hemostasis. For
TORS, one key factor in the ability to achieve hemostasis is the tremendous high magnification and 3-D optics that allow the surgeon to see very tiny tissue vessels prior to transecting them. Also, the typical robotic instruments used are a standard grasper or robotic forceps and a spatula tipped monopolar cautery end effectors. (Published with permission, copyright © 2007 B.W. O’Malley Jr, M.D and G. Weinstein, M.D.)

The use of robotic technology for transoral surgery exposes patients to certain risks that are inherent to either positioning of the robotic arms and the manipulation of the instruments. While it is important to acknowledge the potential for patient injury, the safety record of the da Vinci system in thoracoscopic and laparoscopic procedures established a firm background of overall device safety. For TORS, specific issues related to instrumentation positioning and transoral placement of the robotic arms include the potential for lip and teeth injuries, nose, face, and ocular injuries, mucosal injuries, and neck or spine injuries. These safety concerns have been addressed in preclinical models with TORS and from unpublished results to date in clinical experimentation (Winstein and O’Malley, unpublished). Also, for human TORS procedures, safety goggles with malar cushioned safety shields are used for enhanced patient protection (Figure 12).

Future Applications of Transoral Robotic Surgery. It has been the experience of the authors that the excellent 3-D optics and wristed movements of the robotic instruments provide the surgeon with views of the anatomy including vascular and nerve structures that are not possible even with conventional endoscopic microscopy techniques. These key attributes of visualization and instrument mobility are proving invaluable for manipulating soft tissues and critical structures within the oral cavity, pharynx, and larynx. These key factors of vision and tissue manipulation should allow robotic head and neck surgery to extend well beyond the upper aerodigestive tract and into the retropharynx, parapharynx, neck, and even skull base.

As robotic surgery technology continues to advance and with the design and manufacturing of smaller instrumentation, integrated suction, and drills, and even the addition of tactile feedback or haptic technology, the opportunities to apply robotic surgery to all aspects of otolaryngology head and neck surgery will surely increase.

Airway Management in the Infant and Child

Michael J. Rutter, MBChB
Robin T. Cotton, MD

An infant or child presenting with acute airway obstruction is an emergency and potentially one of the most challenging patients to manage. However, the fundamentals of airway management, whether acute or chronic, child or adult, remain the same. Therefore, developing a mental algorithm for the management of airway compromise is highly desirable.

Management of neonatal and pediatric airway disease reflects in large part the evolution in neonatal standards of care. Prolonged intubation of the neonate in the 1960s effectively gave rise to neonatology as we now know it but, as a consequence, resulted in many infants requiring tracheostomy for the “new” disease of pediatric acquired subglottic stenosis. This in turn led to the development of techniques to repair subglottic stenosis, such as laryngotracheal reconstruction. Historically, the majority of these children were normal children with an airway stenosis. Currently, the advent of neonatal nasopharyngeal continuous positive airway pressure (CPAP) has resulted in far fewer neonates requiring prolonged intubation but with this being balanced by the salvage of more infants with extreme prematurity and complex congenital disorders. As a consequence, children presenting to an otolaryngologist with subglottic stenosis increasingly have their airway obstruction as merely one of a list of complex problems.

PRENATAL AIRWAY COMPROMISE

Congenital causes of neonatal airway compromise are usually discovered at birth or in the first few days or weeks following delivery. However, the increasing sophistication of prenatal fetal imaging has resulted in both a greater appreciation and a rising rate of diagnosis of potential causes of neonatal airway obstruction. Sophisticated Doppler ultrasound and fetal magnetic resonance imaging (MRI) may reveal cervicofacial pathology with the potential to cause acute airway compromise on delivery or in the neonatal period. These may be divided into three main groups, namely massive cervical tumors such as lymphatic malformations or teratoma (Figure 1), severe mandibular hypoplasia, and atresia of the larynx or trachea with complete neonatal airway occlusion. This latter condition is known as the congenital high airway obstructive syndrome (CHAOS) and occurs in association with polyhydramnios, lung hyperexpansion with exerted diaphragms and prune-belly syndrome.

Frequently, fetal hydrops may be seen in association with this. In some rare cases, complete upper airway obstruction may not result in the secondary features of CHAOS because of airway decompression through a tracheoesophageal fistula, and in some of these cases esophageal intubation at the time of delivery may allow fetal oxygenation and ventilation through the tracheoesophageal fistula until such time as the airway can be secured.

In any of the above conditions, if the fetus has impaired swallowing due to the nature of the disease, polyhydramnios may also be noted with a predisposition to premature delivery.

In pregnancies, in which fetal airway compromise at delivery is anticipated, fetal salvage may be achievable through use of the ex-utero intrapartum treatment (EXIT) procedure as originally described by Harrison and colleagues. While there are differing techniques for achieving the same end, the intent is that the fetal airway is secured while the fetus is still oxygenated by the placental circulation. One of the two most commonly used techniques is the EXIT procedure with the mother and fetus fully anesthetized and with a caesarean section exposing the head and one arm of the fetus while maintaining the bulk of the fetus and as much amniotic fluid as possible within the uterus to prevent placental abruption.

This technique has the advantage of allowing time, up to 60 minutes of placental circulation, in which the airway may be secured. However, the disadvantages are that the fetus is fully anesthetized and, therefore, unable to maintain its own airway should this be an option and that access to the fetus is suboptimal as only part of the fetus is exposed to the surgeon securing the airway.

The second technique is for the caesarean section to be performed under spinal anesthesia, so that both the mother and fetus are awake and, therefore, the fetus has the potential to maintain its own airway if this is possible. The whole fetus is delivered through the caesarean section still attached to the umbilical cord and laid on a tray on the mother’s thighs while the airway is secured. The advantages of this technique are that the fetus may be able to maintain its own airway and breathe spontaneously, and if the airway does need to be secured, access to the infant’s airway is optimal. However, the significant disadvantage is that, as the uterus has effectively been evacuated, the placenta will abrupt usually within 5 minutes as the empty uterus contracts, limiting the available time to secure the airway. These interventions are complex, teamwork is essential to achieving a good outcome, and, therefore, the best results are usually obtained in the small number of institutes with a tertiary care fetal therapeutic unit. Needless to say, securing the airway is not the end point for management of the neonatal airway under these circumstances, but rather the commencement of a cascade of intervention designed to both maintain a safe and secure airway while managing the underlying disease process that necessitated an EXIT procedure. Often these children may be intubated at delivery, but this is usually an inherently unstable airway because of the difficulty of intubation; and, therefore, conversion to tracheostomy is usually required once the infant has otherwise stabilized.

EVALUATION OF THE COMPROMISED NEONATAL AIRWAY

The signs and symptoms of airway compromise in the neonatal period reflect not only the severity of the obstruction but also the level of obstruction. Therefore, it is useful to subdivide the presenting signs of airway compromise into nasal, pharyngeal, laryngeal, and tracheal.

Neonatal Nasal Obstruction

The neonate is an obligate nasal breather for the first 6 weeks of life; and, therefore, nasal obstruction may present with life-threatening signs such as refusal to feed, tachypnea, and cyanosis. Neonatal nasal obstruction can be classified as functional or anatomic.

Figure 1 Prenatal ultrasound of a cervicofacial teratoma.
Airway compromise. Presentation may be with life-threatening apnea, usually when sleeping or quietly resting. However, an excellent airway is maintained when upset and crying due to transtracheal respiration. Whereas traditionally evaluation of airway compromise in the neonate has involved evaluation of the ability to pass a 6 French suction catheter or seeing whether a mirror will mist on an inspiratory breath through the nose, the cornerstone of evaluation currently is flexible nasopharyngoscopy and laryngoscopy using a small flexible endoscope placed through the nose. This is complemented by the use of computed tomography (CT) scanning which is the radiological study of choice.

**Pharyngeal Airway Compromise**

Compromise of the pharyngeal airway, whether due to tumor, pharyngomalacia, glossophtisis, or supralaryngeal cysts, usually presents with stridor rather than stridor (higher pitched) and with the compromise being most marked during sleep or when the child is supine. Dependent upon the pathology, symptoms may be markedly worse in certain positions, and presentation may include apnea, cyanosis, retractions, and “dying” spells. If there is significant mass effect in the supralaryngeal pharynx, the cry may be muffled.

**Laryngeal Airway Compromise**

Supraglottic, glottic, or subglottic laryngeal compromise of the neonatal airway classically presents with inspiratory stridor; and, if the pathology is fixed as opposed to dynamic, such as is seen with a subglottic stenosis, expiratory stridor will also be present. While stridor is the most noticeable manifestation of laryngeal airway compromise, the severity of retractions is a more accurate reflection of the severity of the airway compromise. Retractions usually occur in the supravclavicular and suprasternal regions, but intercostal, sternal, or subternal retractions may also be seen. The area of maximal retractions does not seem to have a direct bearing on the underlying obstruction causing the retractions. Infants with laryngeal airway compromise frequently also present with apnea and cyanosis and may have an abnormal cry if the vocal folds are involved.

**Tracheal Involvement**

Compromise of the tracheal airway may be from tracheomalacia, vascular compression, or congenital tracheal stenosis. These children may present with biphasic stridor with a fixed stenosis or inspiratory stridor and expiratory wheeze with a dynamic compromise. Retractions are common while apnea and cyanosis are comparatively unusual; dying spells may be noted in severe cases. In dynamic tracheal obstruction there is often a characteristic “honking” cough, while lower tracheal narrowing is often characterized by a biphasic wet-sounding breathing pattern, sometimes termed “washing machine breathing” with retained tracheal secretions moving in and out through an area of narrowing. Characteristically, these children will occasionally cough and clear the secretions and then sound markedly improved for 15 to 20 minutes until the secretions start building up again. The appropriate investigations for suspected tracheal compromise include bronchoscopic evaluation and contrast enhanced CT scan of both the trachea and surrounding vasculature. Before commencing these investigations, a plain airway (high kilovolt) X-ray will often provide valuable information warning the prospective bronchoscopist of tracheal narrowing or tracheal deviation.

**Evaluation of the Intubated Neonatal Airway**

In neonates who present to the otolaryngologist already intubated, the first question is whether the airway is still compromised despite being intubated. If there is still airway compromise by implication, there is probably pathology distal to the tip of the endotracheal tube. If the airway is adequately maintained with an endotracheal tube, history should be sought on the indications, symptoms and signs that led to intubation; whether attempts at extubation have been made; and, if so, what was the reason for failure. It should also be established how straightforward the intubation was, as an infant known to be a difficult intubation should not be extubated lightly except under controlled conditions. If a child has had a previous failed extubation attempt but did not require immediate reintubation, evaluation of the child in the hours following extubation may provide the most valuable information in terms of the cause of airway compromise. However, if a child immediately failed extubation and required rapid reintubation, reevaluation in the operating room may be the most prudent approach with the child minimally sedated and with both flexible and rigid endoscopy on hand to evaluate the airway immediately following extubation.

In the infant, feeding is the most strenuous form of exercise bar crying. Whereas an older child with a compromised airway may present with exercise intolerance, an infant will present with feeding difficulty. This may be reflected in stridor, cyanosis, retractions, choking episodes, or failure to thrive. The more acute the onset of airway compromise is, the more severe the degree of feeding difficulties is likely to be.

**Oxygenation and Ventilation**

In infants with premature lungs, an ancillary oxygen requirement to maintain adequate oxygen saturations is common, and in extreme prematurity inevitable. However, term infants with a compromised airway frequently do not present with oxygen desaturations until the degree of airway compromise is extreme. Often the presentation is not with an inability to oxygenate but rather an inability to ventilate with this being reflected in the CO2 level. Hypercapnia may be acute or chronic. Acute hypercapnia may result in respiratory depression and with a relative respiratory acidosis. However, chronic hypercapnia may be reflected in a relative metabolic alkalosis. In these children airway compromise may be distal to the trachea with bronchomalacia or bronchopulmonary dysplasia being ultimately the greatest contributing factor.

**Acute Management of Neonatal Airway Compromise**

In a neonate presenting with acute airway compromise, be it at delivery or subsequent to delivery, intervention may be required. Following delivery this may occur in a neonate who is having an acute episode of stridor, an apneic episode, a dying spell, or following extubation with an obvious need for the intubation. The fundamentals of resuscitation, namely airway, breathing, and circulation, are paramount to neonatal resuscitation. Securing the airway may be seen as a cascade of increasing levels of intervention. At the most basic level, providing a high concentration of oxygen whether by face mask, nasal cannula, high flow nasal cannula, or nasopharyngeal CPAP is desirable. If this is not adequate, a bag and mask will provide stability in an acute situation in the majority of infants. However, this does require an adequate mask fit and in some infants and children their underlying anatomy is not favorable to allow the face mask to seal the nose and oral cavity. In some of these patients an oral airway may be useful. If an adequate airway cannot be achieved or be maintained with a bag and mask, intubation is warranted. Intubation in the neonatal period does not mandate use of sedation or muscle relaxation. In a term infant, the age appropriate size of endotracheal tube is usually a 3.5 mm tube with an outer diameter of 4.8 mm. However, the age appropriate size of endotracheal tube is not necessarily the infant appropriate size of endotracheal tube. The ideal size of endotracheal tube for an individual infant or child is the smallest tube that will permit adequate ventilation, ideally maintaining a subglottic air leak pressure of less than 20 cm of water. In some infants, the requirement for adequate positive pressure ventilation takes precedence over the maintenance of the subglottic air leak, and a larger endotracheal tube may be tolerated for a period of time to permit more adequate ventilation of the infant. Infants are tolerant of prolonged intubation, but the longer the intubation and the tighter the fit of the endotracheal tube in the subglottis, the higher the relative probability of complications associated with intubation such as the development of subglottic granulation tissue, subglottic cyst formation, and subglottic stenosis will be. One alternative to the use of a snug endotracheal tube in children is the use of a smaller cuffed endotracheal tube; although cuffed pressure needs to be monitored carefully so there is not an equivalent lesion caused in the trachea from the endotracheal cuff. Tracheal stenosis is a more difficult problem to manage than subglottic stenosis.
While the size of endotracheal tube and the duration of intubation are the most significant factors influencing the risk of development of subglottic scarring, there are several other factors which may be synergistic, including the composition of the endotracheal tube, gastroesophageal reflux disease, and concurrent infection, especially with respiratory syncytial virus. The composition of the endotracheal tube is now almost universally silastic tubing which has low reactivity. Historically, red rubber catheters were used as endotracheal tubes and had a high associated stenosis rate. The other influencing factor is whether the intubation is transnasal or transoral. Transoral intubation is more easily accomplished but the endotracheal tube is less stable, more prone to movement, and the angle of the tube puts a relatively higher pressure on the posterior part of the subglottis. Meanwhile, transnasal intubation is slightly more technically challenging, requires an adequate nasal airway to allow passage of the tube, and places slightly more pressure in the posterior glottic area. However, the tube is more easily secured and, therefore, more stable. The true benefit of a nasal versus oral intubation is relatively small and, therefore, is a minor consideration with regard to neonatal intubation.

**The Difficult Intubation**

Neonatal intubation is normally straightforward; however, under some circumstances intubation may be challenging. Even in children in whom intubation is difficult, laryngeal exposure is limited due to the anterior lying larynx and the larynx may be difficult to see permitting only a limited visualization of the arytenoid cartilages. In the neonate, laryngeal exposure may be optimized by pressure on the cricoid cartilage delivered by the little finger of the left hand that is holding the laryngoscope blade, while the endotracheal tube is manipulated with the right hand in the standard fashion (Figure 3). Other special circumstances in which intubation may be challenging include children with oropharyngeal masses, laryngeal clefts, subglottic stenosis, and tracheal stenosis. The difficulty in children with laryngotracheoesophageal clefts is that the endotracheal tube will pass through the vocal folds but then falls through the cleft into the esophagus. In these children, and in children with oropharyngeal masses, a transnasal intubation flexible endoscope passed through an endotracheal tube may be useful to negotiate the anatomy and place the tip of the endotracheal tube in an appropriate position in the trachea.

Securing the airway with a ventilating bronchoscope is invaluable in the acute situation; however, it does not provide a long-term solution although it may facilitate airway stability until a tracheostomy can be performed. An alternative to securing the airway with a ventilating bronchoscope is to secure the airway with a Hopkins rod endoscope with an appropriate sized endotracheal tube placed over the rigid endoscope (Figure 4), so that once the endoscope is placed in the desired segment of trachea, the endotracheal tube can be advanced and secured. This, of course, can only be performed transorally.

Occasionally, intubation cannot be performed because the degree of subglottic stenosis is such that an endotracheal tube cannot pass the stenotic area. The smallest commercially available endotracheal tube has a 2.0 mm inner diameter with an outer diameter of 2.8 mm. In some forms of congenital subglottic stenosis, even this small tube cannot be passed. In these children, the airway is best managed temporarily with bag and mask ventilation or placement of a small laryngeal mask airway. Tracheostomy is then required to secure the airway. In some children, the subglottis is of adequate size, but the trachea is stenotic and does not allow passage of an endotracheal tube through the area of stenosis. Under these circumstances, an endotracheal tube may need to be placed barely below the vocal folds down to the level of tracheal stenosis but not through the level of stenosis. These children similarly cannot have a tracheostomy placed as the smallest tracheostomy tube is considerably larger than the smallest endotracheal tube; and, under these circumstances, urgent tracheal reconstruction is required.

**Extubation**

In an infant who was difficult to intubate as occurs with severe retrognathia or an infant in whom extubation is not realistically achievable as in severe bronchopulmonary dysplasia, proceeding straight to tracheostomy is appropriate. However, if an infant has the potential to be successfully extubated, then optimizing the extubation is desirable. The infant should be weaned from sedation to permit maximal respiratory effort, and consideration should be given to treatment with corticosteroids to try to minimize any laryngeal swelling at the time of extubation. Our routine is to deliver a single dose of dexamethasone, 0.5 mg/kg, 12 hours prior to extubation. In the 24 hours following extubation, there still may be some reactive glottic and subglottic edema, and the airway status may initially deteriorate before recovery. Over this time period, alternatives to reintubation include the use of racemic epinephrine, nasopharyngeal CPAP, or use of a high flow nasal cannula. If despite these measures, adequate oxygenation and ventilation cannot be maintained, the child will require reintubation. If the child repeatedly fails, attempts at extubation, tracheostomy is indicated. In certain children, an alternative to tracheostomy may be an anterior cricoid split operation which is discussed in Chapter 69, “Congenital Anomalies of the Larynx.”

**Tracheostomy**

Effective tracheostomy in a stable neonate should be a controlled procedure. In an infant in whom a definitive decision has been made to proceed with tracheostomy, it is best to place the tracheostomy before removing the endotracheal tube and evaluating the airway. However, in an infant in whom it is desirable to evaluate the airway before proceeding to tracheostomy, the endotracheal tube may be removed and rigid or flexible bronchoscopic evaluation of the airway may be performed to exclude a correctable anatomical problem, such as glottic granulation tissue or laryngomalacia. In the child known to have had a difficult intubation, it is prudent to inspect the larynx prior to removal of the endotracheal tube; and, if the surgeon is not confident that he or she can reintubate, it is best to proceed directly to tracheostomy before removing the endotracheal tube.
When performing tracheostomy in a neonate, one should appreciate how soft and difficult to palpate structures in the infant neck may be, and, therefore, it is prudent to remove catheters from the esophagus, such as nasogastric tubes and temperature probes, to prevent confusion of the esophagus for the trachea. The initial incision may be vertical or horizontal; and, in the neonatal neck, defatting the area of the tracheostomy is advisable as it allows easier identification of the trachea and improves maturing of the stoma. A child’s neck is a surprisingly easy place to get lost, and frequent palpation of the trachea while separating the strap muscles and dividing the thyroid isthmus is useful. Once the trachea and specifically the tracheal rings have been identified, the location of the cricoid is established; and stay sutures are placed just lateral to the midline in the region of the second to fourth tracheal cartilages. During exposure of the trachea, blunt dissection is employed where possible, staying strictly in the midline as the lung apices in an infant may rise well above the level of the clavicles, particularly in a child who has been ventilated for a long period. The lung apices may cross the midline. In some patients, the innominate artery may be high above the level of the sternum. When placing the stay sutures and incising the trachea, it is best to start distally and work proximally with sharp instruments, be it knife or needle, to prevent injury to the pleura or the innominate artery. Once the airway is open, it is best to sew the skin edges to the trachea, particularly in the lower aspect of the wound, to minimize the risk of formation of a false passage anterior to the trachea should decannulation occur and require emergent replacement of a tracheostomy tube. Once the stoma has been created, the endotracheal tube can be slowly withdrawn until the tip of the endotracheal tube is seen to lie proximal to the incision, and the tracheostomy tube is inserted. Only once the tracheostomy tube has been inserted and both oxygenation and ventilation confirmed, should the endotracheal tube be removed. Infants, in some patients, the innominate artery is also present. Occasionally, children who have had a high tracheoesophageal fistula repair will have a mid-tracheal pouch on the back wall of the trachea comprising the remnant of the tracheoesophageal fistula. In these children, during tracheostomy tube changes, the tip of the tube may be placed into the pouch instead of the trachea resulting in an inability to ventilate. The key to management is recognizing the situation and pulling back on the tube and repositioning it. If this is a recurrent problem, marsupialization of the tracheal pouch effectively manages the problem.

LONGER TERM TRACHEOSTOMY CARE

In most children, conversion from a neonatal length tracheostomy tube to a longer pediatric length tracheostomy tube occurs around 9 months of age. Bronchoscopic airway evaluation should occur every several months to evaluate whether subglottic stenosis has developed and to evaluate whether it is time to consider decannulation. If the underlying airway problem that initially required tracheostomy either spontaneously resolves or is surgically repaired, the child may be decannulated. The airway should be evaluated prior to decannulation to ensure that there is no tracheostomy associated problem such as suprastomal collapse or suprastomal granulation that would preclude decannulation. This also allows evaluation of other pathology or secondary considerations that would counsel against decannulation, such as upcoming major surgery with anticipated prolonged intubation. If there is no anatomical reason against removing the tracheostomy tube, an initial plugging trial or capping trial of the tracheostomy is advisable to ensure that the child is able to breathe adequately without a tracheostomy prior to its removal. When possible, the narrowest diameter tracheostomy tube should be placed in the airway, and a cap placed over it for 24 to 48 hours with the child being observed and closely monitored. In young children, fenestrating the tracheostomy tube may be required to achieve this end. The child may be sent home for a period with the tracheostomy tube being capped to be quite sure that an adequate airway is maintained prior to removal of the tube. When the child is ultimately decannulated, close observation is recommended for 24 to 48 hours. Following decannulation, a final bronchoscopy is performed several weeks later to ensure that the trachea has healed on the inside without the formation of granulation tissue, which may occur in up to 2% of cases.

PEDIATRIC AIRWAY MANAGEMENT

In older children, airway evaluation is more nuanced with an increasing number of factors that should be considered. The role of the pediatric larynx is primarily as a conduit for air passage, secondarily, a guardian against aspiration, and finally as an organ of voice production. Any one of these roles may compromise the other functions of the larynx, and surgical intervention seeking to improve one of these functions may inadvertently compromise the others. Therefore, evaluation of the pediatric airway not only involves evaluation of these disparate laryngeal functions but also evaluation of the rest of the child. Laryngeal and tracheal airway obstruction in the child, similar to the neonate, is characterized by stridor and retractions. However, in the child, exercise intolerance, voice quality, and evaluation of aspiration risk are now considerations. In a child whose symptoms warrant further evaluation, initial evaluation should ideally include flexible laryngoscopy and high kilovolt airway films. Flexible laryngoscopy is an excellent method for evaluating airway pathology from the nose to the vocal folds but is poor at evaluating subglottic and tracheal pathology. If flexible laryngoscopic findings do not explain the symptoms, rigid bronchoscopy is indicated. This is also true in adequate evaluation of the child dependent on a tracheostomy.

Rigid bronchoscopy evaluation of the pediatric airway is performed under general anesthesia either with suspension laryngoscopy, or utilizing an anesthetic laryngoscope blade. The bronchoscopic evaluation may be performed with a flexible bronchoscope, a ventilating bronchoscope containing a Hopkins rod endoscope, or with a Hopkins rod endoscope alone. Comprehensive evaluation should also include the laryngeal structures and surrounding base of the tongue and pharynx, with special attention being paid to the posterior part of the glottis and the subglottis, excluding a posterior laryngeal cleft. The examination should then continue below the vocal folds to the subglottis, trachea and bronchi with any stenotic areas being carefully evaluated for length, severity, and inflammation. The degree of subglottic stenosis may be graded according to the Myer-Cotton grading scale, with the subglottic leak pressures of differing sizes of endotracheal tube being a convenient way to evaluate the degree of stenosis. The size of the airway is determined by the size of the largest endotracheal tube that still maintains a leak with a subglottic pressure of less than 20 cm of water pressure. Most children with a Grade 1 subglottic stenosis (<50% stenosis) will be asymptomatic, while Grade 4 stenosis means...
a complete occlusion of the subglottic lumen, with tracheostomy dependency and aphonia. The resistance to airflow through the area of stenosis is influenced by Poiseuille’s law, namely, that flow is inversely proportional to the fourth power of the radius. This means that halving the radius will result in one-sixteenth of the airflow.

Thorough evaluation should also include consideration of flexible endoscopy looking at airway dynamics including pharyngomalacia, laryngomalacia, glossoptosis, vocal fold paraly-
sis, and tracheomalacia. It should be noted that flexible bronchoscopy is a poor tool for evaluat-
ing the posterior part of the glottis and that poste-
rior glottic stenosis and posterior laryngeal clefts are difficult to evaluate with flexible endoscopy.

COmPLEMENTATORY EVALUATION

In a child in whom airway reconstructive surgery is a consideration, optimization of the patient is critical to ensure the best outcome of surgery. Factors that may strongly influence the outcome of surgery include gastroesophageal reflux disease, eosinophilic esophagitis, pulmonary disease, sleep apnea (whether central or obstructive), and aspiration. It is a disservice to a child to attempt to rid them of a tracheostomy while creating for the child a condition that predisposes to significant aspiration in the process. While not manda-
tory, it is prudent to consider whether esopha-
gogastroduodenoscopy or pH probe evaluation (or more recently impedance probe evaluation) of the patient, anticipating airway reconstructive surgery, is warranted. This is especially true in patients who have already had previous unsuccessful surgery. The outcome of surgical reconstruc-
tion of the airway is less favorable in children with poorly controlled gastroesophageal reflux disease or eosinophilic esophagitis. Similarly, sleep apnea, whether obstructive or central, may have a negative impact on the outcome of pediatric airway reconstruction, and a sleep study may be indicated in some children before or after surgical intervention.

Pediatric aspiration is also an important con-
sideration during evaluation, not only to evaluate the current degree of aspiration, but also to evaluate the relative risk of aspiration following airway reconstruc-
tive surgery. Evaluation may include a video swallow study, functional endoscopic eval-
uation of swallowing, and pediatric dye testing. Pediatric dye testing involves using a green food dye to color food, drink, or the child’s secretions, and then evaluating whether any green material is seen in the airway. This is only useful in a child with a tracheostomy who does not have a Grade 4 subglottic stenosis. Other complementary tests for aspiration include CT scanning of the lungs and flexible bronchoscopy with bronchoalveolar lavage looking for lipid-laden macrophages.

While an adequate airway is a greater con-
sideration than voice in young children, pediatric voice disorders and the influence of airway sur-
gery on a child’s voice have become a greater concern. Pediatric voice evaluation is becoming an increasingly important part of airway evaluation, both before and after surgical intervention. Voice preservation techniques, including avoid-
ance of laryngofissure, balloon dilation of the air-
way, and endoscopic alternatives to open airway reconstruction are all playing an increasing role in the management of the pediatric airway.

SPECIFIC DISORDERS AFFECTING THE PEDIATRIC AIRWAY

Pediatric airway disease may be best considered in a proximal to distal fashion, as may causes of congenital stridor. Stridor is the sound produced by turbulent air flowing through a confined space, and in a child, is the result of laryngeal or tracheal pathology. With dynamic airway compromise, such as occurs with laryngomalacia or vocal fold paralysis, inspiratory stridor is noted with no expiratory component. However, with a fixed stenosis, such as subglottic stenosis or tracheal stenosis, the nature of the stridor is biphasic. The cause and anatomical location of congenital stridor reflect the frequency of the occurrence of the disorder, and a generalization is that the more proximal the location of the obstruction is, the more frequently the disorder is encountered. For example, laryngomalacia is more common than vocal fold paralysis which is more common than subglottic stenosis which is more common than congenital tracheal stenosis. Severe laryn-
geal webs and subglottic hemangiomas may also present with stridor, and these along with laryn-
gomalacia, vocal fold paralysis, and subglottic stenosis are discussed in Chapter 69, “Congenital Anomalies of the Larynx.”

COMMON CAUSES OF SUPRALARYNGEAL AIRWAY OBSTRUCTION

If obstruction of the supralaryngeal airway is con-
sidered in a proximal to distal fashion, starting at the nasal cavities, consideration should be given to piriform aperture stenosis, nasolacrimal duct cysts, choanal atresia, adenontonsillar hypertrophy, retrognathia, and glossoptosis. Choanal atresia is discussed in Chapter 70, “Congenital Anomalies of the Head and Neck,” while adenonto-
sillar hypertrophy is discussed in Chapter 64, “Diseases of the Oral Cavity, Oropharynx, and Nasopharynx,” and chapter 66, “Sleep Ape
ea in Children.”

Piriform Aperture Stenosis

Piriform aperture stenosis is a comparatively rare developmental anomaly characterized by bony obstruction of the anterior nares by bony overgrowth of the lateral walls of the piriform aperture. The presentation is in infancy and may mimic the symptoms and signs that occur with choanal atresia. A posterior rhinoscopy is diagnostic, with confirmation made on CT scan (Figure 5). This may also reveal the other midline anomalies

Figure 5 (A) Piriform aperture stenosis. (B) Computed tomographic scan showing a piriform aperture stenosis.

frequently seen with this condition, including a large single central upper incisor and mid-
line anomalies of the central nervous system. Treatment requires drilling down of the bony overgrowth through a sublabial approach, with temporary placement of transnasal stents.

Nasolacrimal Duct Cysts

Nasolacrimal duct cysts occur as a consequence of failure of the nasolacrimal duct to recanalize during fetal development and may be unilateral or bilateral. Presentation is with nasal obstruction due to a large cyst under the inferior turbinate occluding the anterior part of the nasal airway (Figure 6), and there may be swelling of the nasolacrimal sac in the medial canthal area. Eiphora is present as the tears cannot drain; and, if the cyst is infected, as is frequently the case, there may be abscess formation in the nasolacrimal sac region, and the neonate may be septic. Investigation is with anterior rhinoscopy and CT scanning of the nasal passages (Figure 7). Treatment is transnasal endoscopic removal or marsupialization of the cyst with placement of nasolacrimal duct catheters if required.

Retrognathia and Glossoptosis

Retrognathia is a descriptive term for mandibular hypoplasia and occurs in a variety of conditions, including Pierre Robin sequence, Treacher Col-
lins syndrome, and Stickler syndrome. A conse-
quency of the mandibular hypoplasia is crowding of the tongue posteriorly and superiorly, which
may cause airway obstruction and a cleft of the secondary palate, as the palate anlagen are unable to close around the cephalically displaced tongue. The degree of retrognathia is not always a reliable indicator of the degree of obstruction or of the potential problems with intubation. Although obstructing retrognathia is usually a problem encountered in the neonatal nursery, problems may be encountered years later. While such problems are often triggered by seemingly trivial surgical procedures, the insidious onset of severe sleep apnea is the most notable presentation.

In the neonatal period, management includes prone positioning, the use of high-flow nasal cannula, and occasionally the use of a nasal trumpet (nasopharyngeal airway). CPAP is often not successful, as the mask tends to exacerbate the relative retrognathia. Because these infants struggle with feeding, nasogastric tube placement is often required. If the airway remains compromised, intubation is desirable, but as discussed previously, may be challenging.

In infants with significant obstructive symptoms or feeding problems, surgical intervention is desirable. Performing a tracheostomy is standard; and in most nonsyndromic children, catchup growth of the mandible will permit decannulation within 1 to 2 years. If catchup growth is not apparent by 1 year of age, consideration can be given to mandibular distraction. In some cases, neonatal mandibular distraction may be an alternative to tracheostomy; however, this remains controversial.11,12

Pharyngeal and Laryngeal Cysts
Supralaryngeal and laryngeal cyst formation may be life threatening in the neonatal age group. A significant number of case reports in this age group are of infants in whom the diagnosis was established at autopsy. Supralaryngeal cysts in this age group present with a muffled cry and intermittent positional apnea. In some cases, stridor and retractions may be presenting symptoms. Flexible laryngoscopy is ideal for diagnosis of supraglottic pathology and occasionally may permit evaluation of subglottic pathology. The most commonly encountered cysts are lingual thyroglossal duct cysts, vallecular cysts, laryngoceles and saccular cysts, and subglottic cysts. Laryngoceles and saccular cysts are discussed in Chapter 69, “Congenital Anomalies of the Larynx.” Thyroglossal duct cysts tend to present in the midline of the tongue posterior to the foramen cecum and usually proximal to the glossoepiglottic ligament. They are midline and deep seated with a thick layer of mucosa overlying them (Figure 8). Care should be taken upon induction of general anesthesia as an infant with a lingual thyroglossal duct cyst may have acute respiratory obstruction upon induction. This is not true in the older child. Treatment is complete excision through an endoscopic approach. This may be done with an elongated guarded tip needlepoint Bovi through a medium Lindholm suspension laryngoscope. The resultant raw area is left to heal by secondary intention. Marsupialization of the cyst may be effective, but complete excision is curative. Usually the hyoid bone is not involved; and, therefore, a Sistrunk operation is not required.

Vallecular cysts in contrast are thin walled and usually arise from the lingual surface of the epiglottis, and marsupialization is an effective treatment. In the subglottic region, cysts may occur and are often multiple. Subglottic cysts may be superficial and thin walled (Figure 9); but, if lying deep in the submucosal layer, they may be confused with a subglottic hemangioma or with subglottic stenosis. Invariably they are a consequence of prolonged intubation of a premature infant. They are readily treated by deroofing the cyst using either microlaryngeal instrumentation, powered instrumentation, CO2 laser, or Bugbee electrocautery.13 They have a tendency to recur and may need to be removed on several occasions before complete resolution. Therefore, follow-up bronchoscopy is mandatory. The pathogenesis for the development of subglottic cysts is not similar to the pathogenesis for the development of subglottic stenosis; both problems may coexist.

Tracheomalacia
Tracheomalacia describes any relative dynamic collapse of the trachea; it is more usually applied as a descriptive term for excessive movement of the posterior membranous tracheal wall, namely the trachealis muscle (Figure 10). Although tracheomalacia may occur with normally shaped tracheal cartilages, more frequently it is seen in conjunction with excessively wide and flattened tracheal cartilages. This is a problem that may occur in isolation without any other congenital anomalies but is more commonly seen in conjunction with other congenital anomalies, and tracheo-esophageal fistula, esophageal atresia, and posterior laryngeal clefting are particularly common associations.14 It is also more common in infants who have required prolonged ventilation and in children with Pierre Robin sequence. Tracheomalacia is a dynamic disorder, with the degree of malacia governed by the velocity of nonturbulent airflow, that is, the same Bernoulli principle that applies to airflow generating lift across an airplane’s wing. Therefore, the maximal degree of tracheomalacia occurs in the area with the highest relative airflow and with this occurring at the narrowest point within the trachea. Tracheomalacia may present with a characteristic honking cough, may have symptoms of wheezing, airway obstruction, retractions, and occasionally dying spells and may get worse over the first few months of life before slowly and steadily improving. This is a problem that resolves with time in the majority of children. However, in severe cases interim intervention may be required. The standard for...
intervention in severe tracheomalacia is tracheostomy with the tip of the tracheostomy tube lying relatively close to the carina to bypass the most significant areas of malacia. In severe cases, positive pressure ventilation may also be required. An alternative to tracheostomy is aortopexy whereby the thymus gland is removed, and the aorta pexed forward to the posterior surface of the sternum, bringing the trachea anteriorly with it, thereby decreasing the relative flattening of the trachea and improving tracheomalacia. This is only required in a minority of patients. A more controversial solution is placement of intratracheal stents, either hollow silicone stents, or expandable metal wire stents. There is a significant complication rate with these devices, and this approach is not recommended in a child with isolated tracheomalacia.15

In a child who has required tracheostomy for management of tracheomalacia, decannulation is usually achievable within 2 to 4 years as the tracheomalacia resolves, with the worse segment of malacia often occurring at the tracheostomy site where there is a relative narrowing of the trachea as a consequence of the tracheostomy. A significant number of children with tracheomalacia also have bronchomalacia. Whereas tracheomalacia may be bypassed by placement of a long endotracheal tube, this is not possible with bronchomalacia; and, if there is significant diffuse bronchomalacia, positive pressure support may be required through the tracheostomy tube until such time as the child slowly outgrows this problem.

Vascular Compression

Vascular compression of the pediatric airway encompasses several different disorders. The most common cause of vascular compression is due to anterior impingement of the innominate artery on the trachea as it crosses from the arch of the aorta to the right side of the body (Figure 11). Mild innominate artery compression is a comparatively common incidental finding on bronchoscopy, and is usually asymptomatic or mildly symptomatic with cough, retained secretions, and retractions being notable, and spontaneously improving with time. In severe cases, there may be marked airway compromise with stridor and retractions warranting surgical intervention with aortopexy or even innominate artery reimplantation. Placement of a tracheostomy tube in these children should be done with a certain degree of caution, as the tip of the endotracheal tube may rub against the pulsating anterior impression of the innominate artery, creating a small but real chance of formation of a tracheo-innominate artery fistula, an extremely life-threatening condition.

Other forms of vascular compression are less common and include a right sided aortic arch, a double aortic arch compressing the trachea and esophagus, and a pulmonary artery sling compressing the distal part of the trachea.16 A pulmonary artery sling describes the left pulmonary artery arising to the right of the trachea and passing back between the trachea and esophagus before coursing to the left lung. The characteristic radiographic finding is a barium swallow revealing an anterior filling defect in the anterior wall of the esophagus where the artery passes between the trachea and esophagus. However, all forms of vascular compression may be usefully imaged with MRI scanning or with contrast enhanced CT scanning of the chest. The right-sided aortic arch rarely requires treatment unless there is a complete vascular ring, in which case the ring may be divided, usually with division of the ligamentum arteriosum. With the double aortic arch, the least dominant of the arches is divided, this usually being the left. A pulmonary artery sling requires division and reimplantation into the main pulmonary artery trunk. However, the main consideration in evaluating a child with a pulmonary artery sling is not necessarily the tracheal compression but the high association, up to two-thirds of patients, in whom congenital tracheal stenosis due to complete tracheal rings is also present.

Complete Tracheal Rings

The most common cause of congenital tracheal stenosis is due to complete tracheal rings (Figure 12). The tracheal cartilages are normally in a horseshoe shape with a posterior membrane consisting of trachealis muscle. However, if the cartilages are circular and continuous, varying lengths of the trachea, tracheal stenosis due to complete tracheal rings is present. While rare, this is an important diagnosis as the initial management of these children may have a marked impact on the outcome both short term and long term. Complete tracheal rings are invariably smaller in diameter than a normal trachea, and over 90% of the patients have tracheal rings affecting either the majority of the trachea or the lower trachea. In a full 50% of patients upon presentation, the smallest tracheal ring is smaller than the smallest endotracheal tube. Therefore, these children cannot be intubated or have a tracheostomy tube placed through the segment of complete tracheal rings and as a consequence their care should be delivered with the utmost respect and circumspection. Historically, children with complete tracheal rings had a mortality rate in excess of 80% although currently a mortality rate of less than 10% is expected. Children with complete tracheal rings are usually noisy from birth with stridor and retractions and a characteristic wet sounding “washing machine” breathing pattern. As the child grows over the first few months of life, the trachea does not grow significantly; and, therefore, symptom progression is common, and often decompensation occurs around 4 months of age with the infant presenting in respiratory failure. In over 80% of children with complete tracheal rings there are other congenital anomalies present, sometimes multiple and severe. In approximately 50% of children with complete tracheal rings, the other anomalies are cardiovascular in origin. Initial evaluation should include plain airway films as this will provide a warning that congenital tracheal narrowing may be present. Definitive diagnosis is made with rigid bronchoscopy, and it is important to diagnose that complete rings are present even if the airway cannot be fully evaluated, as passing to large a telescope through a segment of complete tracheal rings may cause mucosal swelling and convert a compromised airway into a critical airway. If the airway has been traumatized and the child cannot be ventilated, the only alternative may be stabilization with extracorporeal membrane oxygenation (ECMO). If a small enough telescope is available, bronchoscopy will show congenital tracheal stenosis with cartilage rings that replace the posterior muscular trachealis, and
frequently the tracheal rings extend down to the carina. Other appropriate investigations in these children include high resolution contrast enhanced CT scanning to evaluate not only the tracheal airway and bronchi but also the major blood vessels within the chest to see if there are any underlying vascular anomalies that also require repair, such as a pulmonary artery sling. Whereas two-thirds of children with a pulmonary artery sling have complete tracheal rings, approximately one-third of children with complete tracheal rings will also have a pulmonary artery sling. Other necessary investigations include echocardiogram to exclude any intracardiac anomalies. Whereas a small proportion of children do not need tracheal repair, 80% of patients require tracheal reconstruction, usually with a sternotomy and consideration of placement on cardiopulmonary bypass. The recommended method of repair of complete tracheal rings is a slide tracheoplasty. Any cardiovascular anomalies that may also require repair may be undertaken at the same time.

ACQUIRED DISORDERS OF THE PEDIATRIC AIRWAY

Foreign Body

Foreign bodies of the pediatric aerodigestive tract have the potential to be life threatening and frequently require emergent management. Foreign bodies in the aerodigestive tract may be conveniently subdivided into glottic and tracheal, bronchial, and esophageal. Glottic and tracheal foreign bodies are true emergencies, and a significant proportion of children present at the emergency room are dead on arrival. These are usually toddlers whose limited dentition does not allow effective chewing; and, therefore, smooth and rubbery consistencies of food may be aspirated and may lodge in the glottis or trachea. The classical foreign body causing glottic obstruction is a hot dog sausage with the presentation usually being abrupt and complete airway obstruction. Under these circumstances, a Heimlich maneuver may be life saving. If the child obtains limited air passage past the foreign body and survives transport to the hospital, emergent evaluation and stabilization of the airway is critical for survival, with attempted removal of the foreign body with an anesthetic laryngoscope blade and anesthetic McGill forceps if the child is in extremis. If the child is maintaining an airway, albeit tenuous, removal under general anesthetic in the operating room is still preferable with a slow induction with a volatile inhaled anesthetic being required due to the airway obstruction. There is a high risk on induction that the airway will be lost, and emergent bronchoscopy may then be required to remove the foreign body.

Modern foreign body forceps utilizing Hopkins rod endoscopes play a pivotal role in the current management of aerodigestive foreign bodies in children, and a variety of such foreign body forceps exists to aid in removal of particular foreign bodies (Figure 13). Once a laryngeal or tracheal foreign body has been removed, the rest of the tracheobronchial tree should be inspected to ensure that there are no remnants of the foreign body or second foreign body present. In the presence of a glottic foreign body without the equipment to remove the foreign body at hand, an alternative form of airway management is emergency tracheostomy with a vertical incision being placed directly down on the trachea below the cricoid cartilage and with insertion of an endotracheal tube through the neck into the trachea.

By contrast, bronchial foreign bodies present an urgent but not emergent problem in that even with one bronchus completely occluded by a foreign body, it is still possible to ventilate the contralateral lung. There is still the potential for an unstable airway in a child who has a foreign body ball-valving across the carina between the bronchi or in a child in whom a bronchial foreign body has been present for days or weeks as this will often induce bronchial granulation tissue and distal stasis of secretions with secondary infection. The most common bronchial foreign body in the United States is the peanut aspirated by a toddler who does not yet have erupted molars with which to crush the peanut. Peanuts, like most forms of vegetable aspirated matter, are extremely irritating to surrounding mucosa and may become buried within granulation tissue within a few days; and, therefore, removal should be performed on an urgent if not emergent basis. This is a frequent enough foreign body that optically guided peanut removing forceps are available to assist with removal (see Figure 13). Whereas a chest X-ray may either show consolidation of the lung distal to the foreign body or hyperinflation distal to the foreign body when air trapping has occurred, a normal chest X-ray does not exclude a bronchial foreign body. History alone is adequate indication for bronchoscopic evaluation, particularly in a child who has had a witnessed choking event. As with appendicitis, it is preferable that a few bronchoscopy be performed with no foreign body being found rather than potentially miss any foreign bodies that later present with sequelae.19

The final group of foreign bodies that deserve consideration are chronic esophageal foreign bodies. A cute esophageal foreign bodies rarely cause airway compromise, but if an esophageal foreign body has been present for weeks, it may cause surrounding ulceration and inflammation leading to posterior compression of the trachea (Figure 14). These children frequently are erroneously diagnosed as being asthmatic, nonresponsive to bronchodilator therapy, and not infrequently the diagnosis is made following chest X-ray evaluation for recalcitrant asthma.20 The classical foreign body in the United States is a swallowed penny, and again, this is a frequent enough event that endoscopically guided coin removing forceps are available to assist with removal (see Figure 13).

Infection

Historically, the most frequent cause of fatal pediatric airway disease was diphtheria, and in the early part of the twentieth century, this was also the commonest cause for tracheostomy in the pediatric age group. The diphtheria toxin was responsible for even more deaths than the associated airway obstruction. This disease has essentially been eradicated by immunization against Corynebacterium diphtheriae. It is notable that immunization has also almost eradicated the commonest cause of infective life-threatening airway obstruction of the late twentieth century.21

In much of the Western World, even as recently as the 1990s, epiglottitis or supraglottitis due to Haemophilus influenzae Type b (Hib) was a feared cause of acute airway obstruction in otherwise healthy children between the ages of 3 and 8 years. This was a disease characterized by rapidly progressive edema of the supraglottic structures, especially the epiglottis, with pain, fever, and severe stridor (Figure 15). Children would present sitting upright and leaning forward drooling as they could not swallow. The severe stridor and retractions would be exacerbated by the child being upset; and the supraglottitis had the potential to precipitate complete loss of the airway, so the child was kept sitting on the parent’s lap, and invasive evaluation (blood tests, intravenous line placement, X-ray, flexible laryngoscopy) was avoided. Emergent transfer to the operating room, for intubation or tracheostomy placement was advocated, with the child being anesthetized with
In more severe cases, systemic corticosteroids or systemic antibiotics may be required. Treatment is usually supportive, with humidification and cool air being useful in the home setting. Investigations for the causative microorganisms, but generally is a more regional disease is bacterial tracheitis, with no specific microorganism being responsible for the majority of cases, but a variety of bacteria may be responsible. Children with it are usually otherwise healthy and between 6 and 14 years of age. There is a severe sore throat, exacerbated by coughing and swallowing, that restricts fluid intake, and the infection results in increasingly thick tenacious tracheal secretions. There is usually associated subglottic edema, and presentation is with stridor and retractions. In advanced cases, the child may be febrile and appear toxic. Airway films may demonstrate tracheal membranes (Figure 16), and flexible laryngoscopy shows thick subglottic secretions that are hard for the patient to cough out. In mild cases rehydration with intravenous fluids, analgesia, broad spectrum antibiotics, and encouragement to cough may be all that is required to manage the disease, but in most cases bronchoscopic airway clearance is required. Bronchoscopic findings are subglottic and tracheal edema, with thick tenacious secretions in the trachea but sparing the bronchi (Figure 17). Frequently, the secretions are so tenacious that they cannot be adequately suctioned, and removal with foreign body forceps may be required. Postoperative intubation for a few days is frequently required.

**Other Causes of Pediatric Airway Obstruction**

Other causes of pediatric airway obstruction are comparatively rare and include trauma, inflammatory diseases, and neoplasms. Inflammatory and neoplastic causes are discussed in Chapter 64, “Diseases of the Oral Cavity, Oropharynx, and Nasopharynx.”

Traumatic causes of airway compromise are highly individualized; if intubation injury is excluded, the two main groups are airway burns and blunt trauma to the neck. Airway burns may be a consequence of a chemical or thermal injury, and the injury may affect the pharynx, larynx, trachea, or esophagus. In the acute situation, airway edema (and other injuries the patient has suffered) requires airway stabilization with intubation, and in severe injuries, prolonged intubation and ventilation may require tracheostomy. The longer-term degree of scarring depends upon the depth of injury, and even extensive mucosal damage may heal without scarring if the injury is only superficial. Chemical injuries are more severe with alkali exposure than acid exposure, as alkalis cause liquifactive necrosis, and therefore tend to penetrate deeply. Pharyngeal and esophageal stenosis may be a severe and long-term consequence of alkali injuries. As with all forms of aerodigestive burn injury, there may be skip lesions, and relative sparing of some areas, with severe injury to others. Inhalational thermal burns may result in supraglottic, subglottic or tracheal scarring, and scarring in these children may take months to years to mature fully; and, until mature, operative intervention is less

---

**Figure 15** Epiglottitis.

**Figure 16** Airway films of a child with bacterial tracheitis and tracheal membranes.

**Figure 17** Endoscopic view of the tenacious secretions seen in bacterial tracheitis.
likely to have a successful outcome. A particularly severe burn occurs with a laser fire, when an endotracheal tube is ignited with a CO₂ laser; the oxygen rich environment causes the end of the endotracheal tube to act like a blowtorch. Immediately removing the endotracheal tube and filling the pharynx with water may limit the depth of heat penetration; but severe scarring is still to be anticipated, and early tracheotomy is indicated.

Blunt trauma to the neck may cause two characteristic injuries, namely a fractured larynx and laryngotracheal separation. A patient with a fractured larynx usually presents with mild stridor, hoarseness, and sometimes with subcutaneous air. Investigation includes plain airway films, CT scan of the neck, flexible laryngoscopy, and rigid bronchoscopic evaluation of the larynx. Undisplaced fractures may require no intervention bar observation, but if the airway is compromised by swelling then intubation may be required, this being with a cuffed endotracheal tube if there is subcutaneous emphysema. In severe injuries with cartilage displacement, open repair of the fractures is indicated, using sutures since in children the larynx is not yet calcified and will not hold miniplates.

Laryngotracheal separation is a more severe injury due to blunt trauma as in a “clothesline” injury. The trachea is ripped off the cricoid, often damaging both recurrent laryngeal nerves. Often there are other associated injuries, including cervical spine fracture and esophageal rupture. While many such injuries result in death at the scene of injury, a surprising number of children may maintain an airway despite quite a long gap between the larynx (which retracts up under the chin), and the trachea (which retracts into the chest). A part from stridor, there is characteristic ecchymosis of the anterior neck, a “flat” neck, and subcutaneous emphysema. Intubation should be approached with great caution as the cervical spine should be treated as though fractured until proven otherwise, and hence neck extension is inadvisable. Induction of anesthesia risks collapse and loss of the airway, while intubation risks the endotracheal tube passing through the vocal folds and into the soft tissues of the neck, rather than into the distal trachea. Under these circumstances, flexible nasotracheal intubation in an awake patient may be the safest method of securing the airway. The alternative is tracheostomy, with the skin incision opening into a large cavity, with the end of the trachea found in the thoracic aspect of the space. When possible, immediate reconstruction with laryngotracheal anastomosis over a T-tube or supratrachal stent is recommended. If this is not possible, then an end-tracheostomy can be performed and later an extended cricotracheal resection may be considered.

Wegener granulomatosis, relapsing polychondritis, and idiopathic subglottic stenosis are rare in children, more commonly occur in females, and have a predilection for the subglottis. Whereas costal cartilage graft laryngotracheal reconstruction is an effective treatment for subglottic stenosis in most children, with inflammatory disorders affecting the subglottis, cricotracheal resection has a much better prognosis for maintaining a long-term adequate airway than laryngotracheal reconstruction. A patient with a cuffed endotracheal tube if there is subcutaneous emphysema. In severe injuries with cartilage displacement, open repair of the fractures is indicated, using sutures since in children the larynx is not yet calcified and will not hold miniplates.

Laryngotracheal separation is a more severe injury due to blunt trauma as in a “clothesline” injury. The trachea is ripped off the cricoid, often damaging both recurrent laryngeal nerves. Often there are other associated injuries, including cervical spine fracture and esophageal rupture. While many such injuries result in death at the scene of injury, a surprising number of children may maintain an airway despite quite a long gap between the larynx (which retracts up under the chin), and the trachea (which retracts into the chest). A part from stridor, there is characteristic ecchymosis of the anterior neck, a “flat” neck, and subcutaneous emphysema. Intubation should be approached with great caution as the cervical spine should be treated as though fractured until proven otherwise, and hence neck extension is inadvisable. Induction of anesthesia risks collapse and loss of the airway, while intubation risks the endotracheal tube passing through the vocal folds and into the soft tissues of the neck, rather than into the distal trachea. Under these circumstances, flexible nasotracheal intubation in an awake patient may be the safest method of securing the airway. The alternative is tracheostomy, with the skin incision opening into a large cavity, with the end of the trachea found in the thoracic aspect of the space. When possible, immediate reconstruction with laryngotracheal anastomosis over a T-tube or supratrachal stent is recommended. If this is not possible, then an end-tracheostomy can be performed and later an extended cricotracheal resection may be considered.

Wegener granulomatosis, relapsing polychondritis, and idiopathic subglottic stenosis are rare in children, more commonly occur in females, and have a predilection for the subglottis. Whereas costal cartilage graft laryngotracheal reconstruction is an effective treatment for subglottic stenosis in most children, with inflammatory disorders affecting the subglottis, cricotracheal resection has a much better prognosis for maintaining a long-term adequate airway than laryngotracheal reconstruction.

Congenital Anomalies of the Larynx
Rodney P. Lusk, MD

Congenital lesions of the larynx are relatively rare; however, in their laryngeal laboratory, Chen and Holinger found congenital laryngeal lesions in 33 of 115 specimens. Of all the anomalies noted, the most common deformities are of the cricoid cartilage. The lesions develop during respiratory differentiation, which occurs during the fourth to tenth weeks of gestation. The clinical manifestations of laryngeal lesions fall into three broad categories:

1. Respiratory distress: which may range from complete obstruction with no air movement to minor types of stridor. The characteristics of the stridor are variable and depend on the site and degree of the obstruction. Most laryngeal lesions produce stridor during the inspiratory phase. The reason for this is found in the Bernoulli principle, which states that when a fluid or a gas is in motion, the pressure exerted on the wall of the airway decreases as the velocity of the gas increases. A well-known example is the wing of an airplane, shown in Figure 1. When the site of the obstruction is in an area not firmly fixed or supported, such as the supraglottis or larynx, as the air rushes into the airway, it produces a relatively negative pressure, which tends to close the airway (Figure 2). The harder the child breathes in, the faster the flow and the greater the created negative pressure, with the net effect of further decreasing the airway lumen. The negative pressure generated during inspiration may also cause supravascular and sternal retractions and nasal flare.

2. Dysphonia: which may be caused by laryngeal lesions that interfere with vocalization, with voice quality ranging from complete aphonia to hoarseness.

3. Failure of the larynx to close the airway during swallowing may cause feeding difficulties, with aspiration, cyanosis, or respiratory compromise.

Incidence
Laryngomalacia is the most common cause of stridor in the newborn. In some children, it may be an autosomal dominant lesion. Hawkins and Clark evaluated 453 patients with the flexible fiberscope and found 84 with primary and 29 with secondary laryngomalacia. Nussbaum and Maggi found that 68% of 297 children with laryngomalacia had other respiratory disorders, as noted with flexible bronchoscopy. It is the most common diagnosis for airway obstruction in children with Down syndrome.

Symptoms and Signs
The most common symptoms produced by laryngomalacia are inspiratory stridor, feeding problems, and gastric reflux. The inspiratory stridor worsens with increased respiratory effort, such as crying or feeding, and in the supine position. The symptoms begin shortly after birth in most patients, increase in severity until 6 to 8 months of age, plateau at 9 months, and steadily improve thereafter. No correlation exists between the duration of stridor and the severity or time of onset. 

Two theories have been proposed to account for the narrowing of the laryngeal inlet. The first is that a neuromuscular abnormality, by not allowing proper support of the supraglottis, causes increased flaccidity. Kelen suggested that the cause is ineffective dilators of the supraglottis, but dissections by Belmont and Grundfast showed the dual insertion of the palatopharyngeus, lateral glossoepiglottic, and stylopharyngeal muscles, which could dilate the laryngeal inlet. The incidence of neuromuscular disorders appears to be higher in children with laryngomalacia. Reports of higher incidence of mental retardation in these patients have not been substantiated.

The other proposed mechanism is anatomic, with the narrowing resulting from (1) a flaccid epiglottis that folds against the posterior laryngeal wall or into the airway, (2) a long, tubular epiglottis that curls on itself, or (3) short and redundant aryepiglottic folds with varying sizes of cuneiform cartilage that rotate medially into the airway (Figures 3 and 4). The W-shaped epiglottis is not thought to be a significant factor because it occurs in 30 to 50% of patients, most of whom do not have stridor.

Figure 1 For a wing to produce lift, the air pressure on the top of the wing must be less than the pressure on the bottom. According to the Bernoulli principle, this can occur only when the velocity of the air is greater over the top of the wing, which is accomplished by increasing its upper curvature.

Figure 2 Demonstration of the arytenoid cartilages and the subglottis as compared to an airfoil. Note that as the velocity of the air increases in the glottis, it creates negative pressure in the airway, pulling the cuneiform cartilages and aryepiglottic folds into the airway.

LARYNGOMALACIA
Laryngomalacia is a condition in which the laryngeal inlet collapses on inspiration, causing stridor. The terminology is confusing, with congenital laryngeal stridor, congenital laryngeal obstruction, congenital stridor of infants, and inspiratory laryngeal collapse all used synonymously. The term laryngomalacia, introduced by Jackson and Jackson in 1942, is most frequently used. Some physicians confuse this entity with tracheomalacia, which is altogether another disease.
Feeding problems are frequent with laryngomalacia. Radiographic evidence of gastric reflux occurs in 80% and regurgitation in 40% past 3 months of age. In the study by Zalzal and colleagues, 5 of 21 patients presented with feeding problems. Some investigators believe that feeding problems are secondary to the high negative pressures generated during inspiration. Aspiration pneumonitis has been reported in 7% of children with laryngomalacia. The mechanism for this is unclear but may be associated with the negative pressure and feeding problems.

Obstructive sleep apnea (23%) and central apnea (10%) have also been noted. Cor pulmonale can develop secondary to laryngomalacia. If untreated, it may also be associated with increased pulmonary arterial pressures.

Diagnosis

The diagnosis is most frequently based on the symptoms and signs, flexible laryngoscopy, and lateral radiographs of the neck and chest and rigid endoscopy to identify possible synchronous airway lesions such as subglottic stenosis. Hawkins and Clark have shown flexible laryngoscopy to be effective, even in neonates. It is more accurate than using a general anesthetic and rigid endoscopy. The advantage of using the flexible scope in an awake patient is that the dynamics of the supraglottis can readily be appreciated. The disadvantage is that the milder forms of laryngomalacia may be missed if the child is crying. The flexible scope can also be used to diagnose other synchronous glottic lesions such as vocal cord paralysis and glottic cysts. Mancuso and colleagues retrospectively evaluated 233 patients with laryngomalacia to assess the necessity of performing a complete diagnostic workup in all patients. Their conclusion was that rigid endoscopy in evaluation of an infant with laryngomalacia is rarely necessary because clinically significant synchronous airway lesions which require surgical intervention are rare. Historically, this has not been the case. Hawkins and Clark and Nussbaum and Maggi used flexible endoscopy to evaluate laryngomalacia, but their recommendation was that all symptomatic children be evaluated with bronchoscopy. Bluestone, Healy and Cotton have gone "on record as recommending a complete evaluation of the tracheobronchial tree in all symptomatic infants." The disadvantage of using a flexible scope is that it does not allow an accurate assessment of the subglottis and trachea. The incidence of other lesions noted by additional authors has ranged from 18% in patients with congenital laryngeal lesions to 59.8% of all patients presenting with stridor. The controversy lies in the likelihood of missing a clinically significant synchronous airway lesion that would have been otherwise treated if rigid endoscopy had been performed. Mancuso and colleagues concluded that rigid endoscopy was not necessary in otherwise asymptomatic children. Bluestone and colleagues reached the opposite conclusion based on their "retrospective analyses of the "all symptoms" children who (they) have encountered: a number of cases in which the diagnosis of laryngomalacia was previously made by flexible laryngoscopy, but rigid endoscopy was omitted. Deaths have been described in patients with severe disease. This controversy is going to require additional data that are prospectively acquired. Currently, it would appear that if symptoms are not compatible with laryngomalacia alone or if the patient fails to thrive, direct laryngoscopy and rigid bronchoscopy should be performed to rule out secondary lesions. It is the surgeon’s obligation to closely follow his or her patients until the symptoms resolve.

Treatment

Expectant observation is sufficient in most cases. The small percentage of patients (10 to 15%) with failure to thrive or more than one lesion may require surgical intervention. Iglauer, in 1922, was the first to alter the supraglottis surgically in laryngomalacia. Schwartz, in 1944, removed a V-shaped wedge from an epiglottis with good results. Fearon and Ellis, in 1971, success- fully treated a patient by suturing the epiglottis to the base of the tongue. In that same year, hyomandibulopexy was advocated in France. Templ and colleagues, in 1981, performed a supraglottectomy in an adult for long-standing stridor and obstructive sleep apnea secondary to laryngomalacia. Lane and colleagues, in 1984, excised the tips of the arytenoids, edematous mucosa, a portion of the corniculate cartilages, and a portion of the aryepiglottic fold with microcapped forceps and Bellucci scissors. Seid and colleagues successfully treated three patients with the laser in 1985. Since then, numerous case reports have appeared in the literature. Zalzal and colleagues trimmed the lateral edges of the epiglottis, aryepiglottic folds, and the corniculate cartilages with microlaryngeal scissors. Solomon and Prescott recommended trimming the supraglottis and performing an anterior epiglottoty. The trimming of the aryepiglottic folds may involve both sides or only one side. Kelly and Gray recommended unilateral removal of redundant supraglottic tissue (supraglottoplasty) and operation on the other side if the patient is not asymptomatic. We have recommended doing both sides at one setting. Either appears to give satisfactory results.

Holinger and Konior prefer the term supraglottoplasty to describe the surgical procedures for removing the flaccid supraglottic tissues. Whyhmark and colleagues, in a large study, used the laser to remove a portion of the cartilage and the aryepiglottic folds and noted effective treatment of laryngomalacia (Figure 5). Care must be taken not to excise or traumatize the strip of mucosa between the arytenoids in the posterior glottis. Holinger and Konior believe that prophylactic antibiotics should be used, and most patients may be extubated in the immediate postoperative period but should be observed overnight in the intensive care unit. A supraglottoplasty may improve the gastroesophageal reflux, however, this remains controversial.
Figure 7  Laryngeal atresia.

**ABSENT OR RUDIMENTARY EPIGLOTTIS**

**Incidence**

These rare lesions can be associated with stridor and aspiration. In 1949, in the only thorough review of the world literature, Montreuil found only five clearly documented cases. Since then, six additional cases have been reported. Most of these patients had a bifold epiglottis.

**Symptoms and Signs**

Patients have presented with respiratory distress secondary to rotation of the two halves of the epiglottis into the airway. The incidence of multiple congenital anomalies is high. A 44% incidence of polydactyly has been reported. Graham and colleagues have reported three cases of hypopituitarism.

**Diagnosis**

The only means of diagnosing a bifold epiglottis is with flexible or direct laryngoscopy (Figure 6). Because of the high incidence of associated airway lesions, direct laryngoscopy is suggested for all patients.

**Treatment**

If the airway distress is significant, a tracheostomy is warranted. Montreuil amputated the epiglottis with good results. Healy and colleagues performed a tracheostomy in two patients, in time the epiglottis matured and both patients were decannulated without surgical intervention on the epiglottis.

**ATRESIA**

Atresia occurs when the laryngeal opening fails to develop and an obstruction is created at or near the glottis. Tracheal agenesis may also occur but is thought to be a rarer lesion.

**Incidence and Etiology**

Congenital laryngeal atresia is a rare lesion, with only 84 cases reported in the world literature in 1987. It is thought to be the rarest laryngeal lesion, accounting for only 1 of 846 congenital lesions evaluated by Holinger and colleagues and none of 433 congenital lesions evaluated by Fearon and Ellis. The lesion is thought to arise from the premature arrest of normal epithelial ingrowth into the larynx during the fourteenth to seventeenth stages of embryonic development. In the embryonic larynx, a pharyngolotic duct divides the larynx into an anterior (membranous) portion and a posterior (cartilaginous) portion.

**Symptoms and Signs**

At delivery, the infant makes strong respiratory efforts but does not move air, cry, or manifest any stridor. The infant becomes markedly cyanotic when the umbilical cord is clamped. Most of these infants die at birth unless an emergency tracheostomy is performed. Some infants survive if they have a large tracheoesophageal fistula and if the esophagus is intubated. Not infrequently, a pharyngotraceal duct is present in the larynx. This should not be confused with a tracheoesophageal fistula, which is located much lower.

**Diagnosis**

The diagnosis is most frequently made at autopsy. With the increased use of ultrasound, the diagnosis of laryngeal atresia can be made before birth by noting enlarged edematous eogenic lungs, dilated airways, inverted diaphragms, compressed fetal heart, severe ascites, and fetal hydrops. This is now termed congenital high airway obstruction syndrome (CHAOS) and can be diagnosed prenatally with ultrasound. Smith and Bain outlined three types of laryngeal atresia deformities; these investigators indicated that these types are not absolute but are gradations of a continuous spectrum. Type 1 involves the supraglottic and infraglottic larynx with fused arytenoids, an absent vestibule, and a deformed cricoid cartilage. Type 2 involves only the cricoid (subglottic area) with normal arytenoids, vestibule, and vocal cords. Type 3 involves a fused glottis with a normal vestibule and cricoid (Figure 7). The extent of the obstruction can be diagnosed with ultrasound. The subglottic lesions have been found to be cartilaginous or membranous.

**Treatment**

The patient will not survive unless an emergency tracheostomy is performed or the patient is ventilated through a tracheoesophageal fistula. Identifying laryngeal atresia prenatally with ultrasound dramatically improves the chance of survival by allowing caregivers with appropriate expertise to be present at delivery. Treatment is a tracheostomy combined with exuero intrapartum treatment (EXIT) which is basically performing the tracheostomy prior to severing the umbilical cord. Tracheoesophageal fistulas are frequently associated with this condition and usually arise at the tracheal bifurcation.

**webs**

Laryngeal webs occur in the glottis. Rarely, webs extend from the epiglottis to the lateral or posterior aspects of the hypopharynx and can result in
significantly airway compromise. Holinger and colleagues described a patient with simultaneous supraglottic and glottic webs. Most webs are located anteriorly and extend a varying length toward the arytenoids. The webs vary in thickness from a thin structure to one that is thicker and more difficult to eradicate. Benjamin and Mair described a rare type known as a congenital interarytenoid web, which limits the abduction of the arytenoids.

Incidence

Congenital laryngeal webs are uncommon, occurring in 5% of all congenital laryngeal lesions. Acquired lesions are more common than congenital lesions, in a 60:40 ratio. Associated anomalies are frequently seen, especially higher in the airway. Posterior glottic webs occur in only 1 to 4% of patients.

Symptoms and Signs

Symptoms of laryngeal webs are present at birth in 75% of the patients and within 1 year in all patients. The types of symptoms depend on the severity of the web. Many children are asymptomatic until they are stressed, have an infection, or are intubated for a surgical procedure. Vocal dysfunction is the most frequent symptom and was noted in 47 of 51 patients evaluated by Cohen. The severity of the dysphonia is not necessarily indicative of the severity of the web. Cohen reported on 11 patients who complained of aphony, 16 with weak or whispery voices, 7 with husky voices, and 4 with some hoarseness. The second most common symptom is airway obstruction, and the severity is directly proportional to the degree of obstruction. The compromise may be so severe that stridor cannot be produced because of limited air movement through the larynx. If stridor is present, it will occur in both inspiratory and expiratory phases, and if stridor is severe, the airway must be secured with intubation or a tracheostomy. Forty percent of Cohen’s patients required a tracheostomy. Croup rarely occurs in children younger than 6 months. Cohen reported 15 of 51 children with a significant history of recurrent croup, of whom 7 required tracheostomy, 9 presented with pneumonia, and 6 had tracheobronchitis.

Diagnosis

The only way to diagnosis the extent of the web correctly is with direct laryngoscopy under general anesthesia. The flexible scope may also have a role in the initial diagnosis, but experience in using it in patients with laryngeal webs is limited. Lateral radiographs of the neck may allow assessment of the width of the web.

Cohen has divided laryngeal webs into four types, based on their appearance and an estimate of the degree of airway obstruction. Type 1 is uniform in thickness with no subglottic extension and with the true vocal folds clearly visible in the web and compromises less than 35% of the airway (Figure 9). Hoarseness is usually only slight. Type 2 is slightly thicker, with a significantly thicker anterior component that may extend into the subglottis. The web restricts the airway by 35 to 50% and usually causes little airway distress unless the patient has an acute infection or is traumatized during intubation (Figure 10). The voice is usually husky. Type 3 is a thick web that is solid anteriorly with the true vocal folds not well delineated. The web restricts the airway by 50 to 75%, creates marked vocal dysfunction, with a weak or whispery voice. Type 4 is a uniformly thick, solid web occluding 75 to 90% of the airway (Figure 11). Respiratory obstruction is severe, and the patient is almost always aphony.

Treatment

Approximately 60% of patients require surgical intervention. Some webs are not repaired because the patients succumb to other systemic complications. Of all patients with laryngeal webs, 30 to 40% require a tracheostomy. The type of lesion dictates the surgical approach. In general, the thinner webs are easier to treat; the more severe webs are resistant to surgical management. It is difficult to obtain a crisp anterior commissure and, even if one is obtained, this does not ensure a good voice.

Type I lesions are not life-threatening. Many do not require surgery, but if surgery is performed, dilations or excisions with a knife, scissors, or laser are effective. Type 2 lesions require treatment, but not in childhood. Multiple procedures are necessary for excising small portions of the web in multiple steps. Corticosteroids and antibiotics decrease the amount of scarring, and speech therapy may be necessary to maximize phonation. Type 3 lesions frequently require
tracheostomy to establish the airway. The child may develop progressive airway distress because of increased airway demands, trauma from intubation, or infection. These lesions may require multiple excisions and frequently necessitate the placement of a keel.78 M. McGuirt and colleagues described a method using the laser to develop flaps of the web and reported near normal results in all patients.72 Type 4 lesions all require a tracheostomy and excision of the web with placement of a keel. Because they are tracheostomy dependent, these patients should be monitored with apnea monitors. Most surgeons would resect the web and place the keel through a laryngofissure. The airway results are good, but the voice is poor.74

SACCULAR CYSTS AND LARYNGOCELES

Laryngoceles and laryngeal saccular cysts are thought to arise from the laryngeal ventricle or saccular appendage79,83 or from retention cysts resulting from obstruction of mucus gland ducts.84 Morgagni incompletely described the saccule, and Galen also had mentioned it previously.85 The appendage arises from the anterior aspect of the ventricle, extends superiorly, and curves posteriorly deep to the false vocal folds and aryepiglottic folds. The orifice opens into the ventricle and measures only 0.5 to 1 mm. The ventriculoseptal saccule probably serves to help store mucus and direct it posteromedially to lubricate the vocal folds.86 In the adult, the appendage extends as high as the superior border of the thyroid cartilage.87 Royles found that 75% of the saccules measured 6 to 8 mm in length, 25% measured more than 10 mm, and 7% measured more than 15 mm.88 In the fetus, 25% extend as high as the thyrohyoid membrane.89 The type of lesion that develops is based on the size of the saccule, whether there is free communication with the laryngeal lumen, and whether there is inflammation within the sac. DeSanto and colleagues believe that the differentiating factor between the development of a cyst or a laryngocele is the patency of the ventricle.85,88

Saccular Cysts

Incidence. Laryngeal saccular cysts are most likely to become manifest in infancy.85 Congenital laryngeal cysts are rare, but the awareness of their possibility is important because almost 50% of these cysts are diagnosed at autopsy after the infant has asphyxiated.86 In 1967, Sues and Powell found 27 reported cases of congenital laryngeal cysts.89

Symptoms and Signs. Forty percent of congenital laryngeal cysts are discovered within a few hours of birth, and 95% of the infants have symptoms before 6 months of age.90 The most frequent symptom is stridor (90%), which is primarily inspiratory, although it may be biphase.86 The stridor improves in some infants during treatment of the lesion (Figure 12). A fluid-filled laryngocele may be difficult to differentiate from a cyst. If it becomes infected, it fills with mucopus and is called a laryngopyocele.

Diagnosis. Chest and lateral neck radiographs, barium swallow, and computed tomographic scan are useful preoperative evaluations of the stridor, but they are not diagnostic.96,97 Hemangiomas, for example, can cause identical findings, although these lesions appear most frequently in the subglottis. The only way to make the diagnosis definitively is with direct laryngoscopy.98 Cotton and Richardson suggested that at the time of endoscopy one should have a large-bore needle, a tracheostomy tray, and an appropriate-size rigid bronchoscope available.99 The cysts are typically divided into lateral wall saccular cysts and anterior saccular cysts. Lateral saccular cysts are most frequently located in the aryepiglottic fold, epiglottis, or lateral wall of the larynx99,100 (Figure 12). An anterior saccular cyst extend medially and posteriorly between the true and false vocal folds and directly into the laryngeal lumen.100,101 They are most frequently sessile but may be pedunculated. Mitchell and colleagues reported four subglottic cysts in patients who had previously been intubated and considered the cysts to be probably secondary to intubation.100

Treatment. Treatment of laryngeal cysts may require emergency tracheostomy.96,97,98 Mitchell and colleagues noted that 20% of their patients required emergency intervention.100 In the infant, the cysts should be treated primarily with endoscopic deroofing or aspiration. Sues and Powell recommended endoscopic incision and drainage as needed.101 Holinger and colleagues thought that smaller anterior saccular cysts could be effectively treated with cup forceps removal (excision biopsy) at the time of direct laryngoscopy.102 These investigators would not attempt endoscopic dissection of the entire sac. A spiration has also been recommended, but the incidence of recurrence is high.103,104 Mitchell and colleagues reported successful treatment of 7 of 17 patients with deroofing or marsupialization.105 A second deroofing was required in 6 of 7 recurrences. The remaining failure was treated with total excision through a laryngofissure.

Laryngoceles

Incidence. As of 1977, 300 laryngoceles had been recorded in the world literature.96 They may occur in infants and children, and they cause airway obstruction.97 The presence of laryngoceles in this age group appears to be rare, however. Laryngoceles are much more common in adults and appear most commonly in the fifth decade.96 Holinger and Brown reported on 12 patients with congenital laryngoceles in infancy,98 Baker and colleagues found an increased incidence of laryngoceles in laryngeal cancer and suggested that obstruction of the sacculae by the carcinoma was a factor in developing laryngoceles.99

Symptoms and Signs. Laryngoceles are symptomatic only when they are filled with air or fluid, so the symptoms may be intermittent. Because the laryngocele may rapidly inflate and deflate, several radiographs may be necessary to document the lesion (Figure 13). A fluid-filled laryngocele may be difficult to differentiate from a cyst. If it becomes infected, it fills with mucopus and is called a laryngopyocele.

Diagnosis. The definitive diagnosis is made with direct laryngoscopy but, because the symptoms are intermittent, more than one examination may be necessary. Laryngoceles originate from the ventricle and bulge out between the true and false vocal folds or dissect posteriorly into the arytenoid and aryepiglottic fold. In general, three types have been described: internal, external, and mixed; however, this classification is artificial. The internal type is limited to the larynx, whereas the external type extends into the neck through the isthmus of the thyrohyoid membrane. The mixed type involves both internal and external cysts and is the most common. Laryngoceles should be diagnosed with direct laryngoscopy and radiographic findings when they are symptomatic. Trapnell has emphasized that the radiographic appearance of a large saccule does not warrant the diagnosis of a laryngocele.98,99

Treatment. Only symptomatic lesions require treatment. DeSanto preferred the external approach; however, most of his experience was in adults. The procedure described by Yarington and Frazer provides adequate exposure for resection.100 Holinger and colleagues emphasized that true laryngoceles are rare in children and should be treated endoscopically by deroofing with cup forceps.86 On occasion, the laryngocele can be aspirated and a more orderly resection can be performed at a later date.101 The laser is also an alternative.
LARYNGEAL CLEFTS

The congenital laryngotracheoesophageal cleft is characterized by a deficiency in the separation between the esophagus and the trachea or larynx. Type one clefts are recognized more frequently, however, the true incidence is not yet known. Larger clefts are associated with a high mortality. Early diagnosis is crucial to prevent permanent pulmonary damage.

Incidence

Most clefts occur through the posterior part of the glottis; however, ventral or rare anterior clefts have been reported. Clefts may be classified into three broad categories. Type I is called the laryngeal cleft and is found only in the posterior part of the glottis. Type II and type III involve the trachea in addition to the larynx (Figure 14). Type II extends down to but not beyond the sixth tracheal ring, and type III can extend to the carina. As of 1983, 85 well-documented cases of clefts have been reported in the world literature. Finlay observed a family in which two of five children developed a cleft larynx. Other investigators have reported similar examples. The inheritance pattern is almost always autosomal dominant. Posterior glottic clefts have been associated with tracheal agenesis, as well as many other congenital anomalies.

Symptoms and Signs

The following manifestations, in order of frequency, are associated with laryngotracheoesophageal clefts: aspiration and cyanosis (53%), postpartum asphyxia (33%), increased mucus production (23%), recurrent pneumonia (16%), voiceless crying (16%), stridor (10%), and impaired swallowing (5%). Aspiration of thin liquids is the most common presenting sign for Type I clefts. The simultaneous occurrence of increased saliva production, low, soundless, or hurried crying, and stridor should lead to the suspicion of a cleft. The inspiratory stridor is produced by the collapse of redundant mucosa around the cleft and from the intrusion of the arytenoid into the airway. Cohen reported that the stridor may be expiratory because of aspirated secretions. One sees a frequent combination of posterior laryngeal clefts and tracheoesophageal fistulas.

Diagnosis

Occult posterior laryngeal clefts have been diagnosed with magnetic resonance imaging. A laryngeal cleft is frequently demonstrated by an esophagram with water-soluble contrast medium or is suggested by aspiration pneumonia on a chest radiograph. A recent endoscopic diagnostic test, functional endoscopic evaluation of swallow (FEES) has been applied to the diagnosis of laryngeal clefts with some success. The most important diagnostic test, however, remains direct laryngoscopy, and it should be combined with a high index of suspicion. If one does not specifically look for the entity, it frequently escapes detection. When the larynx is examined, redundant mucosa in the posterior part of the glottis is usually the first clue to the defect (Figure 15). On inspiration, this redundant mucosa may rotate into the airway. The cleft can best be demonstrated by placing a laryngoscope, such as a Dedo or Jako, into the supraglottis and examining the posterior glottis. If a posterior laryngeal cleft is present, this maneuver will clearly demonstrate the lesion and its extent (Figure 16). The posterior part of the glottis can also be palpated with a spatula or a similar thin instrument to demonstrate the defect. Some authors find microlaryngoscopy helpful. Some clefts are submucous, and diagnosis is made only on laryngeal sections. The clinical significance of submucous clefts is unknown. There is a high incidence of associated esophageal lesions and tracheoesophageal fistulas, for which careful examination must be made.

Treatment

The prognosis for a patient with this lesion is not favorable without early diagnosis to prevent pulmonary damage and associated morbidity or mortality. In the review presented by Roth and colleagues, 24 patients died before surgical intervention; of patients with type III clefts, 13 of 14 died; of those with type II clefts, 13 of 31 died; and of those with type I, 13 of 30 died. Almost two-thirds of the deceased patients had other severe malformations. Clefts were repaired in 48 patients, 13 of whom died. A tracheostomy was performed in 50% of all patients. The first
success operative correction of the defect in the larynx was achieved by Petterson.\textsuperscript{120}

Three surgical approaches to the posterior aspect of the larynx have been described. Minor (type I clefts) can be repaired endoscopically.\textsuperscript{121,122} Recent attempts to perform the repair utilizing robotics have met with some success, however, the application is limited by the exposure available in infants or neonates.\textsuperscript{123} A lateral pharyngotomy has been used frequently, especially for the larger laryngeal clefts.\textsuperscript{108,111} but the major disadvantage of this approach lies in the danger of injuring the recurrent laryngeal nerve. Also, the exposure is limited, and it is difficult to obtain a good layered closure. The anterior laryngofissure does not risk the recurrent laryngeal nerve and has been used in neonates.\textsuperscript{107,108,112,124–126} Evans reported better exposure and a better two-layer closure in type II and III clefts with a laryngofissure\textsuperscript{111} (Figure 17). Prescott\textsuperscript{127} successfully repaired a cleft with a posterior rib graft through a laryngofissure. A disturbance of the laryngeal growth appears unlikely. Intraoperative airway management has been a problem in repairing these lesions. Ahamd and colleagues solved the problem by using a bifurcated endotracheal tube.\textsuperscript{128} Geiduschek and colleagues reported the use of extracorporeal membrane oxygenation for extensive cleft repair.\textsuperscript{129} We have used bypass to repair long-segment tracheal stenosis. Cotton and Schreiber have noted that, after repair of posterior clefts, the patient may have continued esophageal reflux and aspiration of gastric contents.\textsuperscript{130} There appears to be a significant decrease in successful repair if a tracheoesophageal fistula is present.\textsuperscript{131} When this occurs, these investigators recommend a high gastric section with a double gastrostomy to minimize the chance of aspiration of gastric contents. Robie and colleagues reported that of 170 clefts repaired, 19 required revision surgery.\textsuperscript{126}

**VOCAL FOLD PARALYSIS**

Vocal fold paralysis can be categorized into congenital and acquired lesions. One or both of the true vocal folds may be involved, and bilateral vocal fold paralysis is more frequent.\textsuperscript{131–133} Apnea is frequently seen in bilateral vocal fold paralysis.\textsuperscript{134–136} Congenital laryngeal paralysis is frequently associated with central nervous system lesions, including hydrocephalus, meningoencephalocoele, Arnold-Chiari malformation, meningocele, encephalocele, cerebral agenesis, nucleus ambiguus dysgenesis, neuromuscular disorders, and myasthenia gravis.\textsuperscript{137,138} A mold-Chiari is the most frequent malformation and is likely a contributing factor in most cases.\textsuperscript{139,140} A underlying neurogenic cause for unilateral or bilateral vocal fold paralysis must be sought in the pediatric patient.

**Incidence and Etiology**

Estimates of the frequency of vocal fold paralysis range from 1.5 to 23%\textsuperscript{133,141,142} to some authors, it ranks second in frequency among all congenital laryngeal lesions.\textsuperscript{137} Holinger and colleagues found that congenital paralyses were more frequent than acquired.\textsuperscript{133} The acquired group can be further categorized into traumatic, infectious, or neoplastic. Traumatic lesions are most frequent secondary to stretching of the recurrent laryngeal nerve during vaginal delivery or surgical trauma in management of bronchogenic cysts, tracheoesophageal fistulas, or patent ductus arteriosus.\textsuperscript{137} Infectious diseases such as whooping cough, encephalitis, polyomyelitis, diphtheria, rabies, tetanus, syphilis, and botulism are now rarely seen but can cause vocal fold paralysis.\textsuperscript{136} Tumors of the brain and spinal column are also rare but can cause unilateral or bilateral vocal fold paralysis.

The pathophysiology of bilateral vocal fold paralysis is unclear, but the condition may result from (1) compression of the vagus nerve in its course through the foramen magnum, (2) traction of the cervical roots of the vagus nerve by the caudal displacement of the brainstem, or (3) brainstem dysgenesis.\textsuperscript{143,144} Most authors favor the compression theory because, with timely decompression of hydrocephalus or the Arnold-Chiari malformation, the vocal folds regain function. Familial bilateral vocal fold paralysis\textsuperscript{145–147} and persistent apnea after tracheostomy\textsuperscript{134} appear to be most appropriately explained by the dysgenesis theory. Probably, more than one mechanism can cause vocal fold paralysis.

Laryngeal lesions such as subglottis stenosis, laryngomalacia, and posterior laryngeal clefts have also been associated with, but do not cause, vocal fold paralysis.\textsuperscript{147,148}

**Symptoms and Signs**

Any of the three laryngeal functions of respiration, voice production, and deglutition can be affected by vocal fold paralysis. With unilateral vocal fold paralysis, the voice is breathy and weak, but the patient has an adequate airway unless stressed. Stridor, weak cry, and some degree of respiratory distress can be seen in all patients with bilateral vocal fold paralysis.\textsuperscript{144} Children have more problems than adults with reflux, choking, and feeding difficulties.\textsuperscript{149} Dedo noted that, if both the recurrent and superior laryngeal nerves are paralyzed, the vocal folds will be in the intermediate position and the airway will frequently be sufficient to allow adequate ventilation.\textsuperscript{137,138} If the recurrent nerves only are paralyzed, the vocal folds will be in the paramedian position, resulting in an inadequate airway.

Stridor is the most frequent presenting symptom of bilateral vocal fold paralysis.\textsuperscript{138} and its onset may be sudden.\textsuperscript{144} Older children suppress laughing and coughing because of the increased respirator demand. The airway becomes narrower, and there will be an increase in stridor, the development of nasal flaring, restlessness, and the use of accessory respiratory muscles, with an indrawing of the sternum and epigastrium. The stridor may progress to cyanosis, apnea, and respiratory and cardiac arrest if not recognized and treated.

Aspiration and dysphagia are frequently noted in patients with bilateral vocal cord paralysis.\textsuperscript{142,151} Pneumonia may first be apparent when signs of increasing cranial pressure appear.

**Diagnosis**

The diagnosis is made by flexible laryngoscopy or direct laryngoscopy. Vocal fold mobility may be difficult to examine in an infant, and the intermediate versus paramedian position may be impossible to assess.

**Treatment**

Once the diagnosis of vocal fold paralysis is made, the airway should be secured if the patient has significant airway distress. The airway is best established with intubation, followed by a full workup to ascertain the cause of the vocal fold paralysis. One must look specifically for associated findings of meningoencephalocoele, Arnold-Chiari malformation, and hydrocephalus.\textsuperscript{148} If the compression of the nerves is relieved within 24 hours, the vocal folds will regain function within 2 weeks.\textsuperscript{138,144} otherwise, vocal fold function may not return for a year and a half, if at all. If intervention has been timely, the larynx should be...
Stenosis

Stenoses of the subglottic area can be divided into cartilaginous stenoses, which are usually congenital, and acquired membranous or soft tissue stenoses.

Incidence and Etiology. A stenosis is considered to be congenital when the patient has no history of endotracheal intubation or trauma. The normal subglottic lumen is 4.5 to 5.5 mm in a full-term neonate and 3.5 mm in a premature neonate. We do not know in how many infants' extubations fail because of congenitally small cricoid cartilages.

Congenital subglottic stenosis is the third most common congenital abnormality. Cricoid cartilage deformities are usually congenital and consist of abnormal shapes and sizes. The cricoid cartilage may have a normal shape but be small or hypoplastic. It may also be elliptical, flattened, or otherwise distorted. The first tracheal ring can also be trapped under the cricoid cartilage resulting in a narrowed subglottis. The primary causes of acquired or membranous subglottic stenosis (Figure 18) in children are (1) external injury from blunt trauma or a high tracheostomy and (2) internal injury from prolonged intubation and chemical or thermal burns. External injuries are rare in infants. Internal trauma, secondary to prolonged intubation, is thought to account for approximately 90% of acquired subglottic stenosis.153,154 The incidence of stenoses after intubation ranges from 0.9 to 8.3%.155–158

The stenoses (Figure 19) have been noted to cause pressure necrosis of the cartilage, which may eventually occur, with necrosis and collapse of the cricoid cartilage. Benjamin characterized the traumatic lesions formed in the larynx with prolonged intubation.159 He noted that, in the acute phase, one sees formation of posterolateral ulcerations at the vocal processes ("ulcerated troughs") (Figure 19), and usually one sees an "intact median strip" of mucosa and an "annular ulceration" of mucosa in the subglottis. "Tongues of granulation tissue" (Figure 20) form anterior and posterior to the ulceration, and frequently one sees generalized inflammation and edema of the trachea that results in ventricular protrusions. The long-term complications of these lesions are characterized as posterior glottic synchiae, "healed furrows," posterior subglottic and glottic stenoses (Figure 21), "healed fibrous nodules," submucosal mucous gland hyperplasia with ductal cysts, and submucosal fibrosis and stenosis.

SUBGLOTTIC LESIONS

The principal subglottic lesions are stenoses and hemangiomas.

Stenosis

Stenoses of the subglottic area can be divided into cartilaginous stenoses, which are usually congenital, and acquired membranous or soft tissue stenoses.
Congenital subglottic stenosis that is mild and unlikely to need surgical correction. Congenital subglottic stenosis that is mild and unlikely to need surgical correction. 170

Symptoms and Signs
In the intubated neonate, evidence of subglottic stenosis may not manifest until the patient is ready for extubation. If a subglottic ulcer is present, the airway may be compromised immediately or edema may accumulate over a few hours. In some patients, symptoms do not develop until 2 to 4 weeks after intubation. If the patient has mild to moderate congenital subglottic stenosis, symptoms may not appear until an infection of the upper respiratory tract causes additional narrowing and respiratory distress.

If the stenosis is congenital, the only manifestation may be prolonged or recurrent croup. A common dictum is that “there is no such thing as croup under 1 year of age.” As respiratory demands increase, the infant may become symptomatic. 92

The main symptoms and signs relate to airway, voice, and feeding. Stridor is the primary sign and is biphasic, with the inspiratory phase always louder. With progressive narrowing of the airway, respiratory distress ensues. If the vocal folds are affected, hoarseness, abnormal cry, and aphonia will indicate that an anterior web is present. Dysphagia and aspiration pneumonia can occur.

Diagnosis
Soft tissue radiographs of the lateral neck may demonstrate subglottic narrowing. Xeroradiography demonstrates the tissue-air interface better and is believed by many to be the best method for evaluating chronic airway problems. 167-169 Computed tomographic scans do not give adequate additional information.

Direct laryngoscopy is the most important diagnostic step in assessing the thickness and length of the stenosis and involvement of the larynx. Flexible fiberoptic laryngoscopy is most useful in assessing vocal fold function. 168 Because the flexible scope provides only a limited view of the posterior glottis and subglottis, rigid endoscopy is necessary to assess the size and patency of the lumen. The airway may be sized with the bronchoscope or endotracheal tube. Storz Hopkins optical telescopes are especially important in visualizing the extent of the stenosis in the subglottis. Because of the wide-angle view, estimating the actual dimensions of the lumen is difficult. Often the narrowing is so great that only the telescope can be used.

Treatment
Congenital subglottic stenosis that is mild and causing mild symptoms and signs can be treated expectantly. Some patients outgrow their lesions and are unlikely to need surgical correction. Treatment must be individualized.

Tracheostomy is required in fewer than half of patients with congenital subglottic stenosis. 160 Normal growth and development may allow decannulation within 2 to 5 years.

The anterior cricoid split was initially devised to treat acquired subglottic stenosis, 171 and it was later applied to patients with the congenital form. 172,173 This procedure breaks the cartilaginous cricoid ring anteriorly to allow expansion of the subglottis. It is used in patients who have confirmed stenosis and failed extubation but do not require airway support and have mature lungs with oxygen concentration requirements less than 35%. The procedure involves making a vertical incision through the lower third of the thyroid cartilage, the cricoid cartilage, and the first two tracheal rings. Many of the cricoid rings spring open, and the endotracheal tubes are readily seen through the incision. Others do not open to any significant degree. Some surgeons have recommended placement of auricular or rib grafts at the time of the decompression. 174-176

In weighing the advantages of endoscopic and open procedures, the surgeon must take into account the extent of the scarring and the expertise required. The goal of any surgical procedure is to extubate or decannulate the patient by repairing the stenosis with minimal effect on the voice. Dilatation is useful if the ulceration is still present and granulation tissue is forming. It is most appropriately used with immature scar or submucosal fibrosis. Gentle dilation is performed with a round, smooth instrument usually in conjunction with corticosteroid injection. 177 Agressive dilatation with corticosteroid injection can induce additional trauma and cause significant necrosis of the cartilage.

The use of corticosteroids is controversial. They tend to decrease scar formation through their anti-inflammatory action and by delay of collagen synthesis. They may be used systemically or injected locally. Corticosteroids have not been successfully used to treat mature scar in the subglottis. Mitomycin C has been recommended as an agent to help maintain or decrease the amount of scar in the subglottis after laser resection or dilatation of the stenosis. 178 It is thought to interfere with the fibroblasts ability to produce scar without preventing epithelialization. 179 Halofuginone is another agent that has been shown to decrease the amount of fibroblast growth of the trachea even more than mitomycin C. 180 Clinical trials have not yet begun.

A variety of methods for endoscopic correction of subglottic stenosis have been suggested, including microcartilageization, 181 cryosurgery, 182,183 serial electrosurgical resection, 184 and carbon dioxide laser. 185 The carbon dioxide laser appears to be the current modality of choice. 186-189 The laser can only be used to resect membranous stenosis, and the procedure has to be performed in stages. The more aggressively the laser is used, the less the likelihood of a successful outcome and the greater the risk of inducing additional scarring. Cotton and Manoukian identified several factors associated with poor results: (1) circumferential scarring; (2) scar tissue greater than 1 cm in length; (3) scar in the posterior commissure; (4) severe bacterial infection of the trachea after a tracheostomy; (5) exposure of the perichondrium or cartilage with the laser; (6) combined laryngotracheal stenosis; (7) failure of previous endoscopic procedures; and (8) previous loss of cartilaginous framework. Propylactic systemic antibiotic therapy is recommended for endoscopic procedures. A dequate exposure of the subglottis is necessary. The subglottoscope designed by Healy is useful if the patient does not have a tracheostomy in place. Supraglottic jet ventilation provides the best exposure. Thin webs are most appropriately treated with the laser.

The open procedures have been traditionally used for more severe lesions. Surgeons are increasingly using single-stage reconstruction. 185,187 This allows for more rapid correction of the problem and is perhaps more cost effective. The hyoid interposition was first reported by Looper. 187 Bennett also reported the use of a hyoid bone graft for the treatment of subglottic stenosis. 188 Bone resorption was a problem, which led to the development of pedicle hyoid-sternohyoideal (myoosseous) flaps. 189-191

The anterior cricoid split with endotracheal tube stenting has been recommended for treatment of milder forms of stenosis. 190 The standard reconstruction has been with autogenous costal cartilage. 199-201 Because of its abundance, costal cartilage is a better material to use than thyroid cartilage, hyoid bone, or muscle pedicle.

The costal cartilage reconstruction has been the standard method for subglottic reconstruction for the past several years. The fifth or sixth costal or costal margin cartilage is harvested. One incision can be used to harvest two ribs, but this is seldom necessary. The perichondrium is left on the lateral surface of the rib, with incisions through it along the superior and inferior borders, and stripped from the medial surface. Some surgeons use the rib stripper on small double prong hooks and a Freer elevator. The incision in the neck is usually a U-shaped flap through the tracheostoma or a horizontal incision over the cricoid cartilage if a tracheostomy is not in place. The larynx and trachea are exposed, and a midline incision is made through the length of the stenosis. If the stenosis is severe, the lumen can be first identified with a 25-gauge needle under endoscopic visualization. When only an anterior graft is used, the incision usually extends from the tracheal rings through the cricoid and the lower third of the larynx. If a posterior graft and stent are required, a full laryngofissure will be necessary. The intraluminal scar and mucosa are incised strictly in the midline. This is best performed by first marking the lumen transtracheally with a 25-gauge needle. Once the airway is open, the scar is not removed. The length of the trachea and larynx to be reconstructed is measured, and the rib graft is designed to fit the defect. The graft
is elliptical, with the perichondrium toward the lumen. The rib is not thinned, and care is taken to shape the cartilage to be as wide as possible, with a lip or shelf to prevent the graft from falling into the airway (Figure 22).

In patients with greater subglottic stenosis, a posterior graft is needed, and the posterior cricoid lamina is divided in the midline to but not through the hypopharyngeal mucosa. In complete stenosis, a four-quadrant split has been recommended. The cricoid is separated to a distance of approximately 1 mm per year of age up to 10 mm between the two halves. A appropriate wedge of rib with the perichondrium facing the lumen is sutured into the posterior cricoid cleft. If a posterior graft has been performed, a stent will be required to maintain the lumen postoperatively. The current stent of choice is the Aboulker-styled Teflon stent, which is round. Unfortunately, it can cause significant blunting, trauma, and granulation tissue formation at the anterior commissure.

Once the posterior cricoid graft is positioned, the stent is placed and the anterior tracheal wall is closed. Usually, posterior and anterior grafts are used concomitantly. When a stent is used, it first must be positioned in the airway with the tracheostomy in place. The best method of securing the tracheostomy to the stent is with wire, as described by Cotton and Manoukian. Placement must be checked endoscopically. The stent should come to the level of the false vocal folds. If necessary, the stent length should be revised to hold the proper position. The rib is sutured into place with 4-0 Vicryl or polidioxanone suture, taking care to go through the cartilage and not allowing the suture to be exposed intraluminally. If suture is located in the lumen, granulation tissue and chronic infection will result. The neck wound is closed in layers. The stent is left in place for a variable length of time based on the surgeon’s judgment and the severity of the stenosis. Anterior cartilage has been used as a graft material. It is useful because it is malleable, its curved shape allows for greater (anterior/posterior) dimensions than available with the rib graft (Figure 23). The auricular cartilage graft has not been used extensively with staged reconstructions.

Cricotracheal resection has been recommended for Cotton grade 3 or 4 stenosis with success. These are frequently performed as single staged procedures even in young children; however, granulation tissue formation and additional endoscopic procedures are frequently required. This aggressive procedure has a high rate of success in these significant stenoses. Failure to decannulate the patient is usually secondary to unilateral or bilateral vocal fold paralysis. The long-term effect of growth on the larynx and trachea are not clear. Results of successful decannulation depend in part on the severity of the stenosis. Viral infections such as respiratory syncytial virus, and bacterial infections such as pseudomomas, have been associated with an increased failure rate. The ultimate outcome of grade 1 is 92% successful, that of grade 2 is 85% successful, that of grade 3 is 70% successful and, that of grade 4 is 36% successful. The voice is frequently compromised in patients with repaired subglottic stenosis. Ettema and colleagues have noted significant dysphonia in children with repaired subglottic stenosis.

SUBGLOTTIC HEMANGIOMA

Incidence and Etiology

Congenital subglottic hemangiomas are relatively rare lesions and develop primarily in the submucosa. Fifty percent are associated with cutaneous hemangiomas. No correlation exists between the size of the cutaneous lesion and the size of the laryngeal lesion. A 2:1 female preponderance is recognized.

Symptoms and Signs

Subglottic hemangioma develops in a typical growth pattern, with increasing size usually causing symptoms in the first 8 weeks of life. Almost all these lesions will become manifest before 6 months of age. Some lesions extend into the perichondrium and tracheal rings and beyond the trachea. There is a predilection for the left side. A variable and fluctuant respiratory distress usually progresses to persistent distress. The stridor is more prominent on inspiration but is present during expiration. The voice is altered to a varying degree, depending on the involvement of the larynx. A hoarse, hoarseness, barking cough, and failure to thrive are the other frequently noted manifestations. Recurrent croup is the most frequent erroneous diagnosis.

Diagnosis

Lateral radiographic studies suggest a subglottic abnormality consistent with hemangioma. This is not diagnostic, however, and the diagnosis can only be made endoscopically (Figure 24). The appearance of these lesions is characteristic and can be made by the experienced endoscopist without a biopsy. The lesion is sessile, fairly firm but compressible; pink, red, or bluish; and poorly defined. The vessels are rarely, if ever, cavernous. If a biopsy is performed, the bleeding is usually not profuse, but the airway must be maintained, most frequently with a tracheostomy. The lesion is usually unilateral or asymmetric. Multiple hemangiomas of the airway have been reported. A thorough workup of the possible extent of the hemangioma in the mediastinum is recommended.

Figure 22 Drawing depicting the rib graft, which has not been thinned, and a lip to prevent collapse into the lumen.

Figure 23 (A) Preoperative and (B) postoperative photographs of a laryngotracheoplasty with auricular cartilage.

Figure 24 Subglottic hemangioma.
Treatment
If the airway distress is significant at the time of diagnosis, immediate airway control will be necessary. Endoscopy may compromise the airway. If necessary, the airway may be secured with intubation or a tracheostomy. The most significant factors are degree of subglottic narrowing, location of the hemangioma and presence of hemangioma extending outside of the trachea. If the patient is intubated, tracheostomy is more likely to be required.

A wide range of treatments have been advocated. They include the following: tracheostomy with observation and awaiting spontaneous resolution; prolonged endotracheal intubation, with and without intraluminal corticosteroid injection; injection of sclerosing agents; the use of systemic corticosteroids; cryosurgery; external beam irradiation; gold seed irradiation; and laser excision. The judicious use of a laser to excise the lesion in stages, with the patient’s airway protected by a tracheostomy when necessary, appears to be the treatment favored by most surgeons. Bittar and colleagues noted a success rate of 88.9% with laser excision but if it is used too aggressively subglottic stenosis occurred in 5.5% of the patients. External beam irradiation has been reported to strictly limit its use. Gold seeds are the treatment favored by Benjamin. Open resection of subglottic hemangioma resection has been recommended with good results. The microdebrider has also been recently recommended as an effective tool for subglottic hemangioma resection. Unrecognized or improperly treated subglottic hemangiomas have a high mortality rate.

Congenital Anomalies of the Head and Neck

Lee D. Rowe, MD

Congenital head and neck anomalies represent a diverse group of clinical disorders that are the result of errors in embryogenesis or the product of intrauterine events that affect embryonic and fetal growth. Frequently, these present as upper aerodigestive tract neoplasms and neck masses, with thyroglossal duct abnormalities most common, followed by branchial arch defects, lymphangiomas (cystic hygromas), and subcutaneous vascular anomalies (hemangiomas, arteriovenous malformations). Less common are teratomas, heterotopic neural tissue, and nasopharyngeal neoplasms. Additional disorders encountered include congenital disorders of the oral cavity including cleft lip and palate, Pierre Robin sequence (PRS), and other aberrations such as primary ciliary dyskinesia, Kartagener syndrome, and craniofacial anomalies.

CONGENITAL DISORDERS OF THE NECK

Branchial Cleft Anomalies

Lateral cervical lesions termed branchial cleft cysts are congenital developmental defects that arise from the primitive branchial apparatus (branchial arch, cleft, and pouches). First branchial cleft anomalies are discussed elsewhere in this chapter.

Embryogenesis. The branchial arches consist of five parallel mesodermal bars, each with its own nerve supply and blood vessel (primitive aortic arches that develop during the third and fourth embryonic weeks). The branchial arches are separated externally by branchial clefts consisting of ectoderm and internally by endodermally lined branchial pouches. A branchial plate is located between each arch separating pouch from cleft. The nerves are anterior to their respective arteries, except in the fifth arch, where the nerve is posterior to the artery. Caudal to all the arches is the twelfth nerve which arises from the cephalic ridge. The sternocleidomastoid muscle is derived from cervical somites posterior and inferior to the foregoing arches. In each arch, a central artery develops connecting the two ventral and two dorsal aortas. The two ventral aortas fuse completely, whereas the two dorsal aortas only fuse caudally. With continued development, the ventral aortas become the external and common carotid arteries, whereas the arteries of the first and second arch degenerate. Segments of the dorsal aorta persist as the internal carotid artery along with the artery of the third arch. The left fourth arch artery becomes the arch of the aorta, and the right fourth arch artery becomes the proximal subclavian artery. The primitive clefts pass between the corresponding arteries. Development of the pharyngeal region and branchial arches depends on the integration of surface ectoderm, foregut endoderm, paraxial mesoderm, and the neural crest. It is believed that the regional development of the branchial arches is controlled by nested expression of related homeobox genes (HOM-C/Hox). Studies in mutant mouse embryos lacking the homeobox gene (Hoxa3) demonstrate bilateral defects of the common carotid artery, a third branchial arch derivative. Mice homozygous for a hypomorphic allele of Fgfr1 have craniofacial defects, some of which are due to the failure of entry of neural crest cells into the second branchial arch. In addition, hemizygous deletion of chromosome 22q11 in humans involves defects in pharyngeal arch and neural crest development.2 The resulting branchial pouch anomalies are generally lined with stratified squamous cell epithelium containing subepithelial lymphoid follicles, keratin, hair follicles, sweat glands, cartilage, and sebaceous glands.

Clinical Presentation. Typically, branchial clefts present as smooth, round, fluctuant, non-tender masses along the anterior border of the sternocleidomastoid muscle, anywhere from the external auditory canal to the clavicle. During upper respiratory tract infections, a painful increase in size is common and occasionally may be associated with external drainage through an unrecognized fistula. Small cysts may not be recognized until the second decade in life. Male and female incidences are equal, and nearly all these lesions are recognized by the time the patient reaches 30 years of age.

Second Branchial Cleft Anomalies. Second branchial cleft lesions are the most common anomalies and are encountered most frequently in the anterior triangle of the neck along the anterior border of the sternocleidomastoid muscle inferior to the angle of the mandible. The fistula tract, if present, ascends along the carotid sheath, crosses over the hypoglossal and glossopharyngeal nerves, and courses between the internal and external carotid arteries. It ends in the tonsillar fossa, a second branchial pouch derivative. Second pouch remnants may form blind sinuses in the palatine tonsil and frequently cause recurrent unilateral tonsillitis. A tonsillectomy and excision of the sinus tract is necessary.

Third Branchial Cleft Anomalies. Third branchial cleft anomalies are unusual and constitute less than 1% of all branchial cleft anomalies. The external ostium occurs at the same position as the second branchial cleft anomaly, and the cyst may be located anywhere along the fistula. The fistula tract ascends along the carotid sheath behind the internal carotid artery and over the hypoglossal nerve, and it enters the pyriform sinus, piercing the middle constrictor muscle below the glossopharyngeal nerve. Clinically, the anomaly may mimic suppurative thyroiditis or symptoms of an external laryngocele and can cause recurrent infection, discharge, and rarely, stridor.

Fourth Branchial Cleft Anomalies. Fourth branchial cleft anomalies are extremely rare. As of 2004, only 60 cases have been reported. The fistula tract descends along the carotid sheath, enters the chest passing under either the aortic arch on the left or the subclavian artery on the right, and ascends in the neck to open at the apex of the pyriform sinus. The sinus tract or cyst may become clinically manifested by recurrent episodes of neck abscess or acute suppurative thyroiditis which may cause acute airway obstruction in infants. A left neck predominance has been confirmed.

Treatment. Complete surgical excision is the treatment of choice for branchial cleft anomalies and is indicated for recurrent infection, cosmetic deformity, and potential for malignant degeneration. Preoperative assessment with ultrasonography, computed tomography (CT) scanning, and/or magnetic resonance (MR) imaging is essential and may be combined with a fistulogram or pharyngo-esophagogram when indicated. A “stepladder” surgical approach with transverse incisions paralleling skin creases is used to avoid long, cosmetically unsatisfactory incisions, paralleling the sternocleidomastoid muscle. To avoid recurrence, combined endoscopic examination for a pharyngeal pouch and sinus tract with meticulous dissection of a sinus tract, if present, along with endoscopic cautery of the sinus tract’s internal opening will facilitate complete resection. It is essential to excise en bloc any portion of the thyroid involved in the sinus tract. Removal of fourth branchial pouch sinuses can be facilitated via a modified oblique thyrotoomy above the cricothyroid joint after detaching the inferior constrictor.

Branchiogenic Carcinoma. The hypothesis that squamous cell carcinoma arises in a branchial cleft cyst (branchiogenic carcinoma) is controversial.
Cystic squamous cell carcinoma presenting in the neck without an apparent primary is almost universally secondary to metastasis from a neoplasm arising in the faucial or lingual tonsillar crypt epithelium or nasopharyngeal tissue. Malignant transformation with in situ branchial cyst carcinoma is therefore a rarity. Management is wide excision of the tumor and ipsilateral radical neck dissection followed by adjuvant radiation therapy or chemoradiation.

LYMPHANGIOMAS, HEMANGIOMAS, AND OTHER VASCULAR ANOMALIES

Congenital lymphangiomatous malformations of the head and neck represent a wide clinical spectrum. Lymphangiomas result from abnormal development of the lymphatic system at sites of lymphatic-venous connection, with obstruction of lymph drainage from the affected area causing multicystic endothelium-lined spaces. The neck is the most common site (25% of all cases). Over half these lesions are present at birth, with 90% manifesting by 2 years of age. Those lymphangiomas arising above the mylohyoid muscle are more infiltrative and tend to extend from skin to mucosa while those below the mylohyoid are more discreet and cystic.

Cystic Hygroma

Cystic hygromas are large lymphangiomas most commonly found in the posterior triangle of the neck and axilla in children. Cervical cystic hygromas commonly appear before 30 weeks’ gestation and are usually associated with karyotypic abnormalities, various malformation syndromes and several teratogenic agents. The prognosis is poor for these types of hygromas. By contrast, cystic hygroma developing late in pregnancy has a more favorable outcome and is more likely to be encountered by the head and neck surgeon. Cystic hygromas are soft, painless, and compressible masses that may increase when the patient cries. Two-thirds are asymptomatic. After an upper respiratory tract infection, however, sudden enlargement with inflammation, infection, dysphagia, and stridor may develop. This is more commonly seen if the anterior triangle of the neck is involved or in patients with pharyngolaryngeal extension or intraoral involvement.

Vascular Anomalies

Other congenital vascular anomalies of the head and neck include hemangiomas and arteriovenous malformations or lymphovenous lesions. Diagnostic imaging of these anomalies is based on the need for surgical treatment. Only those lesions that cause functional impairment or developmental disturbance are surgically addressed. Angiography, combined with MR imaging, allows separation into low-flow lesions (hemangiomas, venous, and lymphatic malformations) and high-flow lesions (arteriovenous malformations and invasive, combined lymphovascular malformations). Treatment of small cystic hygromas that have not regressed but have enlarged is with surgical excision with staged debulking of larger cystic hygromas. Neural structures such as the facial nerve, vagus nerve, and phrenic nerves should not be sacrificed. Recurrence is uncommon when gross neoplasm is removed. Hemangiomas are frequently multiple with the parotid gland, a common site of occurrence. They proliferate during the first year of life, then involute at a variable rate over several years. Subcutaneous recombinant interferon alpha 2 a or oral methylprednisolone administered over 6 to 12 months is effective treatment if initiated early in the proliferative phase. Alternatively, cyclophosphamide may induce fast regression in neonates with life-threatening hemangiomas. Surgical excision is reserved for severe cosmetic deformity or life-threatening aerodigestive tract impairment.

For low-flow, macrocystic-type lymphangiomas less than 5 cm, sclerosant therapy with the agent OK-432, a lyophilized mixture of low-virulence group A Streptococcus pyogenes with penicillin G potassium, is effective, either alone or combined with surgical resections or embolization (Figure 1). Preoperative embolization at the time of selective angiography and surgical excision are the treatment of choice in high-flow malformations. Ultimately, biomolecular markers will characterize vascular anomalies with specific clinical behaviors. Key cytokines driving angiogenesis include vascular endothelial growth factor (VEGF) family members and receptors (placental growth factor [PGF], VEGF-A, and VEGF-C) and angiopoietins. Distinct patterns of angiogenic factor expression, endothelial vascular mural cell status, and vessel architecture may eventually be used to predict which lesions will involute.

ABERRANT THYROID TISSUE

Ectopic thyroid tissue can occur anywhere from the foramen cecum to the lower neck (Figure 2). Most frequently, it occurs as a thyroglossal duct cyst associated with a normal thyroid gland. Less common is total ectopia, manifesting as a lingual thyroid. True lateral neck thyroid ectopia lateral to the carotid artery and jugular vein cannot be confirmed based upon embryogenesis. As a result, the findings of aberrant thyroid tissue should direct attention to the ipsilateral thyroid lobe. If papillary carcinoma is found in an aberrant position, then thyroidectomy with central lymph node dissection is performed. Because cervical metastases of papillary thyroid carcinoma (PTC) can mimic branchiogenic cysts clinically and histopathologically, it is difficult to distinguish between true PTC arising within a branchial cyst and metastatic disease. Immunohistochemical staining for thyroid transcription factor 1 (TTF-1) is not specific to thyroid tissue as it is positive in 10% of isolated branchial cleft cysts. However, detection of p63 expression in the nuclei of the lining epithelia of the branchial

Figure 1. Computed tomography (CT) of pre- and post sclerotherapy with OK-432 in congenital lymphatic malformation. (Used with permission from reference 6.)

Figure 2. Most common locations of midline aberrant thyroid tissue schematically illustrated.
cleft cyst may suggest that p63 contributes to the development of PTC arising within the cyst.Embryology
In the 4-week-old embryo, the primitive thyroid gland begins as a ventral diverticulum of endodermal origin, arising in the floor of the pharynx between the tuberculum impar and the copula. Ultimately, it becomes the foramen cecum, and the copula becomes the posterior third of the tongue. The thyroid descends caudally through or adjacent to the primitive hyoid bone. The developing thyroglossal duct reaches its final position in the midline of the neck and develops into the median lobe of the thyroid. It normally persists as a hollow stalk for 6 weeks and then atrophies. Thyroglossal duct anomalies result from a failure of complete obliteration of the thyroglossal duct and are located anywhere along the descent of the gland.

Lingual Thyroid
A lingual thyroid presents in the midline as a sessile, nontender reddish mass in the base of the tongue, anterior to the vallecula. It is the most frequent benign mass encountered in the oropharynx and, unlike other aberrant thyroid anomalies, has a female preponderance of 7:1. Symptoms may include dysphagia, cough, dysphonia, dyspnea, and in extremely rare cases, symptoms of obstructive sleep apnea and hemorrhage. A lingual thyroid may become apparent during pregnancy because of increased thyroid function, and approximately 70% will have hypothyroidism.

A lingual thyroid is covered with squamous cell epithelium and often exhibits an abundant aberrant vascular supply. The mass consists of normal or immature thyroid tissue, which may be either functional or dysfunctional. Indications for surgical removal include uncontrollable hyperthyroidism, hemorrhage, symptomatic enlargement, or question of malignancy. Carcinoma arising in a lingual thyroid is rare with only 28 cases reported. Preoperatively, a thyroid uptake study and ultrasound should be obtained to determine whether functioning thyroid tissue exists in its normal cervical location. MR imaging may also be of value because it allows multiplanar imaging and provides the best soft tissue definition. Excision is performed by the transcervical transhyoid route. Alternatively, iodine-131 ablation for benign lingual thyroid is a safe and effective treatment while transposition of the gland via a lateral pharyngotomy incision with random tongue muscle flap revascularization has been used to preserve thyroid function.

Thyroglossal Duct Anomalies
Signs and Symptoms. A thyroglossal duct cyst is the most common congenital neck mass and the second most common of all childhood cervical neck masses. Cysts, sinuses, and fistulas of the thyroglossal duct manifest as anterior midline neck masses from the foramen cecum to the thyroid gland, typically before 20 years of age (most before 10 years). Thyroglossal ducts and fistulas are often asymptomatic. They may also become recurrently infected during upper respiratory tract infections, which can cause cyst enlargement, abscess development, and rupture with external sinus formation. Thyroglossal duct cysts most commonly are found below the hyoid bone and above the thyroid gland, displaying movement with anterior tongue protrusion and swallowing. Usually, the cysts are 1 to 3 cm in diameter and are smooth, round, and fluctuant. A precise pathogenesis of thyroglossal duct cysts has not been determined. However, a hereditary predisposition is suspected. Overall, a predominantly autosomal dominant pattern of inheritance in non-United States families has been reported in older patients (mean age 13.9 years) versus an autosomal recessive pattern in younger patients (mean age 6.2 years).

Histopathologic Features. Thyroglossal duct cysts and fistulas are lined with squamous, ciliated columnar, or transitional cell epithelium. They may be surrounded by fibrous tissue with infiltrating inflammatory cells lacking organized lymphoid tissue. Islands of ectopic thyroid tissue and mucous glands are not uncommonly identified. The cyst or sinus tract is filled with mucoid or mucopurulent material. The male-to-female ratio varies between 1.2:1 and 1.6:1.

Differential Diagnosis. The differential diagnosis includes dermoid cyst, pyramidal lobe hyperplasia or cyst, teratomas, hamartomas, lipomas, sebaceous cysts, cystic hemangiomas, hyperplastic lymph nodes, and malignant primary or metastatic neoplasms.

Treatment. As with a lingual thyroid, a preoperative thyroid scan and uptake study are mandatory, even though concomitant agenesis of the thyroid is extremely rare. Malignant degeneration, recurrent infections, undesirable cosmetic appearance, and rarely, intermittent upper airway obstruction are indications for surgical excision of thyroglossal duct cysts and fistulas. Incision and drainage may be necessary in the interim if an abscess has developed. Because of the high recurrence rate after excision the Sistrunk procedure is recommended to prevent recurrence. This involves a transverse incision over the cyst or a fusiform incision over an external fistula opening. All abnormal tissue including the cyst, fistula, body of the hyoid bone (preferably more than 15 mm), and the fibrous cord extending to the foramen cecum should be resected. Recurrence develops in up to 20% of cases as a result of failure to remove all abnormal tissue including accessory ducts and is significantly increased by the presence of inflammation at the time of surgery and greater than two infections prior to surgery.10 Malignant degeneration of the thyroglossal duct remnants occurs in 1 to 2%.11 A approximately 173 cases of thyroglossal duct carcinoma, predominantly of the papillary type, have been reported. Additional cases of Hürthle cell adenoma have also been described. Most patients with papillary carcinoma are in their forties, although 20% are less than 20 years of age. Typically, the tumor is small and clinically unsuspected, and in rare cases it may be associated with regional or distant metastasis. Rarely, squamous cell carcinoma arising directly from the lining epithelium in a thyroglossal duct remnant has been reported and, as a rule, has a poor prognosis. Treatment of thyroglossal duct remnant carcinoma consists of the Sistrunk procedure, total thyroidectomy, central lymph node dissection, ablative iodine-131 therapy for residual metastatic thyroid carcinoma subsequent thyroid suppression therapy and careful interval follow up with whole body thyroid scanning.

Thymic Cyst
Cervical ectopic thymus and thymic cysts are extremely rare. About 100 cases have been reported in the English language with most occurring asymptptomatically in children and adults. Only 10% have involved patients younger than 1 year of age. Cysts can arise from nests of thymic tissue anywhere along the descent of the thymic primordia from the mandible to the mediastinum and are primarily located anterior and deep to the middle one-third of the sternocleidomastoid muscle. In up to 50% of the cervical thymic cysts there is a mediastinal connection possibly requiring a sternotomy. Thymic lesions are more common in males. Ectopic cervical thymus is best imaged by MRI whereas thymic cyst has a more consistent appearance on CT. Surgical resection provides definitive diagnosis and cure (Figure 3).

Neurogenic Neoplasms
Congenital neurogenic lesions involving the head and neck include all neoplasms or anomalies originating in the neural tissue or its covering. Two groups have been recognized: (1) heterotopic brain lesions with developmental defects, which are discussed in the next section; and (2) neoplasms of neurogenic origin.

Figure 3 Coronal T1-weighted magnetic resonance image of a neonate with a cervical thymic cyst with mediastinal involvement. (Reproduced with permission from reference 13.)
including neoromas, neurofibromas, ganglioneuromas, and meningiomas. Neuroras originating from the connective tissue sheath of the nerve are termed schwannomas. They may appear as multiple neurofibromas arising from cutaneous, visceral, and cranial nerves in neurofibromatosis type 1 (NF1) or type 2 (NF2) and have a predilection to arise in deep planes of the neck. NF1 is a common autosomal dominant disease characterized by complex and multilcellular neurofibromas arising from Schwann cells, pigmentation anomalies, and increased risk of low-grade tumors undergoing high-grade malignant transformation. 95% of patients with NF1 exhibit a mutation in the NF1 gene on chromosome 17 whose product, neurofibroin, functions in Ras signal transduction and cell proliferation and differentiation. Allelic loss and/or basepair deletions in the NF1 gene are associated with malignant transformation.14 NF1 is defined by the absence of bilateral gene are associated with malignant transforma-

tion to arise in deep planes of the neck. NF1 is a type 1 (NF1) or type 2 (NF2) and have a predilec-

tion to originate from displacement of epidermal ele-

ments during the intramembranous growth phase of the nasal bones in the embryo. Because of the variability in clinical presentation and contigu-

ous structure involvement, segregation of peri-

orbital lesions into three distinct subgroups is helpful: (1) frontotemporal region dermoid cysts; (2) orbital region dermoid cysts; and (3) nasogla-

bial dermoid cysts. Midline nasoglabellar cysts may have associated sinus tracts or fistulae (10 to 45%) which, in rare cases, may have intracra-

nial extensions. In those patients with intracranial extension, the sinus tract traverses either the crib-

iform plate or foramen cecum and is attached to the dura, falx cerebri, or other intracranial struc-

tures. The treatment of choice is surgical excision after CT and MR imaging to evaluate intracra-

nial extension.13 All tissue must be removed to prevent recurrences. In patients with intracranial extension, a coronal flap is employed to facilitate removal and to prevent postoperative meningi-

tis and abscess formation. Transnasal endoscopic techniques have been advocated when the der-

moid cyst is confined to the nasal cavity with no cutaneous involvement.

Other congenital midface cysts are those associated with the facial clefts, including the nasoethmoidal cleft cyst, nasolabial cyst, subalar cleft cyst, globulomaxillary cyst, cysts connected with cleft lip or palate, premaxillary cyst, naso-

palatine cyst, foraminal incisor cyst, and Jacob-

son organ cysts.

**Choanal Atresia**

Bilateral atresia of the choanae is the most fre-

quently encountered congenital nasal anomaly (1 in 7,000 to 8,000 live births) and is a common cause of neonatal respiratory distress. Approximately 50% of individuals with choanal atresia have the anomaly bilaterally. A analysis of CT scans and histopathologic sections demonstrates 29% pure bony, 71% mixed bony and membra-

nous and no pure membranous atresia. A 2:1 female predisposition is seen in choanal atresia, and recent evidence points to an autosomal recessive mode of inheritance.

Failure of breakdown of the buccopharyngeal membrane on gestational day 45 is considered to be the cause of choanal atresia. Other theo-

tories include abnormalities in the migration of the cephalic neural crest following neural tube clo-

sure. Several craniofacial abnormalities including skull-base defects and systemic malformations have been described in association with cho-

anal atresia, including the CHARGE association (Table 1). The CHARGE association is a non-

random clustering of congenital anomalies which

**Heterotopic Neural Tissue**

A berrant embryogenesis of the frontonasal and anterior neuropore leads to three main types of anomalies: heterotopic neural tissue (either nasal glioma or anterior cephalocele) and nasal dermal sinus. Heterotopic neural tissue or glioma may manifest as isolated ectopic brain tissue with only a fibrous band connecting it to the endocran-

ium. A glioma may be of the external or endonalas type. The external nasal glioma is typically found in the nasion as a red, relatively firm, mobile mass located subcutaneously that does not increase in size when the patient cries. The endonasal glioma is less common and arises from the middle turbinate or the lateral nasal vault, where it may be mistaken for a polyp. By contrast, a meningioce-

le is a hernial protrusion of the meninges, and if it contains brain tissue, it is called an encephalcele. An encephalcele is caused by a defect of the fetal skull and contains an ependyma-lined cavity filled with cerebrospinal fluid. Two basic types of hernial protrusions are identified: (1) the sincipital type; and (2) the basal type. The sincipital type is uncommon and is associated with termination of the meninges near the base of the nose. This type has three different forms: (1) nasofrontal, in which the encephalcele extends between the nasal and frontal bones, resulting in a midline swelling at the base of the nose; (2) nasoethmoidal, in which a defect among the nasal, frontal, and ethmoidal bones allows the encephalcele to appear as a mass beneath the skin of the bony-cartilaginous junction; and (3) naso-orbital protrusion of the encephalcele through the suture line among the lacrimal, frontal, and ethmoidal bones appearing as a conjunctival mass. The basal type, in which the hernia extends into the naso-orbital and pharyngeal region, is rarer than the sincipital. Three varieties have been identified: (1) sphenoidopharyngeal, in which the encephalcele extends through the ethmoid or sphenoid bones or their sutures lines into the nasal or nasopharyngeal cavity; (2) sphenoid-orbital, in which the encephalcele extends through the sphenoid-orbital fissure into the posterior aspect of the orbit, resulting in pulsatile exophthalmos; and (3) sphenomaxillary, in which the encephalcele herniates through the sphenoid-orbital fissure into the orbit, with exten-

sion inferiorly through the inferior orbital fiss-

ure into the pterygopalatine fissure. This results in a mass bulging into the cheek or into the oro-

pharynx, medial to the ramus of the mandible. In all cases, unlike with gliomas, pulsations and an increase in size of the mass can be observed when the patient coughs or strains. Thin cut axial and coronal CT and/or multiplanar MR imaging are necessary to determine the appropriate combined transfacial and intracranial approach for surgical resection. Three-dimensional CT is helpful in complex cases providing additional information for surgical planning.

**Dermoid Cysts**

Dermoid cysts occasionally occur in the neck, usually in the midline. Overall, fewer than 10% of all dermoid cysts occur in the head and neck. One-fourth of the head and neck dermoid cysts are found in the floor of the mouth, with the remain-

der in the nasal and periorbital region. The most common presentation is a midline nasoglabellar mass. These lesions are seen primarily in children and adolescents during the second decade of life, but they also may occur in infants. Cyst walls consist of squamous cell epithelium containing epidermal appendages. These cysts are thought to origi-

nate from embryonic skin or cutaneous tissue.
that this syndrome is a polytopic developmental

soft tissue formation, osteoneogenesis, and subse-
ding to the new choana and to prevent granulation
the challenge is to provide adequate mucosal lin-
repair choanal atresia. The appropriate method is
determined by the age of the patient and whether
the atresia is bilateral or unilateral. In all methods,
the use of topical corticosteroids to diminish
mucous membrane covering the raw bony surface.
Symptoms. Respiratory distress at birth is the
sine qua non of bilateral choanal atresia. In
spite of vigorous attempts at respiration, effec-
tive air exchange does not occur until the neonate
begins to cry, bypassing the nasal obstruction. Once
the crying ceases, however, the neonate’s mouth closes, and a pattern of cyclic obstruction
gradually develops, resulting in increasing respi-
ratory failure. Because neonates are obligatory
nasal breathers, placement of an oral airway or
McGovern nipple is lifesaving. By contrast, chil-
dren with unilateral choanal atresia present later in
life with unilateral rhinorrhea without respira-
tory distress.
Diagnosis. The diagnosis of bilateral choanal
atresia is confirmed by the inability to pass a
No. 5 or 6 French feeding catheter at least 3 cm
through the nose into the nasopharynx. In addition,
direct observation with nasofiberoptic endoscopy and CT scan is essential to determine the type of obstruction. Specifically, the CT scan
demonstrates the thickness of the atretic plate as well as its medial encroachment of the posterior
aspect of the medial maxilla.
Treatment. Multiple methods are available to
repair choanal atresia. The appropriate method is
determined by the age of the patient and whether
the atresia is bilateral or unilateral. In all methods,
the atresia plate with either a curette or powered
instrumentation and removal of lateral choanal bone and a portion of the vomer with preservation
of mucosal flaps. The use of stenting, laser, mitomycin C or topical nasal corticosteroids is
controversial, and no controlled studies have evaluated their true efficacy.

Transnasal Approach. The most direct and sim-
plest route for choanal atresia repair is trans-
nasal, using a No. 2 Lempert or similar curette
inserted 3 to 3.5 cm beyond the nares along the
nasal floor, and exerting firm pressure against
the bony atresia plate until it is perforated. The
anterior nasal mucous membrane is sacrificed after satisfactory enlargement of the choana to
permit placement of a 3.5 mm Silastic endotra-
cheal tube as a stent. Posterior membranous flaps
are developed in a stellate fashion to cover the
denuded bone (Figures 5 and 6). Care must be
taken to prevent injury to the roof of the choana
and the skull base because reported complica-
tions of this approach have included menin-
giitis, cerebrospinal fluid leaks, brain injuries,
Gradenigo syndrome, and cervical vertebral
subluxation. Reported laser techniques include
the use of the carbon dioxide, KTP, or neody-
mium: yttrium–aluminum–garnet (Nd: YAG)
lasers. An endoscopic approach with a 2.5 mm
or 4 mm telescope and powered instrumentation
using a microdebrider with continuous suctions

has an estimated prevalence of 1 in 10,000 births. It occurs with C, col oboma of the iris or retina; H, congenital heart disease; A, atresia choanae; R, retarded growth and development; G genital
anomalies in males; E, ear abnormalities and deafness. Almost all patients have malformed
pinnae and exhibit hypoplastic incudes, cochlear anomalies and ageneses or hypoplasias of the
semicircular canals on CT scan (Figure 4). The majority demonstrate severe conductive or mixed hearing loss and vestibular dysfunction. Other commonly associated anomalies are
facial nerve palsy (50%), tracheoesophageal fistula (33%) and cleft lip/palate. A rhinencephaly
is a constant feature which is being increasingly recognized antenatally. Chromodomain helicase
DNA-binding protein gene (CHD7) mutations on chromosome 8q12.1 account for the majority of
cases with CHARGE syndrome and exhibit broad clinical expression without obvious genotype-
phenotype correlation. The combination of malformations in the CHARGE association suggests that
this syndrome is a polytopic developmental

surgical failure rate in this population. Although impaired palatal growth is a potential problem in the neonate, the procedure can be safely used in patients older than 5 years of age who are treatment failures, if one takes great care to avoid injury to the posterior palatine canals. The procedure is carried out with the patient in the supine position and the head hyperextended. After infiltration of local anesthesia, a horseshoe-type incision is developed several millimeters posterior to the alveolar ridge, and a mucoperiosteal flap is then raised based on the greater palatine vessels. Once the posterior edge of the hard palate is reached, the mucosa is divided, providing access to the atretic plate. An attempt is made to maintain mucosal flaps on both sides of the atretic plate. The atretic plate, posterior vomer, and medial aspect of the posterior maxilla are removed with a microdebrider, diamond bur, otologic curette, or rongeur (Figure 8). After removal of bone, mucosal flaps are transposed to cover the superior and inner surfaces of the choana, with stents placed as previously described. The palatal flap is reapprroximated anteriorly with absorbable sutures. If stenosis occurs after surgical repair, patients generally slowly develop progressive respiratory difficulties. Revision surgery or dilation may be necessary.

CONGENITAL DISORDERS OF THE NASOPHARYNX AND OROPHARYNX

Tornwaldt Cyst and Rathke Pouch Cyst

If the pharyngeal segments of the primitive notochord remain connected to the endoderm in the nasopharynx, a bursa or embryonic pouch occurs. In approximately 3% of individuals, this invaginated connection persists, and the resulting sac and canal, located in the posterior midline of the nasopharynx, extends posteriorly and cephalad toward the occipital bone. If the bursa is occluded by inflammation, a cyst will develop, and if the cyst becomes infected, an abscess will result. Anterior to the invagination and above the bursa is a small pharyngeal hypophysis developed from Rathke pouch, which sometimes persists as the craniopharyngeal canal running from the sella turcica through the body of the sphenoid.

Most Tornwaldt cysts appear clinically in the second and third decades of life, with males and females affected equally. Symptoms include intermittent or persistent postnasal discharge of tenacious mucus or purulent material, associated with odynophagia, halitosis, unpleasant taste, and occasionally, a dull occipital headache exacerbated by head movement with associated stiffness of the posterior cervical muscles. Nasopharyngoscopy reveals a smooth, submucosal, 1 to 2 cm midline cystic mass, superior to the adenoidal pad. Frequently, a central dimple or fistula is identified. CT scan demonstrates a soft tissue mass located high on the posterior nasopharyngeal wall with sharp borders. MR studies of the nasopharynx reveal high signal intensity on T-1 weighted, T-2 weighted, and fluid attenuated inversion recovery image (FLAIR).
Microscopically, Tornwaldt cyst is lined by respiratory epithelium with minimal amounts of lymphoid tissue in the wall. Treatment requires either excision to the periosteum or wide marsupialization. Rathke pouch cysts, on the other hand, are basically cysts lined by columnar or cuboidal, ciliated epithelium that may become secondarily infected or rupture intracranially and are most commonly associated with headache followed by galactorrhea, visual field loss, and hypopituitarism. Treatment is transsphenoidal drainage of the cyst with complete removal of the cyst wall. If no demarcation between normal and involved tissue is evident at operation, the cyst and residual pituitary are radically removed. Radiation therapy is not indicated.

Chordomas

Chordomas are rare malignant neoplasms arising from primitive notochordal remnants, primarily in the fifth or sixth decade of life. Fifty percent occur in the spheno-occipital area with a mean patient age of 40 to 45 years. Males and females are approximately equally affected. Presenting signs and symptoms include an expanding nasopharyngeal mass, frontal headaches, cranial nerve palsies (sixth nerve involvement is seen in 60% of patients followed equally by ninth and tenth nerve involvement), and pituitary abnormalities.

Children under 5 years of age have a wider range of presenting symptoms, a greater prevalence of atypical histological findings with aggressive behavior and a higher incidence of metastases to lung and lymph nodes. A chordoid component (23%) has been identified in a series of children and adolescents. MR imaging with gadolinium is essential to evaluate the extent of the tumor, and it may be helpful in distinguishing classic chordoma from the chordoid variant. CT scanning frequently reveals extensive bone destruction at the skull base and is used to plan surgical resectability. Because patients with chordomas are rarely cured by surgery alone or combined with conventional radiation therapy, surgical resection via a skull base approach is combined with postoperative radiation therapy or proton-photon particle beam treatment. Particle beam therapy is beneficial for chordomas characterized by poor radiosensitivity and cortical location. Interestingly, skull base chordomas in children and adolescents treated with proton beam radiation have better survival than chordomas in adults. The overall prognosis is directly related to the histologic pattern of the tumor: atypical and poorly differentiated chordomas carry a poor prognosis. There appears to be no significant difference for prognosis in patients older than 5 years of age with a classic or chordoid tumor. At a molecular level, alterations in proliferation, invasiveness, and metastasis in epithelial tumors such as chordomas. Changes in the relative expression of the epithelial cadherin-catenin adhesion protein complex reflect chordoma aggressiveness: decreased expression of E-cadherin and increased expression of N-cadherin may underlie the transition from a less to more aggressive tumor phenotype. For metastatic chordoma multigagent, systemic chemotherapy with intrathecal or intraventricular hydrocortisone, cytosine arabinoside ( Ara-C) and methotrexate has been effective in controlling central nervous system disease due to chordoma.

Cranioopharyngioma

Cranioopharyngiomas arise from Rathke pouch epithelial remnants and are located in the sellar, parasellar and third ventricular regions. They are composed of well-differentiated epithelial elements including bone, cysts, and ameloblasts. Rarely, this lesion is first seen in the nasopharynx; and, most commonly, it occurs intracranially above the sella turcica. It accounts for approximately 10 to 15% of all childhood and adolescent intracranial neoplasms. Clinical manifestations include visual field defects, sudden blindness, extraocular motor paralysis, and hypopituitarism. The median age at presentation in children is 7.5 years, with an approximately equal female-to-male ratio. MR imaging with gadolinium or gadodiamide injection is mandatory for pretreatment assessment. Management of cranioopharyngiomas has been controversial with two main surgical approaches advocated: microscopic complete excision or a conservative subtotal resection. Surgical resection followed by radiation therapy achieves long-term control with low morbidity for tumors smaller than 5 cm. 10-year actuarial overall survival rates are 90%. Despite major microsurgical advances, however, total removal of these tumors is associated with a high risk of visual and endocrinological complications, obesity, sleep disorders and behavioral dysfunction. Transsphenoidal removal of these cranioopharyngiomas located within an enlarged sella that are not adherent to parassella structures have a lower incidence of recurrence. The use of megavoltage linear accelerators and stereotactic radiosurgery (SRS), three-dimensional conformational radiation treatment (3D CRT), stereotactic radiotherapy (SRT) and intensity modulated radiation therapy (IMRT) should reduce complications and improve cure rates.

Teratomas

Teratomas are true neoplasms that contain tissue foreign to the site in which they arise. The haphazard arrangement of tissue with asynchronous maturation is believed to escape the controlling influence of the primitive streak notochord or adjacent structures. Teratomas grow aggressively; and, in the head and neck, they most commonly occur in the cervical area, followed by the nasopharynx. Nasopharyngeal teratomas occur with a female-to-male ratio of 6:1. Overall, teratomas of the head and neck comprise approximately 2 to 9% of all teratomas. Teratomas of the nasopharynx typically arise on the lateral or superior wall. Four basic types are recognized: (1) dermoid cyst, the most common form, composed of ectoderm and mesoderm arising as an epithelial-lined cavity with variable numbers of skin appendages; (2) teratoid cyst; derived from all three germ layers but poorly differentiated; (3) true teratoma, composed of ectoderm, mesoderm, and endoderm, with specific tissue and organ differentiation; and (4) epignathus, in which well-developed fetal parts are recognizable; this type of teratoma arises from the soft or hard palate and is frequently incompatible with life.

Clinically, dermoids are more common than true teratomas, and in the nasopharynx, the dermoid cyst is the most common developmental anomaly found. Known as "hairy polyps," these lesions appear at birth as a pedunculated mass filling the nasopharynx, often with oropharyngeal extension. Patients with teratomas have nasal obstruction, dysphagia, and copious secretions. Infants with nasopharyngeal teratomas have a higher incidence of preterm birth, neonatal airway distress, and associated congenital anomalies along with polyhydramnios than do infants with dermoids. CT and MR imaging is critical to define the extent of the neoplasm and to exclude either a nasoencephalomeningocele or intracranial extension of a sphenoid-based teratoma through the craniopharyngeal canal. Most cervical teratomas occurring in the neonate are benign. The tumor can surround or encroach on the airway, thereby causing progressive dysphagia and airway obstruction.

Surgical removal must be carefully planned to ensure a controlled airway throughout the intraoperative and postoperative periods. Tracheostomy is generally not necessary if orotracheal intubation is combined with a transoral removal of pedunculated nasopharyngeal teratomas or with early excision of cervical teratomas. Operative and postoperative bleeding in patients with nasopharyngeal teratomas is usually only slight because these tumors are poorly vascularized; and, if removal is complete, recurrences are rare. Most sessile tumors arising in the nasopharynx require a transpalatal approach. Malignant metastasizing cervical teratoma is extremely rare. Epignathus, arising from the palate or pharynx that protrude from the mouth, result in life-threatening airway obstruction and commonly cause asphyxia at birth. Antenatal ultrasound diagnosis in these rare cases allows for preparation for an ex-utero intrapartum treatment (EXIT) procedure: intrapartum tracheostomy of the fetus at term while still connected to the placenta and subsequent debulking of the large extraoral portion of the tumor followed by complete introral resection.

CONGENITAL DISORDERS OF THE ORAL CAVITY AND LIP

Numerous congenital defects of the oral cavity and related structures may occur. Common major anomalies, such as cleft lip and palate,
are described in detail, whereas less common deformities are mentioned for completeness.

Congenital lesions of the tongue include aglos-sia, microglossia, and macroglossia (secondary to lymphangioma, hemangiomas, or as commonly found in Down syndrome). A nyloglossia due to varying degrees of underdevelopment of the lingual frenulum is not uncommon. Indications for frenulectomy or a four flap Z-plasty or traditional horizontal-to-vertical repair are notching of the protruding tongue tip, inability to contact the maxillary alveolus with the tongue, or restriction of protrusion of the tongue beyond the mandible.

Other glossal anomalies include dermoid cysts, hamartomas, lingual thyroid, fissured (scrotal) tongue, median rhomboid “glos-sitis,” and enteric duplication cysts.

Nonodontogenic cysts derived from epithelial remnants trapped in embryonic fusion lines during the developmental stage include midline maxillary cysts (median alveolar, nasal palatal, median palatal) and lateral maxillary cysts (globulomaxillary, nasolabial). Nasopalatine duct cysts are the most common cystic lesion of nonsyndromic origin of the maxilla. Treatment varies from marsupialization to enucleation from the palatal side, with or without adjacent teeth. Nonsyndromic tongue congenital anomalies encountered include microstomia, congenital pits, and “double lip,” the latter which usually involves the upper lip.

Clefts of the lip, alveolus, or palate are the most common congenital malformations of the head and neck, occurring approximately once in every 700 births. The risk of additional siblings having a defect increases when an older sibling is affected. Both cleft lip with or without cleft palate and isolated cleft palate may be further classified into those classes associated with (syndromic) or without (nonsyndromic) a recognized malformation. The cause of syndromic clefting may be single gene transmission, chromosomal aberrations, teratogenicity, or environmental factors. Recent evidence points to multigenic inheritance with allelic variation at different loci. However, some pedigrees are monogenic with either autosomal dominance or recessive inheritance and exhibit mutations in the p63 gene. In nonsyndromic clefting, exposure to teratogens such as ethanol, retinoids, or folate antagonists during the first trimester are associated with an increased risk of cleft lip or cleft palate. In addition, a dose response relationship between maternal smoking and an increased risk of having a child with cleft lip or cleft palate has been demonstrated. A associated head and neck anomalies such as maxillary or malar hypoplasia, abnormal pinnae or atresia, facial nerve paresis or paralysis, and mandibular dysmorphism or abnormal excursion may be identified in syndromic clefting. The etiology of nonsyndromic clefting is extremely complex and is associated with no obvious first or second arch anomalies or systemic organ malformation. Mutifactorial inheritance is the cause of these clefts, and calculated risk rates are essential to provide genetic counseling to families. It has been shown that polyvaric variants of genes encoding key proteins of folate and methionine metabolism significantly increase the risk of nonsyndromic cleft lip with or without cleft palate. However, to date, causal mutations with a specific functional effect have not yet been identified.

Anatomy. The lips are a movable muscular sphincter composed primarily of orbicularis oris muscle with motor supply from the seventh cranial nerve. The lips are covered by skin on the outer surface and mucosa on the inner. The vermilion or lip edge forms a junction with the skin (white line) that creates a gentle arching in the upper lip or “Cupid’s bow.” The cephalic extension from the handle of the Cupid’s bow encloses a small depressed area at the base of the columna called the philtrum. These anatomic landmarks plus the protrusion of the vermilion below Cupid’s bow or the tubercle are used for orientation in cleft lip repair.

The palate is composed of a hard anterior portion and a soft muscular posterior portion. The anterior primary palate is formed by the alveolar ridge and four incisor teeth plus the triangular premaxilla. The remaining hard palate is formed by the palatine processes of the maxillary and palatine bones, which, with the soft palate, comprise the secondary palate. The soft palate is a muscular curtain formed by the tensor veli palatini muscle innervated by the fifth cranial nerve and the levator veli palatini muscle, muscles uvulae, and glosso palatine and palatopharyngeus innervated by the pharyngeal plexus.

Embryogenesis. Clefts of the lip, alveolus, or palate are midfacial soft tissue and skeletal fusion abnormalities. In the normally developing fetus, the median nasal process fuses with the maxillary processes to form the upper lip, the premaxilla, and the corresponding segments of the alveolar process. Together, the premaxilla and the alveolus form the primary palate. The palatal processes fuse with each other to form the secondary palate, along with the nasal septum and premaxilla in the vicinity of the incise fornemen between gestational weeks 6 and 10. Palatal growth proceeds posteriorly toward the uvula. Failure of ingrowth of mesodermal tissue at this point results in a lack of cohesion of the palatal segments, causing a cleft palate, which may be seen in conjunction with clefts of the lip or alveolar process or alone. Interruption in the migration of mesodermal tissue during the first 2 months of embryonic life results in cleft lip deformities. Ultimately, a lack of fusion of the median nasal processes with the maxillary processes causes a cleft of the upper lip, premaxilla, and alveolus. The incidence of cleft palate increases in the presence of a cleft lip, which occurs in an earlier stage than cleft palate. Moreover, the tongue is positioned higher in the oral cavity in cleft lip, further interfering with palatal fusion and leading to greater palatal clefting. Recent studies of craniofacial development in animal models have identified components of several major signaling pathways that are critical for proper midfacial development or lip fusion. It also appears that these signaling pathways cross-regulate genetically and cross talk intracellularly to control cell proliferation and tissue patterning.

Management. The head and neck surgeon is part of a cleft palate or craniofacial team that includes pediatrics, ophthalmology, general plastic surgery, neurosurgery, audiology, speech and language pathology, orthodontics, prosthodontics, oral surgery, genetics, dentistry, cytology, psychiatry, social work, and nursing. The goals of this team are to restore normal anatomy and physiology, with an emphasis on muscular reconstruction of the lip and palate to allow normal facial development and to minimize growth disturbance.

The initial priority for infants with clefts is to establish adequate feeding and nutrition. Infants with unilateral or bilateral cleft lip and alveolus feed generally well by either breast or bottle. Infants with bilateral cleft lip, alveolus, and palate have significant feeding problems and require modified nipples, with feeding in the upright position to minimize nasal regurgitation.

Although the timing of surgical repair is controversial, most experts perform cleft lip repair at 3 months of life and cleft palate repair at 12 months, to establish a competence velopharyngeal sphincter. Two schools of thought have evolved: one, advocating early closure of the lip and palate, a procedure imparting a high priority to early speech development; and the other, recommending delayed closure of the hard palate, thus according a high priority to maxillary growth. Surgical treatment is dictated by the anatomic defect, and a classification scheme is helpful in planning surgical repair: (1) cleft lip, unilateral or bilateral; (2) cleft palate, either with unilateral or bilateral cleft lip; and (3) isolated cleft palate.

Unilateral Cleft Lip. In the basic complete defect, the floor of the nose communicates with the oral cavity, and the alveolar defect passes through the developing dentition. One sees significant nasal deformity, including columellar displacement, nasal dome deformity, and alar flattening and retridplacement. The goals of surgical repair are restoration of orbicularis muscle function, alar base, and columellar height and creation of symmetry of philtral columns, tip height, Cupid’s bow, and vermilion. This can be accomplished with a Millard rotation advancement procedure in concert with either preoperative orthodontic appliances or lip adhesion.

Bilateral Cleft Lip. The floor of the nose is absent bilaterally, and the nasal and oral cavities communicate freely. The central alveolar arch is displaced forward and superiorly, whereas the nasal tip is widened and the columna is short.
The goals of bilateral cleft lip repair are the same as for unilateral defects. Bilateral lip adhesion, if indicated is performed when the child is 2 to 4 weeks old, with definitive lip repair followed at 4 to 6 months of age. If no lip adhesion is necessary to align the underlying maxillary segments before definitive lip repair, bilateral lip repair is performed at 3 months.

Cleft Palate. The basic defect, absence of the nasal floor, may be complete or incomplete, with or without associated cleft lip. The goals of cleft palate repair are to close the defect without inhibiting maxillary arch growth, to achieve adequate velopharyngeal function, and to normalize oronasal resonance and speech patterns. Although the exact timing of the repair is controversial, the procedure is performed when the patient is 10 to 18 months old, and may require preoperative orthopedic devices used as an alternative to move the premaxilla posteriorly and to expand the lateral maxillary segments, facilitating surgical closure of the lip. Of the many techniques described for bilateral cleft palate repair, the two-flap palatoplasty by Bardach is commonly employed: (1) complete two-layer closure (oral and nasal sides); and (2) dissection, redirection, and suturing of the soft palatal musculature.

Secondary problems of cleft lip and palate that require subsequent treatment include correction of nasal airway impairment, cosmetic nasal defects, velopharyngeal insufficiency with associated hypernasality, and recurrent acute and chronic otitis media with effusion.

Pierre Robin Sequence

The patients with the Pierre Robin sequence (PRS) are a subgroup of the cleft palate population; and, as with the etiology of cleft lip and palate, the etiology of PRS is unknown. Candidate genes and their loci are on chromosomes 2, 11, and 17. The classic PRS of glossoptosis, micrognathia, and cleft palate (50% of cases) may occur as an isolated, nonsyndromic congenital disorder or as part of a larger syndromic anomaly that may include facial dysmorphism, cardiac defects, mental retardation, and musculoskeletal anomalies. Möbius syndrome or nonprogressive congenital facial diplegia is such an example of PRS, with concomitant brachial and thoracic muscle aplasia along with cranial neuropathies (six and seven). PRS has no sex predilection, and it may be secondary to an intrauterine insult during the fourth month of gestation or due to polygenic mutations. Syndromic PRS is often associated with ocular anomalies (detached retina or glaucoma) or aural abnormalities (chronic otitis media, ossiculopathy deformities, and low-set pinnae which can be traced to defects of the first and second branchial arches). The most frequent diagnoses in patients with syndromic PRS are Stickler syndrome and velocardiofacial syndrome. Ophthalmologic assessment and fluorescent in situ hybridization of chromosome 22 should be performed in all patients with PRS. Heredity also appears to be a factor in isolated nonsyndromic PRS and usually a complete U-shaped cleft palate is the primary determinant of the associated triad.

Infants with PRS are at increased risk of airway obstruction and resulting hypoxemia, cor pulmonale, failure to thrive, and cerebral anoxia. Obstructive sleep apnea and snoring are common. A spiration is a primary cause of death. A ophagia associated with vomiting frequently results in aspiration. When compared with normal infants, infants with PRS exhibit a shorter tongue and mandibular length, with a narrow airway and a posterior inferior position of the hyoid bone resulting in airway compromise. Patients are initially given a trial of prone positional management with high-calorie gavage feeding. Most infants (~70%) are effectively managed in this fashion. When continued respiratory distress and failure to thrive develop, a modified glossoptosis, attaching the tongue at the mandibular alveolus and the lower lip is performed. The genioglossus is also released to lengthen the tongue. Bedside polysomnography may help to identify those infants without clinically severe airway obstruction who may benefit from a modified tongue-lip adhesion. Tracheostomy is reserved for those patients following tongue-lip adhesion who have continued failure to thrive and respiratory embarrassment. Alternatively, early bilateral mandibular distraction osteogenesis is employed for failures of tongue-lip adhesion in which isolated tongue base obstruction is documented. This approach may also be used to avoid tracheostomy or allow earlier decannulation in severely affected infants. Overall, patients with syndromic PRS have a higher rate of tracheostomy and gastrostomy tube placement and exhibit significantly lower Apgar scores and longer hospital stays.

CONGENITAL DISORDERS OF THE SALIVARY GLANDS

Congenital anomalies of the salivary glands are uncommon. Rarely, bilateral ageneses of the parotid glands in association with first and second branchial arch syndromes occur and are associated with severe xerostomia. Congenital sialoadenitis with cystic dilatation of the salivary ducts can occur, resulting in single or multiple cystic spaces. Sialography in the infant under sedation may help to demonstrate ducetal ectasia. If obstruction and stasis develop, recurrent infections may result, necessitating parotidectomy with seventh nerve preservation. Heterotopic salivary gland tissue (HSGT) may also appear in or adjacent to the salivary glands, developing from a defect in the growth of the ductal system or in relation to first branchial cleft anomalies. Usually these congenital lesions present as a discharging sinus in the base of the neck. Embryogenesis of HSGT is probably related to ectodermal heteroplasia of the precervical plias of His.44

First Branchial Cleft Anomalies

A ltered embryogenesis of the first branchial cleft potentially produces a wide array of anomalies affecting the external auditory canal. M aldevelopment results in either absence of a normally patent external auditory canal (atresia or stenosis) or a duplication anomaly (cyst, sinus, or fistula). First branchial cleft anomalies have been classified into two groups: type 1 and type 2. Type 1 anomalies are first cleft ectodermal defects or duplication anomalies of the membranous external auditory canal. Type 1 cysts are found anterior and inferior to the pinnae in association with the parotid gland. The fistulous tract extends superiorly along the facial nerve and parallel to the external auditory canal, where it terminates. Type 2 branchial cysts are primarily first cleft and arch defects (ectodermal and mesoderm) with duplication of the external canal and pinnae. Type 2 cysts are found below the angle of the mandible along the sternocleidomastoid muscle. The fistulous tract, like in type 1 anomalies, is variable and may run lateral to, medial to, or between the main branches of the facial nerve, ultimately ending in the external auditory canal.

Clinically, first branchial cleft cysts are associated with repeated infection and may require incision and drainage of an apparent neck abscess which is typically located above a horizontal plane passing through the hyoid bone. Occasionally, purulent otitis may occur in the absence of demonstrable middle ear disease. A third common clinical presentation is preauricular swelling in the parotid area. Microscopically, the cyst is lined with hair follicles, apocrine or sweat glands, and sebaceous glands. Treatment is surgical excision of the cyst, sinus tract, and skin surrounding the sinus tract orifice. Because of the intimate relationship between the seventh nerve and the sinus tract, it is critical to expose the seventh nerve as in a parotidectomy, using the bony landmarks (styloid process, mastoid tip, and tympanomastoid suture line) to help identify the nerve, instead of the tragal pointer. A nerve integrity monitoring system is essential in these difficult cases because of the variable relationship of the sinus tract to the facial nerve.35 Hemangiomas and lymphangiomas in the face and congenital lesions that may involve the salivary glands and are discussed earlier in this chapter.

PRIMARY CILIARY DYSKINESIA (KARTAGENER SYNDROME)

Primary ciliary dyskinesia (PCD) is primarily an autosomal recessive disease with extensive genetic heterogeneity characterized by recurrent upper and lower respiratory tract infections secondary to dysskinetic or completely absent ciliary motility. Only rarely other modes of inheritance such as X-linked transmission are observed. Also termed immotile cilia syndrome, its most recognizable form is in Kartagener syndrome which occurs in 50% of patients with PCD and exhibits bronchiectasis, chronic sinusitis, situs inversus, and sterility. It has also been recognized in Usher syndrome type I, congenital heart disease, congenital esophageal dysfunction, and cutaneous abnormalities including...

Biofilms and Their Role in Ear and Respiratory Infections

J. Christopher Post, MD, PhD
Garth D. Ehrlich, PhD

To my great surprize perceived that the aforesaid matter [plaque] contained very many small living Animals, which moved themselves very extrava-gantly.
—Antony van Leeuwenhoek, 1684, writing to the Royal Society of London (Plaque is now known to be a complex multispecies bacterial biofilm)

WHAT IS A BIOFILM?

Bacterial biofilms are structurally complex, organized, sessile communities of attached bacteria embedded in an extracellular matrix or glycocalyx (Figure 1). The matrix is a dynamic structure that provides stability and protection for the embedded bacteria and is composed of water and a variety of macromolecules, including exopolysaccharides, proteins, and DNA. The extracellular DNA provides much of the viscoelastic properties of the biofilm and is what allows for remodeling during environmental changes. Recent work has demonstrated the presence of extracellular DNA and protein in *Streptococcus pneumoniae* and *Haemophilus influenzae* biofilms. Biofilms can form on any surface, either biotic or abiotic, and, shortly after attachment, the bacteria start elaborating the matrix and forming various types of three-dimensional (3-D) structures including mushroom-like towers, dense lawns with streamers that form above the canopy, and variegated surfaces. In some biofilms water channels deliver nutrients and remove waste products via convective flow. Biofilms can be thought of as being analogous to the coral reef, with sessile polyps surrounded by a protective matrix, relatively impervious to environmental dangers. Just as the reef will produce free-swimming medusae, biofilms will release free-swimming (planktonic) bacteria to populate distant habitats.

Biofilms are dynamic systems that are much more analogous to multicellular organisms in terms of physiological sophistication and environmental homeostatic mechanisms than they are to simple accretions of unicellular organisms. Some of the organismal characteristics of biofilms include intercellular communication systems, specialized phenotypes, a primitive circulatory system, and differentiated metabolism. A biofilm is composed of multiple ecosystems, each varying in pH, cellular density, and oxygen tension, with the base of the biofilm generally anoxic. These ecosystems are distinct microenvironments, thus biofilms can be composed of a single species or of multiple species. Biofilms are best thought of as symbiotic microbial communities, where the organisms are not simply clumped together, but rather are involved in a wide array of physical, metabolic, and genetic interactions. The communal nature of a mixed species microbial community is a much more sophisticated view of bacteria than we are accustomed to considering (Table 1).

Why Do Bacteria Form Biofilms?

Biofilm formation provides a multitude of advantages to the bacteria. Biofilms are a protected mode of growth that allows bacteria to survive in otherwise lethal environments and broadens the potential habitat range. The biofilm forms a persistent nidus from which the bacteria can populate new niches. The exchange of genetic material is facilitated in a biofilm, thus increasing the genetic diversity of the individual bacteria and improving their chances for survival. Bacteria in a biofilm are much less vulnerable to host defense systems such as cellular and humoral immune mechanisms and phagocytosis. Of great importance clinically is that bacteria in a biofilm have a markedly enhanced resistance to antimicrobial agents, being able to tolerate levels 10 to 1,000 times higher than the minimum inhibitory concentrations of genetically equivalent planktonic envirovars. Originally thought to be the result of poor penetration of the antibiotic molecules through the matrix, the primary reason for the resistance to antibiotics appears to be the decreased replicative and metabolic rates of bacteria living in a biofilm. Bacteria in a...
biofilm have an enhanced opportunity to acquire a resistance phenotype through multiple mechanisms of genetic exchange, including plasmids; however, the phenomenon of antibiotic resistance due to the biofilm phenotype should be distinguished from the antibiotic resistance secondary to genotypic changes.

**Planktonic Bacteria Have Held Center Stage for Too Long**

We have been accustomed to studying planktonic bacteria, which is a phenotype where unorganized clonal collections of individual bacteria grow in liquid suspension or attached to culture plates in homogeneous colonies. This focus on studying planktonic bacteria has helped our understanding of acute infectious processes but fails to inform regarding chronic bacterial infections. Most of our current antimicrobial strategies have largely been developed to control acute systemic infections caused by planktonic bacteria. The fact that our basic understanding of bacteria has been based upon the study of the planktonic form, a form in which bacteria rarely exist, has provided a biased view of microbes, with profound implications for our understanding of the nature of infectious disease.

**The Limitations of Culture**

Another hindrance to a modern understanding of bacterial infections is thinking of culture results as a talisman. Our training has been that live bacteria are able to be grown in culture, thus we confuse the inability to grow bacteria from a specimen with proof that viable pathogens are absent. This confusion is particularly noticeable after several days of antibiotic treatment. Further, just because cultures can quantitatively assess the presence of pathogens, it does not mean that all bacteria in the specimen have been enumerated by culture. The ability to grow bacteria in culture is not the sine qua non of bacterial presence. There are at least four circumstances in which living bacteria are not able to be grown in culture: (1) slow-growing bacteria, such as M ycobacterium tuberculosis; (2) fastidious bacteria, such as Treponema pallidum; (3) bacteria stressed into a dormant viable but nonculturable state; and (4) bacteria in biofilms. Attached bacteria can be difficult to recover, and the bulk of bacteria in a biofilm is slow growing, thus biofilm bacteria are difficult to grow in vitro. Culturing a biofilm would yield only one colony per aggregate rather than one per bacterium; thus, the number of bacteria is often severely underestimated in the best of circumstances.

**Biofilm Formation**

It is important to understand that biofilms are not simply clusters of planktonic bacteria but are a markedly different phenotype; in fact within a biofilm there is phenotypic heterogeneity due to the plethora of microenvironments. Biofilm formation is a coordinated series of developmental events that include: (1) microbial attachment to a surface, although healthy biotic surfaces have a formidable array of antiattachment mechanisms, such as biochemical surfactants, epithelial exfoliation, phagocytosis, innate immunity, and other immune responses, thus mucosal surfaces are generally more resistant to biofilm formation than are abiotic surfaces; (2) after attachment, the bacteria begin to divide and form a monolayer some species then aggregate into microcolonies via twitch motility, which is a form of solid surface translocation dependent upon fimbiae or pili, and once the bacterial density is high enough, the bacteria begin producing an enclosing slimy matrix which hinders phagocytosis because of its sheer size; and (3) maturation into an aggregate structure that can be hundreds of cells thick, with intermittent dispersion of planktonic bacteria for formation of distant biofilms.

The bacteria communicate with one another through a series of processes called quorum sensing, which is a mechanism by which bacteria within a population secrete a signaling molecule, which, in a concentration-dependent fashion, serves as a coordinator of population activity. As more bacteria congregate, the concentration of the signaling molecule increases until a “quorum” is sensed. Once the quorum is achieved, a series of “master switches” or sigma factors, up and down regulate specific bacterial genes, resulting in extensive changes in physiology including the coordinated production of toxins and other secreted molecules. Many different bacteria are known to use quorum sensing to control various aspects of their developmental process, including rate of bacterial division, incorporation of foreign DNA, formation and maintenance of biofilm structure, and virulence factors.

**The Ancient History of Biofilms**

Bacteria have been forming biofilms for over 3.25 billion years; thus, it is an ancient and marked successfully survival strategy and an integral element of the prokaryotic life cycle. In some aquatic environments, biofilms contain over 99.99% of the bacteria present. Biofilms are key factors for surviving environmental hazards such as electromagnetic radiation, mechanical stressors such as shear, temperature fluctuation, and noxious chemical agents. Biofilms have been found in environments as diverse as hot springs in Yellowstone National Park, Antarctica, and subsurface sediments in deep ocean trenches. Evidence of ancient biofilms persists today in the form of stromatolites. Stromatolites are the most ancient macroscopic evidence of life that is our single best view into the emergence of life on earth. These intriguing fossils from “deep time” are laminated accretionary structures that were formed by biofilm bacteria capturing and precipitating particles in ancient seas. Given the primeval nature and survival advantages associated with biofilms, they are considered to be excellent biomarkers in the search for extraterrestrial life.

**Industrial Biofilms**

Biofilms are a major problem in industry (Table 2) and are commonly found at the interface between liquid and solid and also at air–liquid interfaces. Also known as biofouling, the industrial biofilm can have a broader group of constituents, including bacteria, algae, yeasts, and protozoa, as well as suspended solids and corrosion products. Biofouling can lead to contaminated water or petrochemical products, loss of product quality, formation of sludge, deterioration or physical plugging of pipe work and storage tanks, and degrading of sensors. Biofouling enhances microbial-influenced corrosion (MIC), which is the deterioration of metals, either directly or indirectly, by galvanic activity by microorganisms. A variety of bacteria and fungi comprise the microbial community found in aircraft fuel tanks. These tanks contain jet propellant-8 (JP-8), and the community has the potential to cause corrosion of the aluminum alloy. Biofilms were found in the water lines of the space shuttle Columbia, and it has been recommended that all space station materials be carefully evaluated for possible degradability by biofilms before use. The piping in active nuclear plants can be degraded by MIC, which requires the complete replacement of service water systems. Biofilms have also degraded the stone in ancient Mayan archeological sites in the Yucatan Peninsula of Mexico, as well as the Roman catacombs.12,13

**Table 1: Properties of Biofilms**

| Multicellular bacterial communities | Highly resistant to antibiotics |
| Encased in a slime matrix | Highly resistant to host defenses |
| Complex intercellular communication systems | Display rapid phenotypic changes in response to environment |
| Large number of microenvironments | Difficult to culture planktonically |
| Differentiation of function | Utilize coordinate expression for toxins |
| Produce periodic planktonic showers | |

**Table 2: Industrial Processes and Sectors Affected by Biofilms**

| Petrochemical | Paper mills |
| Ships and marine structures | Food and beverage industry |
| Power generating | Brewery pasteurizers |
| Aircraft fuel systems | Milk processing plants |
| Water supply and distribution facilities | Marine |
| Heat exchangers and cooling towers | |
BIOFILMS IN HUMAN DISEASE

Bacterial biofilms are now clearly recognized as a major cause of human disease, with the Centers for Disease Control estimating that greater than 60% of bacterial infections in the United States are biofilm related. Understanding the unique aspects of a biofilm provides an explanation for paradoxical symptoms and signs in an ever-expanding list of diseases. Characteristics of a biofilm infection are: (1) a clinical presentation of a chronic infectious process with cycles of acute exacerbation in which antibiotic treatment results in the suppression of infection with remission of symptoms, only to be followed by recurrence, for example, recurrent otitis media, chronic osteomyelitis, and urinary tract infections (vide infra); (2) chronic sessile attachment to a surface acting as a nidus refractory to antimicrobial therapy, and if the biofilm is at a solid surface-fluid interface, such as the circulatory system, the gallbladder tract, or cerebrospinal fluid, there can be episodic acute systemic events from planktonic showering that can be controlled with antimicrobial therapy; (3) ineffective host defenses, with collateral tissue damage from “frustrated” phagocytes; (4) Problematic diagnosis due to insufficient culturing or sampling techniques; (5) chronic inflammatory response by the host, with the potential for stone formation; and (6) a milieu for the generation of resistant microorganisms, or a safe haven for bacteria to produce systemically acting substances, for example, endotoxins, exotoxins, enterotoxins, or superantigens.

Biofilms on Medically Related Implants

The concept that bacterial biofilm formation is important in human health is well established in regard to infected medical implants and catheters across all areas of medicine. Devices that have been shown to be subject to biofilm infection include urinary and central venous catheters, pacemakers and artificial heart valves, protheses, and contact lenses, orthopedic implants such as joint prostheses and fixation devices, intrauterine devices, biliary stents, and endoscopic shunts and stimulating systems. These biofilms can be refractory to standard cleaning practices, with the potential of nosocomial infection. Biofilms can be refractory to standard cleaning practices, with the potential of nosocomial infection.

The Role of Biofilms in Causing Human Disease

Among the first researchers to recognize the importance of biofilms in human health were those in the field of oral health; dental caries, gingivitis, periodontal disease, and plaque are caused by biofilms attached to the tooth enamel and the gingival mucosal. After dental infections, perhaps the best-known non-device-related medical condition involving biofilms is cystic fibrosis (CF). CF pneumonia begins with an H. influenzae biofilm which is subsequently replaced by biofilms of the opportunistic pathogen Pseudomonas aeruginosa which makes cystic fibrosis refractory to treatment. Biofilm formation is implicated in many other chronic infections including infective endocarditis and cardiac valves, chronic prostatitis, Legionnaires’ disease, biliary tract infections and gallstones, and kidney stones. A particular problem in orthopedics, biofilm infections, such as chronic wound infections, necrotizing fasciitis and osteomyelitis, can involve either soft tissue or bone. Chronic urinary tract infections (UTIs) are also biofilm-related illnesses. Uropathogenic Escherichia coli can invade bladder epithelial cells and mature into biofilms, which create pod-like bulges on the bladder surface. These pods explain the refractory nature of UTIs to antibiotic treatment and provide a reservoir for recurrent infection.

Biofilms in Public Health

Biofilms reside in drinking water distribution systems and are resistant to the effects of chlorine, which readily kills planktonic bacteria and those on the periphery of the biofilm but does not penetrate the depths of the biofilm. One example of this phenomenon occurred in April 1993 when an outbreak of cryptosporidiosis in Milwaukee sickened approximately 400,000 people and left 100 dead, generally those with immune systems weakened from AIDS or cancer. Biofilms growing in sand filters can be used to remove toxic contaminants and biodegradable molecules, a concept known as “biological stability” which is in essence a probiotics approach for drinking water.

Biofilms are important in the lifecycle of Vibrio cholerae, which forms biofilms in aquatic ecosystems such as coastal estuaries but appears to leave the biofilm mode once they are ingested. Legionella pneumophila is the microorganism that causes Legionnaires’ disease, a potentially lethal pneumonia. Legionella readily forms biofilms in cooling water towers, ventilation systems, respiratory care devices, hot tubs, hot water heaters, and fountains, where it can be dispersed as airborne water droplets and aspirated. Mycobacterium, including M. tuberculosis, the causative agent of tuberculosis, most likely forms biofilms.

Biofilms and K. Koch Postulates

Koch developed the following four postulates over one century ago to clarify the cause of acute bacterial illnesses.

1. The organism must be found in all animals suffering from the disease but not in healthy animals.
2. The organism must be isolated from a diseased animal and grown in pure culture.
3. The cultured organism should cause disease when introduced into a healthy animal.
4. The organism must be re-isolated from the experimentally infected animal.

While adherence to his postulates and the use of microbiological culture techniques have allowed us to control many acute infectious diseases, it is well recognized that there are exceptions to his rules. These include individuals who are asymptomatic carriers of pathogenic bacteria, individual susceptibility to infection, and polymicrobial infections. While his postulates are still useful, it is clear that the identification of single pathogens in pure culture is inadequate to explain chronic bacterial biofilm infections (Table 3).

Biofilms and Mucosal Disease

Biofilms and the host’s reaction to them play a role in many mucosal diseases. Bacteria can play an important role as a barrier to pathogenic bacteria, conversely, diseases of the gut, such as Crohn’s disease and ulcerative colitis, may be the result of an aberrant immune response to intestinal bacteria in hosts that are genetically susceptible. While there is no direct proof that bacterial infections cause cancer, there is some suggestion that bacterial biofilms can influence the early stages of colon cancer. Biofilms are certainly known to add to the morbidity of patients with existing malignancies, particularly in the oral cavity. Both aerobic and anaerobic bacteria are found in greater numbers in ulcerated squamous cell carcinomas than on control mucosal, with over a third of neoplasms harboring Candida spp.21

BIOFILM DISEASES OF OTOLARYNGOLOGIC INTEREST

Biofilms in Otitis Media

The surge of interest in biofilms in otolaryngology grew out of an attempt to reconcile a series of molecular-based observations that conflicted with established dogma in the field of otitis media. While it was well established that acute otitis media (OM) was a bacterial process, chronic OM with effusion (OME) was thought to be a nonbacterial, inflammatory process based on several observations: cultures for the known pathogens of acute OM (H. influenzae, S. pneumoniae, and M. catarrhalis) were only positive in 30 to 40% of OME specimens, and a wealth of inflammatory mediators were found in chronic effusions. Clinically, most antibiotics used achieved in vitro killing concentrations in
the middle ear, but chronic OM did not readily resolve with antibiotics. While it had long been recognized that bacteria could be identified on gram stain from chronic effusions that did not support microbial culture, this finding had been dismissed as a curiosity.

A series of studies challenged the established paradigm that OM was a nonbacterial process. Post and colleagues used polymerase chain reaction (PCR)-based assays for H. influenzae, S. pneumoniae, and M. catarrhalis and showed that in 97 OM specimens, while only 28 (28.9%) tested positive by both culture and PCR for the three main pathogens, 75 (77.3%) of the specimens were PCR positive for one or more of the three test organisms. Thus, an additional 47 specimens (48%) were PCR positive, but culture negative, for these three bacterial species. In a second study using a reverse transcriptase PCT (RT-PCR) assay specific for H. influenzae, Rayner and colleagues showed that bacteria detected by PCR in middle-ear effusions are actively synthesizing mRNA, thus are viable, intact, and metabolically active. Dingman and colleagues showed that the presence of endotoxin in chronic OM effusions was highly correlated with H. influenzae and M. catarrhalis organisms detected by the PCR, but sterile by culture. These data suggested that the source of endotoxin was most likely bacteria detectable by PCR but undetectable by culture.

Chinchilla experiments demonstrated that raw DNA, and DNA from intact but heat-killed bacteria, does not persist in the middle-ear cleft in the presence of an effusion, but that live bacteria, while not culturable following antibiotic treatment, persist in a viable state for weeks. Scanning electron microscopy (SEM) studies demonstrated that biofilms readily formed on middle-ear mucosa of chinchillas after transbullar inoculation of H. influenzae but not in controls, and confocal laser scanning microscopy (CLSM) indicated that the bacteria in the biofilms were viable. In the cynomologus monkey model, Pseudomonas otitica is associated with biofilm formation.

Most recently, biofilms have been directly detected on the mucosa of children undergoing tympanostomy and tube placement for OM and recurrent OM. Using an array of techniques including cultures, PCR, fluorescence in situ hybridization (FISH), fluorescent immunostaining, and CLSM with bacterial live or dead staining, biofilms were detected in 46 of 50 specimens, while eight controls (from cochlear implant patients) were negative for biofilms. All 24 effusions that were tested by PCR were positive for at least 1 OM pathogen (H. influenzae, S. pneumoniae, and M. catarrhalis) while only 6 (22%) of 27 effusions were culture positive for any pathogen, again showing the limitations of using culture results to make any definitive statement regarding the bacterial environment of the middle ear.

One of the most surprising results of this study is that biofilms can be found in children with recurrent OM during periods of remission, suggesting that bacteria do not clear from the middle-ear space between acute episodes (Figure 2).

While OM results from an interplay of infectious, genetic, and environmental factors, these data, taken together, clearly demonstrate that biofilms are involved in middle-ear disease. Importantly, the biofilm paradigm integrates other observations regarding the pathogenesis of OM, that is, mucusal compromise from antecedent viral infections, the importance of eustachian tube function, and the fact that a variety of inflammatory mediators are present in OM. Inflammatory mediators, however, are not the engine that is driving the disease process but rather the result of a persistent bacterial presence.

The biofilm hypothesis also explains why the most effective treatment for OM is the placement of tympanostomy tubes. Tube placement is effective because: (1) reventilation of the middle-ear space increases the oxygen tension which promotes the regrowth of a ciliated epithelium and reduces the number of secretory cells; (2) it mechanically disrupts and debulks the biofilm; and (3) host middle-ear mucosal defenses are restored. These physiological changes promote biofilm clearance.

Biofilms in Cholesteatoma

A consistent feature of cholesteatoma is the persistence of infection that is highly resistant to antimicrobial agents. Bacterial biofilms have been shown to be present in cholesteatomas, a finding which helps explain the clinical observation that, in this setting, infection can only be eradicated with surgery. Chole and Faddis evaluated the keratin matrix of 24 human and 22 g Chronam cholesteatomas for evidence of biofilms using light and transmission electron microscopy. They found regions with both gram-positive and gram-negative bacteria with the
characteristic ultrastructural appearance of biofilms in 16 of the 24 human specimens, and 21 of the 22 gerbil specimens. The same laboratory demonstrated that strains of *P. aeruginosa* isolated from cholesteatoma are strongly adherent to keratinocytes, express quorum-sensing genes, and form biofilms in vitro, suggesting that these bacteria can contribute to biofilm formation in cholesteatoma.

**Biofilms in Adenoiditis**

Biofilm formation is markedly increased on the mucosal surface area of adenoids removed from children with chronic rhinosinusitis when compared to adenoids removed from children with obstructive sleep apnea (OSA). Using SEM, adenoids from patients with chronic rhinosinusitis (CRS) had a mean of 94.9% of their mucosal surface area covered with mature biofilms compared to 1.9% in adenoids removed from patients with OSA. The authors hypothesize that biofilms in the adenoids of CRS children may act as a bacterial reservoir and that mechanical removal of the adenoid-associated biofilms may explain the known clinical improvement in pediatric patients with CRS after adenoidectomy.

**Biofilms in Tonsillitis**

The presence of biofilms may underlie the pathophysiology of chronic tonsillitis and adenoiditis. Chole and Faddis used light microscopy and transmission electron microscopy (TEM) to examine 19 tonsils, removed either for a history of repeated infection or to relieve airway obstruction from hypertrophy. A morphous polysaccharide biofilm matrix and bacteria were seen within the tonsillar crypts of 11 of the 15 infected tonsils, and smaller clusters of bacteria were seen in 3 of the tonsils removed for hypertrophy. In a more recent study, Kania and colleagues used CLSM with double fluorescent staining to examine 24 tonsils removed from children with a history of chronic or recurrent tonsillitis and found biofilms in 17 of the 24 (70.8%) specimens. Biofilms were demonstrated in the majority of patients with chronic upper respiratory tract infections that had failed aggressive medical management. Streptococcus pyogenes infections that fail to be resolved with antibiotic therapy could be related to biofilm formation. While Pseudomonas biofilms have long been known to be present in the lungs of patients with cystic fibrosis, biofilms have also been demonstrated in patients with diffuse panbronchiolitis and bronchiectasia due to *P. aeruginosa* or *Klebsiella pneumoniae*. In addition, Murphy and colleagues have demonstrated that chronic obstructive pulmonary disease is associated with *H. influenzae* and *P. aeruginosa* biofilms.

**Biofilms in Rhinosinusitis**

Rhinosinusitis is a multifaceted group of diseases that most likely have a biofilm component. While CRS has a major inflammatory component, the mechanism(s) driving the inflammation are controversial. A variety of theories have been advanced, including superantigens from *Staphylococcus aureus*, allergy, disorders of the innate immune system, or aberrant reaction to fungi; however, there is accumulating evidence that bacterial biofilms play some sort of role in the pathophysiology of CRS. There are certainly parallels between CRS and chronic otitis media, both being diseases of mucosally lined cavities connected to the nasopharynx, with similar resistance to antimicrobials and chronicity of course. A variety of animal studies have been conducted to examine the relationship between CRS and biofilms. In a pioneering study, Perlloff and Palmer, using a rabbit model of maxillary sinusitis, instilled *P. aeruginosa* and found mucosally based biofilms using SEM. Using a sheep model, Wormald and colleagues found *S. aureus* biofilms in experimentally induced CRS. The advantage of the larger animal is that the nasal cavities allow for endoscopic sinus surgery. In human studies, biofilms were initially found on frontal sinus recess stents, and a growing number of studies have demonstrated the presence of biofilms in patients with CRS. Earlier studies used SEM or TEM, but later studies have combined CLSM and FISH to speciate the bacteria isolated. In these approaches FISH was used to determine that *H. influenzae* is the most predominant species forming biofilms in CRS patients. Bendouah and colleagues, investigating the in vitro biofilm-forming capacity of bacteria isolated from patients who had persistent CRS after functional endoscopic sinus surgery, found a positive correlation between the robustness of biofilms and unfavorable outcome.

**Biofilm Formation on Endotracheal Tubes, Tracheostomy Tubes and Voice Prostheses**

Biofilms are readily demonstrated in the lumen of endotracheal tubes (ETT), with the degree of biofilm formation proportional to the length of time of intubation. ETT biofilms can lead to ventilator-associated pneumonia (VAP). Biofilms have been demonstrated on both the inner and outer surfaces of ETT in neonates, many with sterile culture results. Biofilms readily form on tracheostomy tubes, and at least one study has concluded that there is no difference in susceptibility to *P. aeruginosa* and *Staphylococcus* biofilms formation among tube materials, including polyvinyl chloride, silicone, stainless steel, and sterile silver. Biofilms were recognized on silicone rubber voice prostheses over a decade ago, thus they are one of the most extensively studied otolaryngologic devices. The prostheses, inserted in a nonsterile manner, in patients who have undergone total laryngectomy, quickly become covered with mixed biofilms of bacteria and yeast, mostly *Candida* species. The biofilm increases airflow resistance and rapidly degrades the rubber, necessitating frequent replacements. A number of strategies have been tried in an attempt to reduce biofilm formation, including modifying the surface properties of the prostheses, the administration of systemic antimicrobials, binding antimicrobial agents to the surface of the prosthesis, and using biosurfactants. Interestingly, consumption of certain dairy products significantly reduced biofilm formation and increased the life of the prosthesis.

**Biofilms on Facial Reconstruction Implants**

Biofilms on implants used in facial reconstruction may result in delayed union or nonunion and can lead to removal of the implant with additional operations. Biofilms can form on bioimplant materials used in facial plastics such as titanium, silicone, and polytetrafluoroethylene (PTFE), whereas implants composed of PTFE with silver/chlorhexidine appeared more resistant to biofilm formation in an animal model. Biofilms can also form on sutures. Interestingly, Emery and colleagues were unable to demonstrate *S. aureus* biofilm formation on titanium or resorbable implants using an in vitro model, speculating that the absence of biofilm formation could be attributed to surface charge or polarity properties. A study using SEM to examine biomaterials removed from 11 patients with persistent infections refractory to antimicrobial therapy and local wound care revealed adherent bacteria, often polymicrobial, but without frank biofilm formation.

**Biofilms on Tymanostomy Tubes**

Robust biofilms are visualized on tubes removed from children with refractory post tympanostomy tube otorrhea, and removal of the tubes often results in clinical resolution. It follows that a tube surface resistant to biofilm formation might decrease the incidence of otorrhea. Various parameters of tubes that have been manipulated include changing the surface morphology or surface energy to reduce bacterial attachment and adhesion and incorporation of antimicrobial agents into the tube material. While some studies show a variation in biofilm formation among different tube surfaces, the ideal material for tube construction has not yet been identified.

**Biofilm Formation on Cochlear Implants**

Biofilms were first recognized on the silicone outer surface of a cochlear implant internal receiver device and electrode array after explantation in 2003. Cristobal and colleagues in the Wackym laboratory reported the clinical course of a child with chronic OM who underwent cochlear implantation and, after prolonged treatment with Floxin Otic (ofloxacin otic solution), she developed a secondary yeast infection with *Candida albicans* which extended from the middle ear to the auditory prosthesis. Despite prolonged antifungal therapy, she required explantation of the device to clear her infection. In addition to the *C. albicans* grown in culture, they found SEM evidence of fungal biofilm on all aspects of the implanted device as evidenced by extracellular polymeric substance (EPS) in association with the yeast elements. Interestingly, there was no evidence of labyrinthitis or fibrosis of the cochlea.
at reimplantation (P. Ashley Wackym, personal communication, April 22, 2007).

Subsequently, it has become apparent that cochlear implants, like all other abiotic implantable devices, are subject to bacterial biofilm infection. Atonelli and colleagues compared the surfaces of implants removed from patients due to infection with those removed because of device failure, as well as with unimplanted devices. They found bacterial biofilms on all implanted devices as evidenced by EPS but not on the unimplanted devices. They did, however, identify bacteria on the unimplanted devices suggesting that better sterilization techniques prior to surgery may reduce the infection rate. Similarly, Pawlowski and colleagues identified S. aureus biofilms on the receiver/stimulator device removed from a cochlear implant patient with infection that failed to resolve despite prolonged antibiotic therapy. They reported that the entire surface was covered with EPS and embedded bacteria but that the biofilm was thickest in depressions on the device surface. They also identified polymorphonuclear leukocytes interspersed with the bacteria in the biofilm.

TECHNOLOGIES FOR THE STUDY OF BIOFILMS

Standard culture methods are not adequate to detect or enumerate bacteria in a biofilm; furthermore, culture results do not provide information regarding the complex ultrastructural aspects of a biofilm. Therefore, a suite of technologies have been developed to study biofilms. These include SEM, TEM, CLSM, and atomic force microscopy (ATM). Fixing specimens for SEM and TEM introduce drying artifacts, especially in the biofilm matrix. A nother limitation is the reliance on bacterial morphology for speciation, which is nonspecific at best. CLSM can obtain 3-D reconstructions of intact, thick specimens without the need to fix and section the specimens. Images are obtained throughout the specimen at various depths throughout the Z-axis, reconstructed with a computer, and viewed on a monitor screen, rather than through an eyepiece, thus the CLSM is analogous to a computerized axial tomographic system. The focal plane is determined by using a laser to excite fluorescence in the sample; thus, fluorescent dyes must be used. Alternatively, bacteria can be engineered to produce their own fluorescence, using such molecules as green fluorescent protein. FISH can be used in a species-specific manner to identify bacteria in the specimen. Thus, CLSM combined with FISH provides the investigator with the capacity for noninvasive optical sectioning of intact specimens, with positive identification of the component bacteria.

ATM has also been used to study biofilms and the surfaces to which they adhere (Ehrlich and Avci, unpublished data). The atomic force microscope (AFM) does not obtain direct images but rather works by running an atomic tip over a surface, analogous to a phonograph needle running over a record. AFM can obtain images at the angstrom level, making it possible to study bacterial and surface interactions at the nanoscopic level, particularly in terms of bacterial adhesion and whether a biomaterial of interest attracts or repels bacteria.

TREATMENT AND PREVENTION OF BIOFILMS

Given the pervasive problem of biofilms in medicine and industry, there is tremendous interest in developing effective strategies to prevent or control biofilms. Overall biofilm strategies either attempt to develop a biofilm-resistant surface or have a bacteri centric approach. The search for the "biofilm-resistant surface" has become a holy grail of material's engineering, but results to date have been disappointing. Considering that bacteria have been forming biofilms for over 3 billion years, there is little with which the bacteria have not dealt successfully. A great deal of effort has been expended modifying various physicochemical properties of the surface or using biosurfac- tants. Binding of antimicrobial agents to the surface is an attractive strategy but has the potential to develop resistant microorganisms. Various forms of energy have been applied to the surface to disrupt biofilms, including ultraviolet and bioelectric. Shearing forces on catheters can break off flocs of biofilm which are then disseminated distally, so strategies that decrease shear forces can reduce infectious complications associated with biofilms.

Approaches that focus on the bacteria have several strategies, including preventing initial bacterial attachment, interference with quorum sensing, or inducing the bacteria to return to the planktonic state. Targeted peptides or phages are being developed to kill biofilm bacteria. Chronic administration of antimicrobials to the patient induces the development of resistant strains, but prophylactic antibiotics in selected surgical procedures can kill the planktonic bacteria before they attach. Disruption of the biofilm matrix is an attractive treatment strategy, with the goals of releasing planktonic bacteria that are susceptible to antibiotic treatment or to induce detachment. Matrix disruption using recombinant human DNAs, an enzyme which selectively cleaves DNA, has been shown to be an effective strategy in the treatment of patients with cystic fibrosis.

**Medical Treatments of Biofilms**

Long-term use of low-dose macrolide antibiotics can be efficacious in some patients with diffuse panbronchiolitis and cystic fibrosis. This clinical effect is nonribosomal, as the doses used are well below the minimum inhibitory concentrations for Pseudomonas species. It is thought that low-dose macrolides are effective through both an immunomodulatory effect in which the host neutrophils are paralyzed thereby leading to a decrease in bystander damage from oxidative burst and an antibiofilm effect in which the macrolides suppress quorum-sensing associated genes and inhibit twitch motility. Lactoferrin, an iron-chelating protein that is a component of the innate immune system, blocks biofilm development by P. aeruginosa by stimulating bacterial motility and thus preventing biofilm formation.

**Probiotics**

One very interesting approach is the use of probiotics, or "beneficent bacteria," either to prevent pathogenic biofilm formation or to disrupt existing biofilms. Biofilms and humans have a long-standing symbiotic relationship, such that the average human has $10^{13}$ cells, and is home to $10^{14}$ bacteria. Biofilms are an integral part of the human oral cavity, gut and vagina, and the normal human flora serves as a barrier against pathogenic bacteria. Given that bacteria can form biofilms in the most hostile environments and can quickly develop new strains in response to environmental pressures, we will never defeat biofilms but should rather adapt their good characteristics to desired outcomes. We already take this approach when we ingest live culture yogurt or drink acidophilus milk. Such an approach has proven successful in such disparate arenas as preventing caries or Salmonella infections in chicken farms. In otolaryngology, alpha hemolytic streptococcus has been used in an attempt to prevent recurrences of acute OM and OME, as well as streptococcal pharyngitis, and "interfering" microorganisms help prevent recurrence of upper respiratory tract infections.

**CONCLUSIONS**

Microbiologists now understand that biofilms are universal and are the preferred milieu for bacteria. Biofilms are an ancient strategy of bacteria and occur at every air- or aqueous-surface interface yet examined. Our previous narrow focus on planktonic bacteria, and culturability must be expanded to understand the complexities of biofilms and their profound differences from planktonic bacteria. The diagnostic, therapeutic, and preventive strategies that have served us so well in our fight against acute infections will not be effective against chronic biofilm diseases. Most bacterial infections are dependant upon attachment to tissue, but the distinctions among "bacterial attachment," "colonization," "commensalisms," and "infection" become blurred. Most likely, the distinctions are not absolute but rather more a matter of degree. We do not understand why some biofilm-associated microorganisms elicit disease, yet others do not. Pathogenesis appears to be as much related to the host inflammatory and immune responses as to the specific actions of the bacteria. Additionally, we need to understand bacteria and human health, as well as we understand bacteria and human disease.

**REFERENCES**

The human larynx is a complex organ that functions as a sphincter at the junction of the digestive and respiratory tracts and participates in the diverse roles of airway protection, respiration, and phonation. In his classic phylogenetic observations, Negus prioritized three functions of the larynx. In order of their priority, these are (1) protection of the lower airway, (2) respiration, and (3) phonation. To perform these roles, the internal and external structures of the larynx interact under precise neural control, producing in humans the most complex of laryngeal functions. Thus, the anatomy of the larynx reflects the specialization required by these multiple roles and is best understood in relation to its diverse physiologic behaviors.

**EMBRYOLOGY**

The larynx, trachea, and lungs begin to form during the fourth week of embryologic development (Figure 1). The respiratory diverticulum, also referred to as the laryngotracheal diverticulum, begins as a thickening on the ventral wall of the foregut lumen immediately caudal to the fourth branchial arch. The lining of this diverticulum is derived from the endoderm of the foregut and gives rise to the epithelial lining and glands of the larynx, trachea, and lungs. As the diverticulum elongates, it becomes invested by the splanchnic mesenchyme that will give rise to the cartilaginous and muscular structures of the lower respiratory organs. The caudal extent of the diverticulum begins to dilate by the end of the fourth week, giving rise to the primordial lung buds or bronchopulmonary buds. Contrary to the notion proposed by His of an ascending tracheoesophageal septum, Zaw-Tun and Burdi demonstrated that the esophagus forms as a result of the continued ventrocaudal elongation of the respiratory diverticulum as an outgrowth of the caudal aspect of the forogut.

**Larynx**

As stated above, the epithelial lining of the larynx is derived from endoderm. The laryngeal cartilages are derived from the fusion of mesenchymal neural crest elements within the fourth and sixth branchial arches. The thyroid, cricoid, and arytenoid cartilages are hyaline cartilage, whereas the epiglottic, cuneiform, and corniculate cartilages are composed of elastic cartilage. The anlage of
achieve its mature shape. The hyoid bone and grow at an accelerated rate and the epiglottis will begin to recanalize in a dorsoventral fashion and, when complete, link the supra- and pharygoglottic duct with the laryngeal cecum.3–5

By the tenth week of development, the epiglottis is derived from the hypobranchial eminence, which is a proliferation of mesenchyme in the ventral ends of the third and fourth branchial arches. The cricothyroid muscle is derived from the fourth branchial arch and is, therefore, innervated by the superior laryngeal nerve. All other intrinsic laryngeal musculature is derived from the sixth branchial arch and is innervated by the recurrent laryngeal nerve.

The primitive pharyngeal floor, which is the site of origin of the respiratory diverticulum, becomes the glottis. Separating the primitive pharyngeal floor from the pharyngeal floor formed by the fourth branchial pouch is a segment of the foregut that will become the supraglottic portion of the larynx. The infraglottic portion of the larynx develops from the cephalic aspect of the respiratory diverticulum. As the foregut and respiratory diverticulum elongate in the coming weeks, the esophagus will lengthen, and the infraglottis will become separated from the carina by the developing trachea.2

Beginning in the sixth week, mesenchyme in the ventral portion of the developing larynx proliferates rapidly, causing eventual obliteration of the lumen and the creation of the epithelial lamina. The artenoid swellings develop in the median pharyngeal floor, causing the laryngeal inlet to assume a T-shaped appearance between the artenoid swellings and the developing epiglottis. The epithelial lamina will continue to enlarge in a ventral to dorsal fashion and almost obliterate the primitive laryngopharynx except for a narrow pharyngoligopharynx. In addition, between the artenoid swellings and the epiglottis, the laryngeal cecum appears and descends toward the glottis ventral to the epithelial lamina.3–5

By the tenth week of development, the epithelial lamina will begin to recanalize in a dorsoventral fashion, which will connect the dorsal pharyngoligopharynx with the laryngeal cecum ventrally and, when complete, link the supra- and infraglottic areas. The laryngeal ventricles also form during the recanalization period as caudal outpouchings of the laryngeal cecum, the lower lips of which form the vocal folds. Disruption of the recanalization process is believed to be responsible for congenital laryngeal webs and atresias.6,7

During the ensuing fetal period, the cartilaginous elements will continue to mature. At birth, the larynx is situated at a much higher position at the second or third cervical vertebrae than the adult larynx at the fifth cervical vertebra. During the first several years of life, the larynx will grow at an accelerated rate and the epiglottis will achieve its mature shape. The hyoid bone and larynx descend during growth and maturation, which is something unique to human beings and necessary for the larynx to perform its complex functions described in the Physiology section.8

### Trachea and Lungs

The endoderm lining the respiratory diverticulum caudal to the larynx forms the epithelium and glands of the trachea and lungs. The tracheal cartilages develop from the mesenchyme that surrounds the diverticulum. After the fourth week of development and the formation of the bronchopulmonary buds, further outpouchings develop and enlarge into the primordial pleural cavities. By the fifth week, the right and left bronchi develop. These will further subdivide into secondary and tertiary bronchi by the seventh week.3

### Esophagus

The early stages of esophageal development are described above. The esophagus reaches its full length by the seventh week of development. It is lined by an endodermal epithelium that proliferates and obliterates the lumen. Subsequent recanalization is usually completed by the end of the embryonic period. The upper one-third of the esophageal musculature is striated and derived from the caudal branchial arch apparatus. The inferior one-third of the esophagus is composed of smooth muscle that develops from the surrounding splanchnic mesenchyme.3

### Anatomy

#### Laryngeal Cartilages

**Thyroid Cartilage.** The thyroid cartilage is a shield-shaped structure that serves to protect the internal anatomy of the larynx.9–14 It is the largest cartilage of the larynx and is composed of two wings, the alae or laminae. The alae are fused in the midline and open posteriorly (Figure 2). In the male, the alae fuse at about 90°, making a laryngeal prominence or Adam’s apple. In the female, this prominence is absent owing to the more oblique fusion angle of 120°. Superiorly, the fusion of the alae is deficient, accounting for the thyroid notch. Posteriorly, each ala has a superior and inferior horn or cornu. The inferior cornu articulates with a facet on the cricoid cartilage by the cricotracheal ligament. This is a synovial joint that allows rotation of the cricoid cartilage. This rotation varies the tension placed on the vocal folds. The superior cornu attaches to the greater cornu of the hyoid bone by way of the lateral thyrohyoid ligament. This ligament sometimes contains small triticeal cartilages.

The two lateral thyrohyoid ligaments, along with the median thyrohyoid ligament, are condensations of the thyrohyoid membrane; these structures attach the hyoid bone to the thyroid cartilage. At the attachment of the superior cornu to the ala of the thyroid cartilage, a prominence called the superior tubercle is found. About 1 cm anterior and superior to this tubercle, the superior laryngeal artery and the internal branch of the superior laryngeal nerve and associated lymphatics pierce the membrane to supply the supraglottic portion of the larynx. At this point, transcutaneous anesthesia of the internal branch can be performed. Running obliquely from the superior tubercle to the inferior tubercle (along the inferior margin of the thyroid cartilage) is a ridge called the oblique line, which serves as the attachment point for the thyrohyoid, sternohyoid, and inferior constrictor muscles.

The relationship of the surface anatomy to internal laryngeal anatomy merits consideration. Most important is the level of the true vocal folds in relation to the thyroid cartilage. An understanding of this relationship is crucial to performing supraglottic laryngectomy and phonosurgery (thyroplasty type I). In this regard, the midline vertical distance from the thyroid notch to the inferior border of the thyroid cartilage ranges from 20 to 47 mm in men and from 15.5 to 38 mm in women.9,10 The anterior commissure is found at the midpoint between these landmarks. The posterior extent of the folds is anterior to the oblique line and is found in the middle third of this line.3

The thyroid cartilage is lined by a thick layer of perichondrium on all surfaces except the inner surface at the anterior commissure. At this point are attached five ligaments, which form the scaffolding for the corresponding laryngeal folds. From superior to inferior, they are the median thyroepiglottic ligament (median thyrohyoid fold), bilateral vestibular ligaments (vestibular folds or false folds), and bilateral vocal ligaments (vocal folds) (Figure 3).

The attachment of these ligaments penetrates the inner perichondrium, forming Broyle ligaments. This ligament contains blood vessels and lymphatics and constitutes an important barrier to the spread of laryngeal neoplasms.

**Cricoid Cartilage.** The cricoid cartilage is a complete ring.9–14 It is the only supporting structure that completely encircles the airway and serves as the major support for the functioning larynx. Its shape is classically described as that of a signet ring, with the anterior arch measuring 3 to 7 mm in height and the posterior lamina about 20 to 30 mm in height.5–7 Its inferior border is nearly horizontal and is attached to the first tracheal cartilage by the cricotracheal ligament.

On the posterior surface of the cricoid, the posterior cricoarytenoid muscles are attached in depressions, which are separated by a midline vertical ridge. These muscles are the only abductors of the vocal folds. Attached to this midline vertical ridge are two fasciculi of longitudinal fibers of the esophagus.

Housed on the superior surface of the posterior lamina of the cricoid are the paired arytenoid cartilages. Posterior to anterior, the cricoid lamina slopes steeply downward to form the anterior arch of the cricoid. In the midline, between the superior portion of the arch and the inferior border of the thyroid cartilage is the criocartilaginous membrane. It is this structure that must be incised in performing an emergent cricothyrotomy.
Arytenoid Cartilages. The arytenoids are paired cartilages that articulate with the posterolateral portion of the cricoid cartilage.\textsuperscript{9–14} Movement of these cartilages and their attached vocal folds is involved in the diverse and complex functions of the larynx. Each arytenoid is roughly pyramidal in shape, giving it a base, an apex, and three sides. The base of the arytenoid provides the articular facet as well as the

Figure 3 (A) Sagittal view of the ligaments and articulations of the larynx. (B) Posterolateral view of the intrinsic musculature of the larynx. (Reproduced with permission from reference 15.)
muscular and vocal processes. The cricoarytenoid joint is a synovial joint with complex movements that are somewhat debated. It appears, however, that the most important movement of the joint is a rocking motion of the cartilage around the long axis of its facet. Laterally, the base forms a broad muscular process, and anteriorly, it forms the thinner vocal process. The anterolateral surface receives the vestibular ligament as well as the thyroarytenoid and vocalis muscles. The posterior surface receives muscular attachments, and to the medial surface is attached the prominent posterior cricoarytenoid ligament. Sitting at the apex of the arytenoid is the corniculate cartilage.

**Corniculate and Cuneiform Cartilages.** The corniculate and cuneiform cartilages are small, paired fibroelastic cartilages. The corniculate, or cartilage of Santorini, is housed on the apex of the arytenoid cartilage. The cuneiform, or cartilage of Wrisberg, when present, is lateral to the corniculate cartilage and is embedded in the aryepiglottic fold. Although some feel that these cartilages are vestigial, they do appear to add rigidity to the aryepiglottic fold. This rigidity augments the important rampant function of these folds, thus diverting swallowed matter laterally away from the larynx into the pyriform sinuses.

**Epiglottis.** The epiglottis contains a leaf-shaped elastic fibrocartilage that functions mainly as a backstop against the entrance of swallowed matter into the laryngeal aditus. During swallowing, the larynx is raised anterosuperiorly. This action pushes the epiglottis against the base of the tongue, displacing it posteriorly over the laryngeal aditus. The epiglottis has two anterior attachments. Superiorly, it is attached to the hyoid bone by the hyoepiglottic ligament. Inferiorly to the lateral margin of the epiglottis and its subdivisions. Note the valve-like nature of the true and false vocal folds. (Reproduced with permission from reference 19.)

**Ossification of Laryngeal Cartilages.** It has long been recognized that incomplete ossification of the laryngeal cartilages can be mistaken for a foreign body on plain roentgenograms of the neck. This particularly applies to ossification of the superior and inferior cornua of the thyroid cartilage and linear ossification of the posterior portion of the cricoid. Thus, the need for understanding the normal ossification pattern of the larynx is self-evident. It is important to realize that only those structures composed of hyaline cartilage will undergo ossification, ie, thyroid, cricoid, and arytenoid cartilages. It should be noted that the hyoid bone is completely ossified at 2 years of age and is generally not a point of radiographic confusion.

The thyroid cartilage undergoes ossification in the male about the age 20 and in the female a few years later. Ossification begins posteroinferiorly on the lamina. It then extends anteriorly on the inferior border and superiorly at the posterior border. At this time, nuclei of ossification can be seen in the inferior and superior cornua. The cricoid and arytenoid cartilages undergo ossification somewhat later than the thyroid cartilage. Ossification of the cricoid cartilage generally begins at the inferior border, although the superior margin of the quadratoalae lamina may be an early site of ossification.

Neoplastic invasion of the laryngeal cartilages generally takes place in the ossified portion of the cartilage. The incomplete ossification pattern may make it difficult to appreciate small areas of invasion.

**Elastic Tissues**

The elastic tissue of the larynx consists of two main parts: (1) the quadrangular membrane of the supraglottic larynx and (2) the thicker conus elasticus and vocal ligaments of the glottic and infraglottic portion of the larynx.

The quadrangular membrane attaches anteriorly to the lateral margin of the epiglottis and curves posteriorly to attach to the arytenoid and corniculate cartilages. This structure and the overlying mucosa constitute the aryepiglottic folds. Each fold forms part of the medial wall of each pyriform sinus. The inferior edge of the quadrangular membrane constitutes the vestibular ligaments.

The conus elasticus is a thicker elastic structure than the quadrangular membrane. It attaches inferiorly at the superior border of the cricoid cartilage. It then projects upward and medial to its superior attachments, the anterior commissure of the thyroid cartilage, and the vocal processes of the arytenoids. Between these superior attachments, the conus thicken to form the vocal ligament. Anteriorly, the conus forms the cricothyroid membrane, and in the midline, this membrane condenses to form the cricothyroid ligament (Figure 2-4). The superior extension of the conus (thyroglottic membrane) parallels the superior surface of the true vocal fold. Because it may normally be incomplete, it forms an imperfect barrier to the inferior extension of the transglottic cancers (Figure 5).

**M uscles**

**Extrinsic Muscles.** The extrinsic muscles of the larynx are those muscles of the laryngohyoid complex that serve to raise, lower, or stabilize the larynx. Those muscles that elevate the larynx are the thyrohyoid, stylohyoid, digastric, geniohyoid, mylohyoid, and stylopharyngeus. These muscles are important in the elevation and anterior displacement of the larynx during swallowing. They also help to suspend the larynx, via the hyoid bone, from the skull base and mandible. The principal depressors of the larynx are the omohyoid, sternothyroid, and sternohyoid. These muscles displace the larynx downward during inspiration. The middle...
constrictor, inferior constrictor, and cricopharyngeus muscles are also important extrinsic laryngeal muscles. The proper functioning of these muscles is crucial to the precisely timed swallowing reflex.

**Intrinsic Muscles.** The intrinsic muscles of the larynx are those muscles that are anatomically restricted to the larynx proper. They modify the size of the glottic opening along with the length and tension on the vocal folds. They consist of multiple adductors but only a single abductor. With the exception of the interarytenoid, the intrinsic muscles are paired, and these paired muscles appear to act synchronously (Figure 6).

**Cricothyroid Muscle.** The cricothyroid muscle is located on the external surface of the laryngeal cartilages. It is classically described as consisting of two bellies. The straight portion or pars recta attaches the lateral portion of the anterior part of the arch of the cricoid cartilage to the inferior border of the thyroid cartilage in a fairly vertical direction. The second belly, the pars obliqua, also from the anterolateral border of the cricoid arch, travels obliquely upward to insert on the anterior portion of the inferior cornu. When the right and left cricothyroid muscles contract, they rotate the cricoid at the cricothyroid joint. This action brings the anterior arch of the cricoid superiorly toward the inferior border of the thyroid laminae while displacing the posterior cricoid lamina (and the arytenoid cartilages) inferiorly. This inferior displacement increases the distance between the vocal processes and the anterior commissure; the result of this action is to lower, stretch, and thin the vocal folds while bringing them into a paramedian position. The stretching of the vocal fold also sharpenes the edge of the vocal fold and passively stiffens the component layers of the vocal fold (Figure 7). Biomechanically, this translates into a higher fundamental frequency produced by the vocal folds.

**Posterior Cricoarytenoid Muscle.** This muscle is the sole abductor of the vocal folds. It is seated in a depression on the posterior surface of the cricoid lamina, and its fibers run obliquely superior and lateral to attach onto the muscular process of the arytenoid cartilage. It is composed of two compartments: horizontal and vertical bellies. Contraction of these fibers brings the muscular process medial, posterior, and inferior while laterally rotating and elevating the vocal process. This action abducts, elongates, and thins the vocal folds while causing the vocal fold edge to be rounded. The stretching of the vocal fold leads to passive stiffening of its layers. The complex function of this muscle has been studied in the canine in which three distinct neuromuscular compartments are found. It is proposed that the vertical and oblique bellies normally cause vocal fold abduction during respiration, whereas the horizontal belly is primarily used to adjust the position of the vocal process during phonation.\textsuperscript{21,22}

**Lateral Cricoarytenoid Muscle.** The lateral cricoarytenoid muscle is the main antagonist of the posterior cricoarytenoid. It attaches along the superior border of the cricoid cartilage and sends fibers posteriorly to insert on the anterior portion of the muscular process. Contraction of this muscle brings the muscular process anterolaterally while adducting and lowering the vocal process. This results in adduction, elongation, and thinning of the vocal folds. The edge of the vocal fold becomes sharper, and its component layers are passively stiffened.

**Interarytenoid/Aryepiglottic Muscle.** The interarytenoid muscle is the only unpaired intrinsic muscle, consisting of two types of muscle fibers. The bulk of the muscle consists of transverse fibers passing from the posterior surface of one arytenoid cartilage to the posterior surface of the other. This muscle contracts to bring together the arytenoid cartilages, thus assisting in closing the posterior portion of the glottis. This does not significantly affect the mechanical properties of the vocal folds. A long with these transverse fibers are oblique fibers. These oblique fibers pass from the posterior portion of the arytenoid on one side to the apex of the arytenoid on the other side, thus crossing in the midline. Some fibers insert at the apex, whereas others travel along the quadrangular membrane. These fibers contract to narrow the laryngeal aditus. Those fibers traveling along the quadrangular membrane (thus the aryepiglottic fold) constitute the aryepiglottic muscle.

**Thyroarytenoid Muscle.** The thyroarytenoid muscle is classically divided into the thyroarytenoid internus and externus. These have the same attachments, but the internus lies deep or internal to the externus. In addition, the internus is more well developed than the externus. The thyroarytenoid externus arises from the anterior commissure and inserts onto the lateral surface of the arytenoid cartilage. It contracts to bring the vocal process and anterior commissure closer to each other, thus adducting the vocal folds. It also contracts to adduct the false cords. The externus sends a few slips of muscle fibers onto the quadrangular membrane to establish the thyroepiglottic muscle. This muscle, like the aryepiglottic muscle, acts to narrow the laryngeal inlet.

The thyroarytenoid internus or vocalis muscle attaches at the anterior commissure and inserts onto the vocal process, sending a few slips of fibers below the vocal ligament onto the conus elasticus. It contracts to adduct, shorten, thicken, and lower the vocal fold while rounding its edge. The body (muscle) of the vocal fold is actively stiffened, whereas the cover is passively slackened. Recently, immunohistochemical staining for myofibrillar adenosine triphosphatase reveals that the majority of fibers in internus are slow-twitch and those in externus fast-twitch, suggesting its unique human specialization for speech function.\textsuperscript{24,25}

**Internal Anatomy**

The internal anatomy of the larynx consists of three compartments separated by two folds\textsuperscript{9,10} (Figure 4). The three compartments are the...
Vestibule, ventricle, and infraglottic cavity. The false and true vocal folds separate the above compartments. These mucosa-lined compartments demarcate two spaces of importance: the preepiglottic space and the paraglottic space.

**Vestibule.** A laryngoscopic view of the larynx reveals the vestibule as that portion of the larynx from the tip of the epiglottis to the false vocal or vestibular folds. Thus, the vestibule is bound by the epiglottis anteriorly, the aryepiglottic folds laterally, and the arytenoid and corniculate cartilages with the interarytenoid muscle posteriorly. In the laryngoscopic view, the anterior commissure is frequently hidden by the protuberance of the epiglottis known as the tubercle. As previously discussed, the vestibular folds are formed by mucosa overlying the vestibular ligament (inferior border of the quadrangular membrane). The submucosa of the vestibule contains numerous seromucinous glands. The secretions produced by these exocrine glands provide both mechanical and immune (lysozyme) protection for the vocal folds.26

**Ventricle.** The ventricle or sinus of Morgagni is the small space between the false and true vocal folds. The ventricle is often hidden during laryngoscopic examination of the larynx unless exposed by lateralization of the false vocal fold. At the anterior end of the ventricle is a diverticulum known as the laryngeal saccule. The saccule (of Hilton) is lined with mucous glands, which are thought to lubricate the vocal folds. Fibers of the thyroarytenoid muscle line the walls of the saccule and are thought to express mucus from the saccule when they contract. The size of the saccule is quite variable; however, it seldom extends above the superior border of the thyroid cartilage. Abnormal dilatation of the saccule results in an air-filled laryngocele that should be distinguished from a mucocele of the saccule (saccular cyst), which lacks free communication with the ventricle and thus is not air filled.27 The vocal folds that form the inferior boundary of the ventricle are described in more detail below.

**Infraglottic Cavity.** The infraglottic cavity extends from the glottis down to the inferior border of the cricoid cartilage. Its lateral boundary is formed by the conus elasticus and walls of the cricoid cartilage.
Pyriform Sinus. Although the pyriform sinus is anatomically part of the hypopharynx, understanding its anatomy and its relationship to the larynx is essential. The pyriform sinus is a gutter formed by the aryepiglottic fold, arytenoid cartilage, and superior part of the cricoid cartilage medially and the thyrohyoid membrane and internal surface of the thyroid lamina laterally. Superiorly, it begins at the lateral glossopiglottic fold. Inferiorly, the apex of the sinus blends with the esophageal inlet at about the superior border of the cricoid (Figure 8). Thus, cancer invasion of the apex implies the necessity of removing a portion of the cricoid if conservation laryngectomy is planned. There are two important markings within the pyriform sinus. Anteriorly in the floor of the sinus, a small fold can be seen, which marks the course of the superior laryngeal nerve. This submucosal course of the nerve makes it possible to anesthetize the nerve topicaly in the pyriform sinus. The second, more variable landmark is the protrusion made into the sinus from the superior cornu of the thyroid cartilage. This smooth protrusion, which usually presents in the elderly, should not be confused with neoplasm.

Mucosa. The mucosa of the larynx is of two types: pseudostratified ciliated columnar cell (respiratory) epithelium and squamous cell epithelium. Much of the larynx is surfaced by respiratory epithelium; however, the superior portion of the epiglottis, upper portions of the aryepiglottic folds, and free edges of the vocal folds are surfaced by squamous cell epithelium. Beneath this covering epithelium is a variable basement membrane, and separating these two is a layer of loose fibrous stroma. It should be noted that this loose fibrous layer is absent on the true vocal folds as well as the laryngeal (posterior) surface of the epiglottis. The absence of this layer on the posterior surface of the epiglottis accounts for the more intense swelling of the lingual (anterior) surface of the epiglottis in inflammatory conditions of the larynx.

Figure 8 Coronal section through the human larynx, demonstrating the relationship of the cricoid cartilage [C] with the apex of the pyriform sinus (arrow). A = arytenoid cartilage; T = thyroid cartilage. (Courtesy of Dr. John A. Kirchner.)

Preepiglottic Space. The preepiglottic space, as its name implies, lies anterior to the epiglottis, which serves as its posterior boundary. It is bound superiorly by the hyoepiglottic ligament and mucosa of the valleculae and inferiorly by the thyroepiglottic ligament. The anterior boundaries are the thyrohyoid membrane and the inner surfaces of the thyroid laminae. Laterally, the preepiglottic space opens in the paraglottic spaces. Cancer on the infralaryngeal portion of the epiglottis can penetrate the epiglottis and gain access to the preepiglottic space.

Paraglottic Space. A paraglottic space, as its name implies, lies on each side of the glottis. This space lies above and below the true and false vocal folds and is important in the transglottic and extralaryngeal spread of neoplasms. Medially, the space is bound by the quadrangular membrane, ventricle, and conus elasticus. Laterally, it is bound by the perichondrium of the thyroid lamina and the cricothyroid membrane. Anterosuperiorly, the space opens in the posterior portion of the preepiglottic space. The mucosa of the pyriform sinus forms the posterior boundary. The relationships of this paraglottic space make it important in considering the spread of laryngeal cancer. Supraglottic cancer invading into this space may quickly extend extralaryngeally.

Vocal Folds

The anatomy of the vocal folds is complex and is thus considered separately. The vocal fold is considered the structure between the vocal process of the arytenoid and the anterior commissure. The vocal folds and the slit between them (rima glottidis) constitute the glottis. The glottis can be divided by a horizontal line between the tips of the vocal processes. This imaginary line divides the glottis into an intermembranous portion and an intercartilaginous portion. The anterior to posterior (length) ratio of the intermembranous portion to the intercartilaginous portion is 3:2; however, the ratio of cross-sectional areas defined by them is 2:3. Thus, owing to its more rectangular shape, the intercartilaginous portion is larger. Some have called this the respiratory portion of the rima. The membranous or vibratory portion of the vocal folds consists of three well-defined structural layers. From superficial to deep, they are the epithelium, lamina propria (three layers), and vocalis muscle. Hirano divided these layers according to a body-cover concept (see Figure 7A). The cover consists of the overlying epithelium and the gelatinous superficial layer of the lamina propria. The body consists of the vocalis muscle, which he likened to thick rubber bands. Between these exists a transition zone composed of the intermediate (elastic) and deep (collagenous) layers of the lamina propria. According to this concept, the vocal folds consist of a multilayered vibrator with increasing stiffness from the cover to the body. Thus, the cover is responsible for most of the vibratory action of the vocal folds. At the anterior and posterior ends of the vocal folds exist an anterior and a posterior macula flava, respectively. These are essentially a thickening of the intermediate (elastic) layer of the lamina propria and are thought to function as “cushions” protecting the ends of the vocal folds from vibratory damage. It should be noted that the same body-cover concept does not apply to the larynx of children, because of the more homogeneous nature of the lamina propria. It is not until nearly the end of adolescence that the lamina matures into its adult form. In the senile larynx, the elastic layer and the vocalis muscle tend to atrophy, whereas the collagenous layer thickens. The cover becomes thickened and edematous secondary to changes in the superficial layer of the lamina, whereas the epithelium itself changes little.

The shape of the true and false vocal folds carries biomechanical significance. When seen in coronal section, both appear as valve-like structures, with the leaflets of the false folds pointing inferiorly and those of the true folds pointing superiorly (see Figure 4). Thus, the false folds passively impede egress of air, whereas the true folds impede its ingress. Working with cadaver larynges, Brunton and Cash demonstrated that the false folds offered a resistance equaling 30 mm Hg to the egress of air from below, whereas the true folds offered a resistance equaling 140 mm Hg to the ingress of air from above. Both structures offered little resistance to the opposite flow of air; i.e., they act as one-way valves.

Vessels

Arteries and Veins. The arterial supply to the larynx consists of the superior and inferior laryngeal arteries. After the superior thyroid artery branches off the external carotid, it courses lateral to the laryngohyoid complex and gives off the superior laryngeal artery at approximately the level of the hyoid bone. This artery then runs anteromedially with the internal branch of the superior laryngeal nerve to enter the thyrohyoid membrane inferior to the nerve. It then enters the submucosa of the pyriform sinus and is distributed to intralaryngeal structures. The superior thyroid also gives off a cricothyroid branch that courses horizontally below the thyroid cartilage. The inferior laryngeal artery is a branch of the inferior thyroid artery that comes off the thyrohyoid complex and gives off the inferior laryngeal artery at approximately the level of the hyoid bone. The artery then runs anteromedially with the internal branch of the superior laryngeal nerve to enter the thyrohyoid membrane inferior to the nerve. It then enters the submucosa of the pyriform sinus and is distributed to intralaryngeal structures. The superi
PHYSIOLOGY

As previously stated, the three functions of the larynx in order of priority are (1) protection of the lower airway, (2) respiration, and (3) phonation. A flawless performance of these functions requires an intact neuromuscular system to respond to both volitional and reflex signals presented to the larynx.

Innervation

The pattern of innervation to and from the larynx and the type and distribution of its receptors determine the functional capabilities of the larynx. The larynx is innervated by the superior and inferior laryngeal nerves. The superior laryngeal nerve leaves the nodose ganglion to pass between the superior laryngeal vessels and the internal branch of the superior laryngeal nerve. The external branch innervates the larynx by synapsing in the ganglion nodosum. The external branch of the superior laryngeal nerve supplies the vocal folds and extends caudally along the aryepiglottic fold. The sensory innervation to the mucosa of the supraglottic portion of the larynx is carried by the internal branch of the ipsilateral superior laryngeal nerve, which is divided into three divisions. The superior division mainly supplies the mucosa of the aryepiglottic folds and the arytenoid cartilage. The middle division supplies the mucosa of the true vocal cords and the ventricular bands, and the inferior division supplies the mucosa of the arytenoid cartilage, the false vocal cords, and the aryepiglottic fold. The sensory supply to the mucosa of the arytenoid cartilage is via the anterior laryngeal nerve. The posterior laryngeal nerve supplies the muscular innervation to the larynx except the cricothyroid muscle. This nerve innervates the intrinsic muscles of the larynx by synapsing in the superior laryngeal ganglion located in the carotid bifurcation. The true vocal cords are innervated by the recurrent laryngeal nerve. This nerve also innervates all the intrinsic muscles of the larynx except the cricothyroid, which is innervated by the external branch of the superior laryngeal nerve. It is responsible for the production of laryngospasm. Protective closure of the larynx occurs in three tiers. In the first tier, the laryngeal inlet is contracted by collapsing the aryepiglottic folds medially. The anterior and posterior gaps are filled by the epiglottic and arytenoid cartilages, respectively. In the second tier, the false vocal folds are brought together. The final and most important tier occurs at the level of the true vocal folds. Because the valvular action of the true vocal folds resists ingress of material, they offer the most important level of protection. It should be noted that it is the thyroarytenoid or slips from this muscle that contract at each level of closure. This muscle is one of the fastest contracting of all striated muscles in the body. Classically, the afferent limb of this reflex occurs through stimulation of touch, chemical, or thermal receptors in the supraglottic portion of the larynx.

Laryngospasm occurs when stimulation of the superior laryngeal nerve leads to a prolonged adductor response. This response is maintained well after the initiating stimulus is removed, and section of the superior laryngeal nerves abolishes the response. Clinically, this is typically seen in the setting of endotracheal intubation or extubation or after manipulation of the airway, especially if blood has contaminated the laryngeal inlet. The response is dampened in the face of barbiturates, hypercapnia, positive intrathoracic pressure, and severe hypoxia.

The glottic closure reflex is a polysynaptic reflex that allows the larynx to protect the lower airway from penetration and aspiration. However, when exaggerated, this reflex accounts for the production of laryngospasm. Protective closure of the larynx occurs in three tiers. In the first tier, the laryngeal inlet is contracted by collapsing the aryepiglottic folds medially. The anterior and posterior gaps are filled by the epiglottic and arytenoid cartilages, respectively. In the second tier, the false vocal folds are brought together. The final and most important tier occurs at the level of the true vocal folds. Because the valvular action of the true vocal folds resists ingress of material, they offer the most important level of protection. It should be noted that it is the thyroarytenoid or slips from this muscle that contract at each level of closure. This muscle is one of the fastest contracting of all striated muscles in the body. Classically, the afferent limb of this reflex occurs through stimulation of touch, chemical, or thermal receptors in the supraglottic portion of the larynx.

The sensory innervation to the mucosa of the supraglottic portion of the larynx is carried by the internal branch of the ipsilateral superior laryngeal nerve, which is divided into three divisions. The superior division mainly supplies the mucosa of the aryepiglottic surface of the true vocal cords, the middle division supplies the mucosa of the true vocal cords and the aryepiglottic fold, and the inferior division supplies the mucosa of the arytenoid cartilage, the false vocal cords, and the aryepiglottic fold. The sensory supply to the mucosa of the arytenoid cartilage is via the anterior laryngeal nerve. The posterior laryngeal nerve supplies the muscular innervation to the larynx except the cricothyroid muscle. This nerve innervates all the intrinsic muscles of the larynx except the cricothyroid, which is innervated by the external branch of the superior laryngeal nerve. In this nerve is responsible for the production of laryngospasm. Protective closure of the larynx occurs in three tiers. In the first tier, the laryngeal inlet is contracted by collapsing the aryepiglottic folds medially. The anterior and posterior gaps are filled by the epiglottic and arytenoid cartilages, respectively. In the second tier, the false vocal folds are brought together. The final and most important tier occurs at the level of the true vocal folds. Because the valvular action of the true vocal folds resists ingress of material, they offer the most important level of protection. It should be noted that it is the thyroarytenoid or slips from this muscle that contract at each level of closure. This muscle is one of the fastest contracting of all striated muscles in the body. Classically, the afferent limb of this reflex occurs through stimulation of touch, chemical, or thermal receptors in the supraglottic portion of the larynx.

Laryngospasm occurs when stimulation of the superior laryngeal nerve leads to a prolonged adductor response. This response is maintained well after the initiating stimulus is removed, and section of the superior laryngeal nerves abolishes the response. Clinically, this is typically seen in the setting of endotracheal intubation or extubation or after manipulation of the airway, especially if blood has contaminated the laryngeal inlet. The response is dampened in the face of barbiturates, hypercapnia, positive intrathoracic pressure, and severe hypoxia.
Although not classically considered part of the protective reflex, reflex swallowing from stimulation of the superior laryngeal nerve may have protective functions. It has been shown that reflex swallowing occurs with application of hypotonic fluids to the supraglottic portion of the larynx, particularly the laryngeal surface of the epiglottis, glottis, and interior of the larynx. Although this is not the normal mechanism to initiate swallowing, it may serve to protect the larynx against fluid that enters the laryngeal inlet.31

Neurophysiology of Respiratory Function

It is intuitive that if the larynx is the sphincter to the lower airway for respiration to occur, the sphincter should actively open during inspiration. Also, the opening of the folds must be synchronous with, but slightly precede, the descent of the diaphragm. Through the work of many individuals, this observation is well supported.35,39,40 The rhythmicity of the phrenic nerve and particular respiratory input, maintains eupneic respiration. It drives the synchronous opening of the glottis and descent of the diaphragm during inspiration. The opening of the glottis is primarily through the action of the posterior cricoarytenoid. However, in hyperpneic conditions, the cricothyroid contracts rhythmically with the posterior cricoarytenoid.39,40 The contraction of both these muscles increases the glottic aperture in both anteroposterior and horizontal dimensions. During phonation, the cricothyroid lengthens and passively addsucts the vocal folds. However, during respiration, when contracted in concert with the posterior cricoarytenoid, the effect is to lengthen the open glottis, thus increasing the cross-sectional area for airflow. Understanding the role that the cricothyroid plays as an accessory muscle of inspiration underlies the rationale for superior laryngeal nerve section in the face of bilateral recurrent laryngeal nerve paralysis. Bilateral paralysis produces dyspnea, which will lead to cricothyroid contraction, further adducting the paralyzed folds. Unilateral superior laryngeal nerve section reduces glottic resistance by preventing full adduction.

The rhythmicity of the phrenic nerve and the posterior cricoarytenoid can be increased by hypercapnia and ventilatory obstruction. It is lessened by hypocapnia. The effect of ventilatory resistance on posterior cricoarytenoid activity has been extensively studied in the canine model. In this model, when ventilatory resistance is eliminated, so is the reflex abductor activity of the posterior cricoarytenoid. It is felt that the afferent limb of this reflex resides within the ascending vagus nerve and that the end-organ receptors are located within the thorax, although their precise location is unknown. The longer abductor activity is lost, the more difficult it is to reestablish.41 This is the rationale for downsizing tracheostomy tubes (thus gradually increasing ventilatory load) prior to decannulation.

The role of the larynx in controlling expiration must also be considered. It is well known that the control of respiratory rate occurs primarily through variation of the expiratory phase. The time of expiration is dependent on the ventilatory resistance produced by the glottis. As discussed above, the cricothyroid contracting with the posterior cricoarytenoid will give the maximal glottic opening and hence the lowest ventilatory resistance. In this regard, cricothyroid contraction during expiration occurs when the critical subglottic pressure change of 30 cm H2O is exceeded and continues as long as positive subglottic pressure is maintained. As expected, this threshold for activation is reduced in hypercapnia (allowing for quicker expiration and a faster respiratory rate) and increased in hypocapnia.42

Neurophysiology of Phonation

The complex mechanisms of phonatory control coordinate central and peripheral components. Electromyographic investigation of the control of peripheral neuromuscular systems involved in phonation has demonstrated specific intrinsic and extrinsic muscle function in humans. Central mechanisms are less well understood, and their understanding often relies on animal models, from which the function in the unique phonatory systems of the human may only be inferred.

As a general model, the larynx, as a system, must respond to central commands from linguistic and motor centers. Signals are relayed to the motor cortex in the precentral gyrus and on to motor nuclei in the brainstem and spinal cord. These signals are transmitted to the respiratory, laryngeal, and articulatory muscles responsible for speech and voice production. These messages are influenced by the extrapyramidal system, including the cerebral cortex, cerebellum, and basal ganglia, exerting fine control of respiration, phonation, and articulation.21

Specific connectivity and the central control of brainstem motor neurons responsible for voluntary control of phonation remain illusive. Laryngeal reflexes, which are key to the coordination of respiration, phonation, and deglutition, are understood primarily from the research focused on respiration and deglutition.31 Further, central projections to laryngeal mechanisms are not consistent across species and may differ...
from nonhuman primates to humans as well. The nucleus tractus solitarius, periaqueductal gray matter, parabrachial nucleus, locus caeruleus, and ventromedial nucleus of the thalamus are all areas anatomically associated with the laryngeal system.31 Figure 9 illustrates branching of the superior laryngeal nerve with central connectivity and projections of the nucleus tractus solitarius. However, specific mechanisms of control are not well defined. In some cases, the central terminations of specific sensory receptors and the origin of the motoneuron fibers are known, as in somatotopic organization for the face and limbs. To date, studies of the role of the cerebral cortex in phonation in primates reveal no such individual muscle representation or somatotopic mapping of the laryngeal system.31 The role of peripheral mechanisms in phonatory control has been studied more successfully using electromyography, airflow, and pressure studies in the vocal tract as well as imaging techniques, which allow observation of the vocal tract during phonatory postures. It is important to consider that phonation takes place in concert with upper articulators, the lip, tongue, jaw, and velum.

Mechanical tissue deformation and, in particular, the pull of the upper articulators on the larynx via the laryngeal–hyoid complex necessarily influence the phonatory environment. For example, Figure 10 illustrates vocal tract shaping for four distinct vowels. Note the apparent pull of the tongue high and forward for production of /i/ (labeled “iy”), in contrast to posterior and low posture for /a/ (labeled “aa”). The consequent /i/ (labeled “iy”), in contrast to posterior and low posture for /a/ (labeled “aa”). The consequent constriction or, conversely, the opening of the posterior part of the pharynx plays a key role in the acoustics of sound produced for each of these postures and influences laryngeal posturing for phonation.35

Electromyographic studies of specific muscle function indicate firing rates uniquely suited for fine control of laryngeal function. Contraction times for the intrinsic muscles in several species are presented in Table 1. Further, the high innervation ratio for human laryngeal muscles, estimated at 100 to 200 cells per motor unit,46 makes laryngeal muscles capable of a great degree of precise control as required for adjustment of speaking frequency and intensity.

Intrinsic and extrinsic musculature, described previously in this chapter, influence specific action of laryngeal muscles during phonatory shaping of the glottis in sound production as described by Hirano (see Figure 6).20 Table 2 summarizes the influence of each of these muscles on the shape and tension of the glottis during phonation.

It has been shown that the laryngeal muscles start to contract about 100 to 200 ms prior to the onset of phonation.42 Further, the most important muscle in varying the phonation style (from hypotense to hypertense) is the thyroarytenoid muscle.48 The frequency of vibration depends on the following: (1) vibratory mass of both vocal folds, (2) the anterior to posterior tension, (3) functional damping at high pitch, and (4) subglottic pressure. In this regard, Gay and associates showed that in the chest register, the cricothyroid and vocalis, with the possible contribution of the posterior cricoarytenoid, most consistently control changes in fundamental frequency.49

Lovqvist and others later described electromyographic recordings obtained from four intrinsic laryngeal muscles with simultaneous transillumination and acoustic signals.30 The vocalis and lateral cricoarytenoid muscles were observed to participate in the control of both articulation and phonation. The interarytenoid muscle appeared to be involved only in articulatory adjustments. Activity in the cricothyroid was primarily related to changes in fundamental frequency. This muscle also showed an increase in activity for voiceless sounds. In addition, the vocalis muscle appeared to participate in glottal adduction without complete closure in voiceless clustered sounds, with the lateral cricoarytenoid and the interarytenoid playing no particular roles. Studies such as these underscore the complex interactive nature of laryngeal musculature in phonatory and articulatory interaction.

In considering the phonatory process, a variety of factors necessarily contribute to the acoustic product as defined in Table 3. The psychoacoustic parameters of pitch, loudness, quality, and fluctuation are correlated with acoustic qualities of fundamental frequency, amplitude, waveform, and acoustic spectrum. High-speed photography and observation of vocal fold vibration via videostroboscopic endoscopy reveal much about the behavior of the glottis during phonation.20,51 The vibrations of the vocal folds are a passive phenomenon and represent the basis of the aerodynamic theory of sound production. Vibration of the vocal folds changes DC airflow to AC airflow, converting aerodynamic energy to acoustic energy. The mucosal wave produced by these vibrations has been captured on ultrahigh-speed photography by Hirano.21 The vibratory cycle is described

as having three phases: opening, closing, and closed. By convention, the cycle is described as beginning with the vocal folds closed. Frames 1 to 5 (see Figure 7B) represent the opening phase. During this phase, subglottic pressure increases, forcing the vocal folds apart from an inferior to superior direction until the glottis opens, letting air escape and thus releasing subglottic pressure. As the elastic recoil of the vocal folds forces them back together, the portion of the vocal fold that was the last to open (superior portion) is the last to close. Thus, the vocal folds close from inferior to superior (frames 6 to 8). The folds then remain closed until the subglottic pressure builds up enough to force them open again. Anatomically, the movement of the mucosal wave depends on the soft and compliant lamina propria and a healthy layered structure. In extracting complex details of glottal area waveforms from videostrobolaryngoscopic recordings using modern computers and software (Figure 11), Woo demonstrated male and female differences as well as influences of pitch and loudness. Women commonly demonstrate shorter posterior glottal gaps that seem to have no pathologic acoustic significance, whereas their glottal cycles have shorter closed phases than those of men. Mean peak glottal area is smaller in women, not only because of their smaller anatomic size but also because their higher frequency of vibration limits the lateral excursion of the vocal folds, thereby reducing the amplitude of vibration. As intensity increases, the closing phase becomes shorter, and the closed period becomes longer, suggesting that the closing patterns of vocal folds are an especially important feature in normal and pathologic phonation. The coordination of higher cortical centers interacts with specific musculature in the vocal tract to produce acoustic products recognized as speech. The laryngeal contribution to this product continues to be revealed in basic studies of phonation as an interactive process.

Assessment of Vocal Function

Christine M. Sapienza, PhD
Gayle E. Woodson, MD

Standard tests of voice assessment for patients with voice disorders are not analogous to the battery of audiometric tests that have evolved for assessing hearing loss. In audiology, the testing paradigm determines how well subjects can perceive specific sounds. In contrast, voice evaluation sets out to assess the performance of voluntary tasks, in which there is considerable performance variability, not only among subjects but also within the same person. A flexible instrument, the healthy human voice is able to produce a wide variety of “sounds.” Even when a vocal task is tightly specified, with respect to pitch and loudness, the vocal quality can vary almost infinitely. Further, it is difficult to describe objectively and quantitatively the range of vocal qualities that a person can produce and perceive. Finally, there is great variation in the types of voice distortion that can be caused by a disorder, ranging from a perceived breathy voice quality to a strain, strangled voice quality. Thus, there is not a single parameter that can distinguish a normal from an abnormal voice, particularly when the alterations to the voice are only mildly or moderately distorted. Despite these problems, data in the literature support the use of certain vocal measures in managing patients with voice disorders. The diagnosis is based on the history and physical examination, while vocal function tests are used to quantify a voice disorder’s severity and document treatment effectiveness.

Categories of voice assessment methods include perceptual assessment, quantitative analysis of acoustic signals, physiologic measurement of airflow and pressure, observation of the vibratory vocal fold movement during voicing tasks with videostroscopy and patient’s self-assessment (Table 1). There are some who believe that quantitative measures of vocal function are only relevant if they correlate with perceptual assessment; however, in most cases, it is unlikely that a strong correlation will exist between quantitative and qualitative measures because instrumental measures are focused on one component of the voice signal (frequency or intensity) while perceptual evaluation is influenced by multiple factors. Until further research is done to determine the specific components of the voice signal that strongly correlate with perception, each of the testing procedures should be considered separately but important facets of the assessment process.

**Patient’s Self-Assessment**

The patient’s self-assessment is the sine qua non in defining whether a voice disorder warrants treatment. As abnormal as a voice may sound to others, including clinicians, if it serves the patient’s daily needs, it is an acceptable voice. Although there are general expectations of what a normal voice should sound like, it is important to realize that there is a broad spectrum of normal voice quality, even within age, gender, and ethnic categories. Patient’s self-ratings of voice quality are subjective and can be influenced by the patient’s mood and other intrinsic and extrinsic factors as well as their illness perception as described by Buck and colleagues. A patient’s responses lend insight about the desire to change the voice and can help the clinician realize the impact the voice disorder is having on the patient’s quality of life. There are times in which the patient’s insight does not match the severity of the voice disorder. This can be largely due to poor patient understanding, other cognitive deficits, or simply denial. Furthermore, patients are often not aware of how their voice sounds to others, and they may be acclimated to some level of dysfunction. On the other hand, a patient whose voice improves after treatment may not have an accurate recollection of what the voice was like before treatment, and thus may under- or overestimate the effectiveness of the treatment. Such inaccuracy of self-assessment is known as the Rosenthal effect.

A further issue in the patient’s assessment of the effectiveness or efficacy of voice treatment is that individual expectations vary considerably. For example, a patient who has had a laryngectomy may be so happy to be able to speak at all that he or she will rate his or her voice favorably, even if it sounds hoarse and requires much physi-
VHI was performed with 819 patients representing a wide spectrum of voice disorders, and the two were shown to be statistically comparable.

**PERCEPTUAL ANALYSIS**

The clinician forms an impression of a patient’s vocal function during the interview, and the notation of this in the patient’s record is the simplest form of perceptual analysis. More formalized and systematic assessment involves using standardized rating scales and attending to specific individual aspects of vocal quality. A recent study examined the reliability of two separate and routinely used scales (Consensus on Auditory Perceptual Evaluation of Voice (CAPE-V) and Grade, Roughness, Breathiness, Aesthesia, Strain (GRBAS)) found that the differences between clinician-based and patient-based data are significant, as patients experience and consider dysphonia differently. What that means is that the patient who fills out the VHI or VHI-10 will score their dysfunction differently than the clinician. However, the study also indicated that a clinician is consistent in rating regardless of the scale used. The GRBAS scale, which has been used faithfully, although without validation of its dimensions, rates five voice qualities, each on a five-point scale. The qualities include grade (severity), roughness, asthenia (thinness or lack of resonance), breathiness, and strain. Other perceptual assessment methods include paired comparison, visual analog scales, and direct magnitude estimation. Eadie and Baylor indicated that either direct magnitude estimation or scales which use equal appearing interval scales were both appropriate selections for making auditory-perceptual judgments of pleasantness, but only the direct magnitude estimation scale was recommended for judging overall voice quality in the patient. Most recently, there has been much attention given to the development of a consistent rating scheme so that the recorded speech sample, elicitation techniques, and variables rated are identical across clinical settings. This process was guided by a consensus conference sponsored by the American Speech-Language-Hearing Association’s (ASHA) Division 3: Voice and Voice Disorders and the Department of Communication Science and Disorders, University of Pittsburgh, held in 2002 in Pittsburgh. From that conference a consensus document/statement was produced by a working group subcommittee and entitled the CAPE-V. More details about the development of the CAPE-V can be found at the URL http://www.asha.org. As stated in the consensus document, the CAPE-V is not intended to be used as the only means of determining the nature of the voice disorder such as is the case for rating scales in general. It is not to be used to the exclusion of other tests of vocal function and should be supplemented by visual examination of the larynx and other more objective means for quantifying vocal fold vibratory behavior.

When making judgments of voice production, the most reliable perceptual ratings are the result of blinded analysis of recorded samples. This level of rigor is important for research purposes but is too time consuming and complex to be practical in most clinical situations. Therefore, most clinical ratings are unblinded. The aspects of voice, which are most commonly assessed, include pitch, loudness, and vocal quality. The first two can also be physically measured and can serve as some validation of the perceptual analysis. Vocal quality is essentially the esthetic impression that the voice invokes in the listener. Descriptive terms include such aspects as smoothness versus roughness, resonant versus thin, breathy versus full. Breathiness tends to correlate with increased airflow and appears to be cued by changes in the vowel spectrum. These changes are related to alterations in the intensity of aspiration noise and spectral slope of the harmonic energy. Further research is needed to determine the acoustic correlates of voice qualities such as hoarseness.

**VOCAL PERFORMANCE ASSESSMENT**

The dynamic ranges of pitch and loudness have long been accepted as relevant parameters of vocal function, by singing teachers and clinicians alike. These ranges can be assessed with varying levels of rigor. The habitual pitch range is informally evaluated simply by listening to spontaneous speech during a patient’s interview. A monotonous voice or one that lacks any variation in the pitch of the voice sounds as if it lacks emotional projection. The pitch range capacity of one’s voice can be easily measured by having a patient match pitches on a keyboard. A healthy subject with no structural or functional problems with the vocal folds should be able to span two octaves. An octave is a doubling in pitch. To determine a patient’s dynamic range in loudness, a simple sound level meter may be used. Dynamic range of loudness typically spans about 50 dB from 30 to 80 dB.

The objective correlates of pitch and loudness are frequency and intensity, respectively. One of the most common clinical tools that has been a mainstay in the clinic is the Visi-Pitch, which provides a computerized assessment of pitch and loudness by providing information about the fundamental frequency of the voice and the relative intensity of the voice. The Visi-Pitch is easy to use and can also provide patients with biofeedback, allowing them to match pitch and loudness targets using visual feedback. The Phonogram is another formal process for defining the pitch and loudness range, by determining dynamic range for specified pitches throughout the frequency range (Figure 1). This is widely used in Europe and has been validated in several studies, but it is time consuming and fatiguing, and thus not widely use in the United States.

One of the simplest performance measures to acquire is the maximum phonation time (MPT). It can be acquired with a stopwatch, or even a wristwatch, simply asking the patient to take a deep breath and then phonate “ee” as long as possible at a comfortable pitch and loudness. It is also one of the most relevant and useful clinical tests. A multicenter study in Belgium several years ago compared several measures of vocal function and found that the MPT was the one test that was most often clinically useful. The average MPT for males ranges from 22 to 34 seconds, while for females, the ranges is from 16 to 25 seconds. While a clinically useful measure, MPT data collection must consider patient fatigue and ensure that the directions for the task are consistent. Patients may not do the task as prescribed resulting in a high amount of performance variability. The clinician should ensure that the patient rests between MPT trials and is instructed to take a maximum inhalation prior to phonating on expiration. Phonation time will be diminished with glottal incompetence, as due to vocal fold paralysis or presbyphonia, and can also be decreased by decreased lung capacity. Sometimes excessive glottal closure, as in adductor spasmodic dysphonia, can prolong the MPT reserve, glottal incompetence, or submaximal effort. Pulmonary function testing is useful to clarify the cause of a low MPT. Lung function testing can be completed in the clinical setting using a digital spirometer; or, with more complex cases, patient referral to the pulmonary clinic is warranted to help identify the potential influence of lower airway disease on laryngeal function.

**ACOUSTIC ANALYSIS**

The sound of the human voice is not a pure tone, but like any complex waveform, it can be described mathematically as a sum of pure sine waves of varying frequency and amplitude. The basic for computerized acoustic analysis, which uses the waveform analysis to generate specific parameters. This process is objective and reproducible and would, therefore, seem to be the ideal approach for standardized testing of vocal function. However, there are a number of issues that limit applicability. Objective voice measures are relevant only if they correlate with differences in voice quality that can be perceived, and many parameters cannot. Conversely, some of the qualities that are easily perceived have not as yet been mathematically defined. But more significantly, most of the algorithms begin by identifying the fundamental frequency of the voice, and significantly hoarse voices are often so irregular that there is no fundamental frequency.

Over 10 years ago a document was put forth by the National Center for Voice and Speech (NCVS) in Iowa City with the intent of providing a standardized method for the use of acoustic analysis in the study of voice. Within the document, specific recommendations were made for the use of a standard set of test utterances to be used for voice recording and analysis, and a
workshop convened by the NCVS concluded that not all acoustic parameters were appropriate for all levels of voice severity. Most acoustic measures are only valid for nearly periodic voices. Visual displays, such as spectrograms, are needed for more irregular voices. Acoustic analysis of any type is invalid for severely hoarse, aperiodic voices.

Spectral analysis performs a Fourier analysis of a sound and displays the amplitudes of all component frequencies, either as an x-y plot or as a “voice print” (Figure 3). The resulting image can be appreciated qualitatively. Harmonic components can clearly be identified as regularly spaced bands, while noise appears as continuous frequencies. Voice or pitch breaks are also well documented. A broadband filter can be used to identify formant or peak frequencies. The formant structure is determined by the resonance of the upper vocal tract, which can be voluntarily altered to produce different vowels or vocal qualities. Thus, spectral analysis is highly influenced by the specific sound uttered, and a single utterance does not adequately characterize the overall quality of a subject’s voice. Long-term average spectrum (LTA5) can provide spectral information from longer or multiple utterances, even paragraphs. This provides a more accurate assessment of the voice. It has been used successfully to document improvement with treatment. However, the results can be markedly affected by the characteristics of the microphone or recording system. Thus, assessments from a given patient can only be compared if recorded with identical systems using identical settings.

Fundamental Frequency
The fundamental frequency ($f_0$) is the rate at which the vocal folds open and close. This is usually the slowest frequency obtained by Fourier analysis. The duration of one cycle of opening and closing is the fundamental period ($T$ or $1/f_0$). The $f_0$ should be determined from a stable period of vocalization within a sustained vowel utterance. The sample to be analyzed should include at least 25 cycles or about 2 seconds, to be accurate. We can perceive pitch during connected speech. However, a computer requires sophisticated software and is still less accurate in tracking pitch during speech. The fundamental frequency is used as the basis for computing most other acoustic parameters. Unfortunately in severe dysphonia, the vibratory cycle is often aperiodic. Therefore, whenever computerized analysis is used, the raw waveform must be checked to assure adequate periodicity. If the voice is too irregular, none of the resultant analyses will be valid.

Harmonic to Noise Ratio. In common parlance, harmony means pitches that sound pleasing together. This is because harmonics frequencies are integer multiples of the fundamental frequency, and a sound that contains only a fundamental and harmonic frequencies will be smooth, with each sound cycle being identical. Frequencies that are not integer multiples will result in cycles that vary greatly in amplitude and shape, and if there is sufficient energy in nonharmonic frequencies, the sound becomes completely aperiodic, or noise. The harmonic to noise ratio of a sound reflects the amount of energy in $f_0$ and its harmonics divided by the energy in nonharmonic frequencies. A voice with a high harmonic to noise ratio is perceived as normal.

Perturbation Measures. An unstable voice has variations in the cycles of vocal fold vibration, in either pitch or loudness or both. This is perceived as harshness. Jitter is a parameter that reflects pitch instability, while shimmer measures differences in the amplitudes of neighboring cycles. Jitter is expressed in milliseconds or as a percentage of cycle length. Shimmer is expressed as a percentage of the mean amplitude. Although these measures have been used for many years, they have not proven to be clinically useful or relevant. The short-term variations in normal or near normal voices are frequently imperceptible, while in hoarse voices, the sound is too aperiodic to permit accurate derivation of perturbation measures.

Standard Deviation of the Fundamental Frequency. Standard deviation of the fundamental frequency ($SDF_0$) is a parameter that detects instability of the vocal signal over a longer sample than that used to calculate jitter. These fluctuations over longer cycles are more easily perceived, as fluctuating pitch. Pitch fluctuations are characteristic of motor control problems, as seen in neurologic disease and old age. It can also result from laryngeal pathology, such as scarring from surgery or radiation.

AERODYNAMIC ANALYSIS
Voice is sound: successive compressions and rarefactions of air created by the interplay of air exhaled by the lungs, and the valving activity of the larynx. Thus measurements of airflow and pressure can provide precise and objective indicators of vocal function. One can measure either steady state values, as indicators of glottal competence and vocal efficiency, or the rapid cycle-to-cycle changes that provide information about the vibratory capacity of the glottis. The airflow exiting the mouth and nose can be directly and easily measured using a facemask, usually in terms of liters per second. Mean airflow during a
A sustained vowel can provide an estimate of glottal competence: a high flow is seen with poor glottal closure, whereas in a strained voice, such as adductor spasmodic dysphonia, airflow is low. However, measuring airflow without the context of pressure can be misleading. A decrease in phonatory airflow can indicate either an increase in laryngeal resistance or a decrease in expiratory effort. The driving force in phonation is subglottal pressure. Laryngeal resistance is a derived measure, calibrated from airflow and subglottal pressure, and usually expressed as centimeters of water per liter per second. Accurate measurement requires calibrated instruments, a standard protocol, and clear instructions to the subject.

**Mean Phonatory Flow Rate**

Mean phonatory flow rate has been one of the traditionally easier measures to collect and is the most common aerodynamic parameter to be reported on in the literature. Airflow usually is measured by a pneumotachograph, mounted in a full facemask. It should be measured during sustained phonation of a vowel at comfortable pitch and loudness, and normal mean phonatory airflow is about 200 cc/s. It is higher in conditions of glottal incompetence, such as laryngeal paralysis, a mass deficit in the vocal fold, or a mass lesion that prevents glottal closure. It is lower with increased laryngeal resistance, such as adductor spasmodic dysphonia, muscle tension dysphonia, or vocal fold scarring. Laryngeal resistance can also be increased volitionally. Decreased airflow can also reflect reduced expiratory effort or pulmonary insufficiency. The pneumotachograph can also detect sudden airflow changes, such as voice breaks in patients with spasmodic dysphonia.

The pneumotachograph calculates airflow by measuring the pressure decrease across a known resistance. The resistance is usually a fine wire mesh screen, and the pressure produced prior to the screen and after the screen (P1-P2) allows for the calculation of airflow. It is crucial to select the appropriate pneumotachograph and transducer as stated above for the flow range to be validly measured and so that airflow will be detected with the minimal possible resistance. While some may argue that the facemask constrains airflow during phonation to some degree, research indicates that the full facemask in fact interferes little with the reliability of respiratory volume and did not alter frequency measures made from a glottal airflow waveform. While more time consuming and requiring more expensive and sophisticated equipment, airflow may be measured without obstructing outflow by the use of plethysmography. These techniques are more common to pulmonary function laboratories or clinics. A body box, called body plethysmography, is most reliable, but it requires a great deal of space. Indirect plethysmography uses induction coils. Both extrapolate expired airflow by detecting changes in chest volume and, therefore, do not obstruct airflow from the mouth and nose. Indirect plethysmography measures the summation of changes in the cross-sectional area within the thoracic and abdominal compartments and creates a weighted summation of these changes to provide a signal that is proportional to lung volume. Careful calibration is required, body movement artifact must be kept to a minimum, and interpretation may be subject to user error.

Another method of measuring airflow is the use of hot wire anemometry, which offers little resistance. The hot wire anemometer has a high frequency response but does not measure actual volume. Further, it can be distorted by turbulence and or changes in the ambient temperature.

**Glottal Airflow**

Airflow at the level of the glottis can be estimated by using a Rothenburg mask. This mask is circumferentially vented with multiple holes covered by fine wire mesh and uses a high frequency differential pressure transducer to measure airflow from the mouth and nose. The signal is processed by "inverse filtering," which is designed to subtract the resonant frequencies of the upper vocal tract. The resultant waveform is considered to
reflect rapid airflow changes at the level of the glottis. Several derived values have been defined for use in assessing glottal function.\textsuperscript{18}

**Airflow Open Quotient.** Clinically, the airflow open quotient (OQ = 20%) provides duration information about the length of time the glottis is open relative to the duration of the entire cycle of vocal fold vibration. Since glottal opening allows airflow to occur, this measure is useful for cases in which glottal closure is deemed inadequate or incomplete (hypofunctional vocal pathologies) or in cases where a high glottal resistance is suspected, that is, an obstruction, spasm, hyperfunction, or loud voice production.

**Maximum Flow Declination Rate.** Maximum flow declination rate can be used to define hypofunctional glottal configurations. Assuming no compensatory strategies exist, hypofunctional voice cases would predictably yield a low maximum flow declination rate value because of the disability in completely closing the vocal folds and the slowness in the return of the weakened vocal fold toward the midline. Maximum flow declination rate would be predictably higher in those with hypofunctional voice disorders due to an increase in subglottal pressure and greater vibrational amplitudes. However, since those with hypofunctional voice disorders can also have increased vocal fold stiffness, declination rates are not always predictable.

**Peak Glottal Airflow.** Peak glottal airflow relates to the maximum glottal area during vocal fold vibration. Increased stiffness, decreased mucosal wave, or any other pathological condition, which restricts the maximum displacement of the vocal folds, can alter the peak airflow during phonation.

**Alternating Glottal Airflow.** Changes in vocal fold tension and stiffness affect alternating airflow because the biomechanical changes to the vocal folds change the displacement of them during voicing. With increased stiffness of the vocal folds, alternating airflow typically decreases.

**Minimum Glottal Airflow.** Minimum glottal airflow relates to the amount of airflow through the glottis during the closed phase of vocal fold vibration. Theoretically, the higher the minimum airflow the more incomplete the glottal closure. This measure provides a way to document the hypofunctional component of vocal pathologies such as adductor vocal fold paralysis or other cases where there is glottal incompetence.

**Subglottic Pressure**

Subglottic pressure is the driving force for phonation. It results from expiratory effort against an upstream resistance. Subglottal pressure can increase because of greater expiratory effort or because laryngeal resistance increases. Unfortunately, subglottal pressure is difficult to measure directly in a clinical situation. Direct measure would require tracheal puncture. One can also lower a solid-state pressure transducer between the vocal folds, but such a transducer interferes with glottal closure and phonation. Thus, subglottal pressure is estimated by measuring intrathoracic pressure as the subject repeats the syllable /p/ at a rate of 1.5 syllables per second. The theory is that subglottal pressure and intrathoracic pressure are the same when the lips are sealed to form the consonant "P." The accuracy of the intrathoracic pressure in predicting subglottal pressure was developed by Smith and Hixon and has been validated for use in normal subjects.\textsuperscript{19}

However, it may not be accurate in the presence of pathology. An alternative approach to estimating subglottal pressure is to use an esophageal pressure transducer since intrathoracic pressure is presumably equivalent to subglottic pressure and is transmitted transhoracically to the esophagus. This technique is not sensitive to rapid pressure changes in the airway.

Patients with disorders of voice or speech motor control often have difficulty in producing the precise repetition of syllables. Careful review of the literature will indicate that results of estimated subglottic pressure have only been reported for patients with a voice or speech disorder that is mild enough that they can produce the target rate. Subglottal pressures for comfortable effort level voice range from about 5 to 8 cm H\textsubscript{2}O and increase with elevations in vocal loudness as well as rise slightly with increased fundamental frequency. Singers, because of their larger dynamic range, produce higher subglottal pressures during song production.

**Laryngeal Resistance**

Laryngeal resistance is calculated by dividing subglottic pressure by mean phonatory airflow rate. It varies greatly with vocal task and should always be measured at a standard pitch and loudness. Although it is a calculated parameter, it reflects the actual physical function of the larynx. Laryngeal resistance is low in glottal incompetence, such as in laryngeal paralysis or fixation, tissue deficit of the vocal fold, or in the presence of a mass lesion that prevents laryngeal closure. It is higher in glottal strain, as in spasmodic dysphonia or muscular tension dysphonia. It can be increased voluntarily, as one technique for increasing loudness. Laryngeal resistance is increased by vocal fold stiffness, as in patients with laryngeal scarring from surgery, trauma, or radiotherapy. Because so many factors can alter laryngeal resistance, this measure should always be interpreted in combination with patient history and laryngeal examination.

Laryngeal resistance can be used to calculate vocal efficiency, a measure of how much effort is required to generate a given level of sound. It is calculated by dividing the sound pressure level of the voice by a simultaneously determined laryngeal resistance. In fact, it reflects more than just glottic efficiency. The entire vocal tract, including the skull, chest, nasal cavity, and throat, can modulate the sound and thus has a considerable influence on vocal efficiency. Recently, Grillo and Verdolini showed that laryngeal resistance but not vocal efficiency distinguished normal, pressed, resonant, and breathy voice qualities from one another further supporting the measure of laryngeal resistance as a useful method for examining vocal fold dynamics.\textsuperscript{20}

As the vocal folds become stiffer, as with scarring or edema, greater pressure is required to induce oscillation of the vocal folds, and it becomes difficult to speak softly. The minimum pressure threshold for phonation (the minimum pressure that can produce a sound) is a relevant clinical measure.\textsuperscript{21} An easier way to get a rough estimate of vocal fold stiffness is simply to measure the softest sound that can be produced.

**PULMONARY FUNCTION TESTING**

Those with voice disorders may have multiple reasons why breathing symptoms might be associated with their laryngeal condition. First, it may be that the patient has low muscular effort due to a primary disease process such as motor neuron disease. Second, it may be that the patient has a laryngeal disorder creating high laryngeal airway resistance. Cases such as adductor spasmodic dysphonia, muscle tension dysphonia, or other dynamic conditions resulting in increased glottal closed time can result in high laryngeal airway resistance, restricting airflow. Static laryngeal conditions, which result in high laryngeal airway resistance, include webbing, stenosis, abductor vocal fold paralysis, arytenoid joint dislocation, and others. Finally, the patient who presents with low laryngeal airway resistance and cannot control expiratory airflow may also complain of breathing symptoms. These cases of hypofunctional voice disorders include vocal fold paralysis or any other condition that limits the mobility of one or both vocal folds. In each of the conditions mentioned, the voice is often abnormal and the patient presents with a secondary complaint of breathing abnormality. This breathing abnormality is a sensation of breathlessness or dyspnea and is one of the most commonly perceived symptoms. Flow-volume loops and the measurement of forced inspiratory volumes are essential to document the severity of the problem and to track response to treatment. In clinical practice, pulmonary function testing should be available in the pulmonary function laboratory at the medical center, therefore preventing unnecessary duplication of services. These laboratories are equipped to maintain and calibrate the equipment correctly.

**VOCAL FOLD MOVEMENT**

Rapid oscillation of the vocal fold was first documented by high-speed motion picture photography. This required precise and expensive equipment, was only used in a few research laboratories, and was never available commercially for widespread use. Other techniques have
been developed. Some are available clinically, whereas others remain research tools.

Videostroscopy provides a slow motion image of vibration and is readily used as a clinical tool today. Keep in mind that the image acquired from videostroscopy is not a true record of motion, but a composite that represents an average of motion over many cycles. There are many commercially available options for performing stroboscopy in the office. Stroboscopy can be qualitatively assessed, essentially as an extension of the physical examination. It can also be systematically analyzed, rating several measures. Stroboscopy is discussed in Chapter 83, “Laryngoscopy.”

Glottographic measures are noninvasive techniques to track indirectly motion and contact of the vocal folds during phonation.22,23 There are two forms of glottography, electroglottography (EGG) and photoglottography (PGG). They provide complementary information and are, therefore, more accurate and relevant when performed simultaneously. However, only EGG is commercially available.

EGG measures the electrical impedance between two plates on opposing sides of the neck over the thyroid cartilage, at the level of the vocal folds. A low-voltage, high-frequency current is passed between the plates. Impedance is highest when the glottis is open and decreases when the vocal folds come into contact. Impedance changes in proportion to the surface area of contact between the vocal folds. Impedance is highest during maximal glottic opening with minimal or no vocal fold contact. Impedance increases during the opening portion of the closed phase and decreases during the opening phase. Although changes in impedance are proportional to contact area, they cannot be calibrated to produce actual area measurements, since the contact area cannot be directly measured for calibration. Therefore, EGG is used to document the timing of vibration. Further, changes in distance between the edges of separated vocal folds do not affect impedance; therefore, EGG only provides information about the closed phase of the cycle. The filtered output of impedance is viewed and recorded as a waveform, termed “LX.” The LX signal is less robust in obese individuals since impedance is measured against all neck tissue between the plates.

EGG is an effective tool for deriving f0. LX reflects events at the level of the glottis, without modulation of the waveform by the resonance of the upper vocal tract. Thus, the LX waveform is much less complex than the acoustic signal, and the algorithm for deriving pitch is much simpler. The f0 is a relevant measure in itself, and the signal can also be used to determine the frequency of a stroboscope during laryngal stroboscopy.

Some useful parameters can be derived from EGG. The duration of the open and closed phases is easily extracted. In pressured phonation, the duration of the closed phase increases. With glottic insufficiency, the closed phase decreases and the open phase increases.

EGG can differentiate between modal and falsetto phonation, because there is a significant difference between these two registers in the thickness of the vocal folds and the duration of the closed phase. Vocal folds are thicker during modal phonation, and the mucosal wave progresses superiorly along the vibratory edge. Therefore, there is a “knee,” or sharp turn in the LX waveform at the onset of glottal closure in modal phonation when the inferior edges of the vocal folds begin to separate. During falsetto phonation, the vocal folds are thinner and tenser, and only the superior edges of the vocal folds come into contact. There is no mucosal wave, and the LX waveform is less complex, nearly sinusoidal.

PGG measures light transmitted from the mouth or pharynx, through the larynx, and then through the soft tissues over the trachea. It does this by means of a photoelectric transducer placed on the skin over the trachea. This light can be supplied by as simple a mechanism as a flashlight in the mouth or transmitted through an endoscope. Minimal light is transmitted during glottic closure, and more light is transmitted as the vocal folds separate. Thus, PGG provides information about the open phase of the vibratory cycle and is complementary to EGG.22,23

As mentioned above, the two techniques provide the more useful information when performed simultaneously (Figure 4). With both measures, one can differentiate between the opening and closing phases of the total closed phase of the cycle. Flaccid vocal folds are quickly blown apart, resulting in a quick opening phase and then return to midline more slowly. In tight glottal closure, or with stiff vocal folds, the vocal folds are more difficult to open, resulting in a longer opening time. The edges then snap closed quickly. Opening and closing times can be quantified to derive the speed quotient, by dividing the opening time by the closing time. However, the different patterns are also easy to detect qualitatively on visual inspection of the waveform.

Recently, high-speed laryngeal imaging by digital video has been developed. The equipment is less unwieldy and is becoming commercially available. It is a promising new clinical tool for the assessment of voice disorders yet is still only available to those with expertise in its operation and interpretation. Sophisticated edge detection algorithms are required to track vocal fold movement accurately.

**EQUIPMENT REQUIREMENTS**

Many systems are commercially available for voice analysis, with varying degrees of complexity. A clinical practice is best served by the most user-friendly system, without complex assessment or calibration requirements. For research laboratories, off-the-shelf products generally lack the flexibility needed to modify software or to perform special tests. However, an audiotape recording system is an absolutely indispensable component of any voice laboratory. In patients treated for vocal problems, a voice recording is analogous to a photograph before cosmetic surgery. Voice recordings also are the substrate for acoustic voice analysis in clinical practice and research. An audio computer with the appropriate sound card selection may directly acquire input, but it is more efficient to record onto digital tape and select the samples to be analyzed post hoc. This also provides a means to archive the acquired recordings. It is essential that all components of the audio recording system, including microphones, amplifiers, and recorders, be of equal fidelity because any system is only as good as its poorest component.

Acoustic recordings must be made under controlled, standardized conditions, without background sound. The microphone should be at a standard distance to the mouth. The microphone’s frequency response should be flat across both low and high frequencies. A standard reference tone should be used to calibrate recording levels,
and the same protocol should be followed in each recording session, giving subjects the same instructions to utter the same speech samples at the same comfort levels.

Ideally, tests should be individually selected for each patient, depending on the disorder being evaluated, as not every parameter is relevant in every case. However, it is more efficient for each laboratory to define a core set of vocal function test which will be performed routinely on all subjects. Further, particularly in research laboratories, a parameter initially thought to be irrelevant may in fact demonstrate significant correlations to dysfunction. Therefore, the tests to be used can be selected to be appropriate for the majority of patients and subjects. Finally, a comprehensive voice laboratory must have a computer-based data acquisition system.

CONCLUSIONS

Although many techniques are available to assess vocal function and have been used frequently, most have not been validated. It is important to develop standards for voice assessment to permit documentation of dysfunction and response to treatment, and to allow valid clinical studies of treatment outcomes, thus developing the evidence our field needs to help justify our assessment and treatment plans. A standard voice battery is not actually a necessary goal since vocal quality is multidimensional and voice disorders vary greatly in types of distortion or dysfunction. A more achievable goal would be to develop consensus as to the relevant parameters for specific clinical voice disorders and to validate and standardize their use.

Disorders of Speech and Language

Raymond D. Kent, PhD

The faculties of speech and language are the core behaviors of human communication, and disorders of these faculties can carry severe consequences that affect virtually every aspect of life. Speech is the oral expression of language, which, in turn, is the faculty for the reception, manipulation, and expression of symbols that carry meaning. The components of language include syntax (grammar), semantics (lexicon), phonology (sound patterns of words), and pragmatics (the way language is used socially). Language can be expressed orally (speech), manually (sign language), graphically (print or writing), or by other means, depending on culture and the sensorimotor and cognitive abilities of the individual. Worldwide, speech is the primary, and first-acquired mode of language. But so intimate is the association between speech and language in both learning and use that their division is not always sharp. Laypersons often do not distinguish speech and language and may be inclined to think of them as a single behavior. However, speech and language can be distinguished functionally and clinically, and they are recognized here as distinct but closely related behavioral domains.

Collectively, speech–language disorders occur with considerable frequency, with prevalence estimates generally ranging from 6 to 10% in the general population. There is considerable variance in the prevalence estimates for some disorders, owing largely to differing criteria for diagnosis, methodology (eg, screening or diagnostic techniques vs population surveys), and demographic characteristics (eg, age, socioeconomic status) of individuals studied. Many of these disorders are complex and behaviorally based, so that adequate assessment and diagnosis often requires a battery of tests or evaluation instruments. Furthermore, certain of these disorders in children (stuttering, language impairment, speech sound disorder) have a spontaneous or natural resolution as high as 60 to 80%, although the persistence of disorders into later childhood or adulthood can have severe effects on educational, vocational, and social achievements. Speech and language disorders may be associated with later-identified difficulties in reading and other cognitive achievements. For many of these disorders, males are affected more than females by ratios that average approximately 3:1 but sometimes higher, especially in disorders that persist beyond childhood. Clearly, male sex must be considered as a risk factor for communicative disorders of many types, and this male vulnerability is observed in both children (speech sound disorder, developmental language impairment) and adults (aphasia related to stroke).

Disorders of speech and language can be classified as shown in Table 1, with a basic division by age in that childhood or developmental disorders are distinguished from adult or acquired disorders. Within each of these age categories, further divisions are made with regard to type or etiology of disorder. Unfortunately, a satisfactory etiologic taxonomy is not possible because some of the most frequently occurring communication disorders in children are of unknown or a complex multifactorial origin. Comorbidity is a complicating factor, as several of the disorders considered here have high rates of co-occurrence with other disorders. Specific comorbidities are identified in this chapter as the individual speech and language disorders are discussed. In adults, speech and language disorders usually are secondary to other conditions, such as a neurologic lesion, trauma, or various disease processes.

### SPEECH–LANGUAGE DISORDERS IN CHILDHOOD

#### Developmental Milestones

Speech–language disorders in children reflect processes of disorder interacting with processes of development. The interaction of these two factors complicates the understanding of disorders and introduces challenges into considerations of epidemiology, diagnosis, and treatment. A assessment and management of childhood disorders require background knowledge of typical development in its anatomic, physiologic, and behavioral aspects.

| Table 2 lists some of the major milestones in speech and language development along with related milestones in the anatomic and physiologic development of the speech production system. Oral cavity and pharyngeal anatomy and physiology are discussed in Chapter 63, "Anatomy and Physiology of the Oral Cavity," and laryngeal development, anatomy, and physiology are discussed in Chapter 72, "Development, Anatomy and Physiology of the Larynx." It should be emphasized that there are large variations in developmental patterns even among typically developing children, and, therefore, milestones should be used advisedly. The pattern of milestones in Table 2 shows that speech and language are gradual accomplishments in childhood and that they involve an interaction of linguistic, phonetic, motor, sensory, and anatomic changes. A neonate's vocal tract anatomy resembles that of the chimpanzee or other nonhuman primate and is capable of rather limited sound production compared to the phonetic repertoire of adults. An elevated laryngeal position truncates the pharyngeal cavity and creates a velo-epiglottal apposition that may support nutrition (eg, breathing while sucking) but is unsuited to adult-like vocalizations that require reliable control of velopharyngeal function for nasal versus nonnasal sounds. The neonatal vocal folds are short and un laminated (ie, the lamina propria is not evident). By the age of 2 years, a child's vocal tract anatomy is decidedly human-like (with a well-defined oral and pharyngeal two-cavity morphology), and a child at this age typically has the capability to produce two-word utterances formed from about 20 different sounds. By the age of about 6 or 7 years, children have an overall mastery of the sounds in English, although errors may persist for a few sounds to be described later in this chapter. Maturation of the anatomic and physiologic aspects of speech production continues until the age of 16 or 18 years and includes several remarkable changes, including (a) lamination of the vocal cords... |

appropriate terminology.

Definiition and Characteristics. Speech sound disorders pertain to errors in the production of speech sounds (lisping is a common example). They are also known as phonological or articulatory disorders, and opinion is divided regarding the more favorable ambient language.

Speech as a motor skill basically parallels language in its development, such that refinements in the production, frequency of occurrence of the sound as a percent of all consonants, cumulative percent frequency of occurrence, and typical age of mastery for the sound. Several conclusions can be drawn: (1) Only a dozen consonants account for 80% of all consonant productions, a conclusion that reflects large differences in the

* Place-manner description, with place of articulation indicated first and manner of articulation indicated second, and voicing indicated third, as relevant. Place refers to location in the vocal tract where articulatory constriction is formed. Manner refers to the way in which sound is formed. Voicing is shown as +vce for voiced or -vce for voiceless.

† Based on data summarized in reference 4.
informational load of individual sounds; (2) The alveolar place of articulation (involving the tongue tip and alveolar ridge) is very important in American English, accounting for about 50% of all consonant production; (3) Age of mastery varies markedly across consonants, with some consonants being accurately produced at 3 years or younger, but others at 6 years or older. This developmental pattern is highly important in assessment and treatment; (4) Among the last sounds to be mastered are the initial sounds in the keywords thin, this, she, Joe, chew, so, zoo, low, and row. Table 3 is relevant to understanding the effects on speech of various kinds of trauma or surgery on the oral tissues. Although speech is highly robust because of articulatory compensations, it can be difficult to overcome certain kinds of structural alteration (the tongue tip being particularly exercised in speech).

**Epidemiology.** The median prevalence estimates for speech sound disorders are in the range of 1 to 9%, with more recent estimates being in the range of 1 to 3%. People are affected more than females by a ratio of about 3:1. Peak prevalence occurs at around 5 years for males and around 3 to 4 years for females. The comorbidity profile of children with speech disorders includes co-occurrence with disorders of mental health, hearing, and respiration (especially asthma). General allergies also occurred with relatively high frequency among children with speech sound disorders. Not surprisingly, children who have speech sound disorders accompanied by respiratory disorders or allergies also have a high frequency of voice disorders. Approximately 11 to 15% of children with persisting speech delay also have a language impairment.

The severity of speech sound disorders ranges from mild (eg, distortion of a single sound, such as s as in say or r as in ray) to severe (multiple errors that interfere with speech intelligibility and effectiveness of communication). These errors may be termed as either disorder or delay.

**Etiology.** Speech sound disorders arise from several factors, including sensory impairment (hearing impairment is the most common), motor dysfunction, psychosocial problems, and the interaction of these factors. But for the majority of children who are classified as having a speech sound disorder, etiology is unknown or at least uncertain. Shriberg proposed a classification system that links characteristics of speech sound disorder with causal origins including genetic, hearing, motor-speech, and psychosocial factors.

In addition, speech disorders are likely to develop in certain medical conditions, including craniofacial anomalies (especially oral clefting), cerebral palsy, various congenital syndromes, and other developmental disabilities including autism. Neurogenic speech disorders occur especially in cerebral palsy, which has a prevalence of more than 2.0 per 1,000 live births, with speech impairment occurring in up to 80% of affected individuals. As summarized in Table 4, chromosomes 3, 6, 7, and 15 have been related to speech sound disorder. A disorder of particular interest in genetic studies is childhood apraxia of speech, which is an often severe disorder affecting the organization and coordination of speech movements. It is classified as a childhood motor speech disorder and is suspected to result from subtle neurologic abnormalities that have not been identified. Speech sound disorders can also arise in children who are learning English as a second language, which is another reason why a complete history is important in determining etiology. Because some speech sound errors are related to a child's language background rather than to a disorder per se, it is appropriate to distinguish disorder from difference.

**Assessment.** The typical clinical assessment includes an articulation test that examines the proficiency of sound production. The term speech or speech articulation usually refers to the motoric expression of language through actions of the respiratory, laryngeal, and especially supralaryngeal (articulatory) systems. In contrast, phonology is a component of language that deals with the ways by which sounds are combined to form words. The articulation test can be accompanied by a variety of other tests, depending on the depth and scope of the communication disorder. Conversational samples can be analyzed with relatively simple but informative measures such as the percent of consonants correct (PCC). Because consonants carry a major part of the informational load in speech, they are of particular importance in gauging the effect of a speech sound disorder. Phonological assessment determines the error patterns for speech sounds as they combine to form words. This kind of assessment is based on the principle that certain error patterns occur across words; that is, they have a generality that is important to recognize in clinical assessment. For example, children may omit word-final consonants so that the word nose is produced as no, and the word tooth is produced as too. Recognition of these patterns occurring across several words is a primary motivation for phonological descriptions of speech sound errors. Deletion of final consonants is typical of young children in the early stages of word learning, but when this error pattern persists into later development, it can interfere greatly with intelligibility.

Speech sound errors are broadly categorized as omissions (deletions of the sound), substitutions (replacements of the sound by another phoneme, such as t for s), and distortions (modification of the sound). Generally speaking, the severity of error decreases across these three categories (omission being the most severe form of error). Patterns of speech sound errors can be complex, including combinations of omission, substitution, and distortion in a given child. Speech articulation is considered relative to a child's overall language ability to arrive at a developmental assessment of communicative ability. Typically, several other tests or evaluations are performed to determine if the status of a child's hearing, oral mechanism, or other factors contribute to the speech sound disorder. As noted previously, one form of speech sound disorder that can be especially severe is childhood apraxia of speech, a poorly understood disorder that appears to reflect exceptional difficulties in the coordination and positioning of the articulators.

**Implications for Treatment.** Behavioral treatments are tailored to a number of factors, including severity of the problem, etiology (if known), presence of accompanying disorders (eg, a language disorder), and characteristics of the child. Treatment is often based on consideration of information like that contained in Table 2. That is, sounds are targeted for treatment according to their expected, or normative, pattern of development, with treatment given first to deviant sounds that are acquired relatively early in normal development. Frequency of occurrence may also be considered, on the assumption that frequently occurring sounds contribute more to speech intelligibility than rarely occurring sounds. But other strategies have been proposed, including one approach that focuses on later acquired sounds in the belief that normalization of these sounds may induce normalization of deviant sounds that typically are acquired earlier. A number of different treatments have been described, ranging from emphasis on minimal sound contrasts (eg, the contrasts that distinguish the words zip, sip, tip clip) to language-based methods that emphasize overall communicative behavior. Particularly when a motor speech involvement is suspected, clinicians may use oral nonverbal exercises (non-speech movements of the articulators), but, unless there is clear evidence of weakness, there is no evidence for the efficacy of these procedures and there are substantial theoretical arguments against their use.

Phonological awareness is a concept that bears on both speech sound disorders and reading disorders. It is the ability to detect and manipulate sound segments in speech and to demonstrate access to the sound structure of language. Children are considered to demonstrate phonological awareness when they show the ability to recognize sounds independently of the words in which they occur. Phonological awareness is manifested in tasks such as sound detection, rhyming, alliteration, deleting sounds, and moving sounds within words or syllables. Phonological awareness is relevant to literacy in that a number of studies have linked phonological awareness to reading ability. A link between phonological development and reading is a major direction of contemporary research in reading disorders. A connection between early phonological disorder and a later reading disorder would carry important implications for early intervention.

**Specific Language Impairment**

**Definition and Characteristics.** Specific language impairment (SLI) is diagnosed in children who have significant language deficits in the
face of normal nonverbal intelligence, adequate educational opportunity, and intact sensorimotor abilities. Diagnosis is performed largely by exclusion insofar as careful clinical assessment rules out other conditions such as mental retardation, autism, hearing loss, craniofacial anomalies, or neurological disorders that may cause language impairments. Children with SLI often have a delay or deficit in using functional morphemes (such as the words a, the, is) and other grammatical morphemes (such as the elements marking plural forms or verb tense forms).

According to some sources, SLI is perhaps the most common impairment in childhood. Other sources question the validity of prevalence data because of variability in diagnostic criteria. Questions about their child’s language development are among the most frequent that parents ask of medical specialists, especially pediatricians. It has been estimated that, at any given time, about 20% of parents have questions concerning their child’s language. Clearly, health specialists should be prepared to offer advice that is based on an understanding of language development and its disorders.

**Epidemiology.** Speech and language delay in children aged 2 to 4.5 years has a prevalence ranging from 5% to 8%, and language delay alone has reported prevalence rates of 2.3 to 19.0%. The large variation in these figures is explained in part by inconsistencies in the criteria for diagnosis. Because SLI is diagnosed largely by exclusion, careful and thorough assessments are required for a confident diagnosis. Statistics on the persistence of these difficulties also vary considerably across studies, with figures ranging from 30 to 90% but mostly in the range of 40 to 60%. Even if the midrange value of 50% is taken as an estimated persistence, then it is clear that a large number of children are affected by language disorder. The disorder is heterogeneous, and it has been concluded from one study that it represents four distinctive linguistic domains: (1) lexical-semantic abilities, (2) auditory conceptualization, (3) verbal sequential memory, and (4) speech production. Such heterogeneity complicates epidemiologic studies and raises challenges for both assessment and treatment. SLI is comorbid with other communicative disorders, and it has been reported that approximately 5 to 8% of children with persisting SLI also have speech delay.

**Etiology.** The etiology of SLI is not well established, although progress has been made in identifying genetic and environmental correlates. As shown in Table 4, language disorder has been linked to chromosomes 7, 13, 16, 19, and 22. The most well known of the genetic factors is the FOXP2 gene on chromosome 7, which has been described in the popular media as the “language gene.” In fact, FOXP2 is a transcription factor that influences the actions of several other genes, and chromosomes other than 7 have been associated with language abnormalities. One challenge in the genetic studies is to insure that the SLI phenotype has been clearly established, which usually means extensive testing in language and related domains. There is evidence that SLI is associated with differences in brain morphology, particularly a small pars triangularis in the left hemisphere and a more rightward asymmetry of language regions.

Several hypotheses have been advanced on the nature of the functional deficits in SLI. One proposal is that the difficulty that children have with grammatical morphology is related to a delay or difficulty in acquiring a specific underlying linguistic mechanism, such as the principle that verbs must be marked for tense and number (consider the contrasting verb forms in the three sentences He goes fast, They go fast, They went fast). Another hypothesis is that children with SLI have a poor short-term memory for speech sounds, which can be demonstrated in a task of nonsense-word repetition in which children are asked to repeat nonsense utterances. If the auditory representation for speech sounds is weakly developed or fades quickly, this would hinder a child’s efforts to learn and use language. A third hypothesis is that children with SLI experience a particular difficulty in auditory temporal processing for sounds that are brief or that change rapidly in their spectral properties (stop consonants fall in this category). The difficulty could be in the processing itself, in remembering the temporal order of auditory events, or both of these. This third proposal is considered further in the section “Implications for Treatment” in relation to an intervention called Fast ForWord. These different views of the nature of SLI hold different implications for both assessment and treatment. Another complicating factor is that the population of children diagnosed with SLI may actually consist of subpopulations who have somewhat different characteristics of language impairment.

Autistic spectrum disorders (ASD) are pertinent here both because of the role of speech-language symptoms in the identification of the disorder and because of the apparent increase in the prevalence of ASD, which has alarmed health-care and educational specialists, along with society in general. Epidemiological studies affirm that autism prevalence has been increasing, as shown by higher prevalences among younger birth cohorts. Reasons for this increase are not known. One possibility is that the diagnosis of autism has been substituted for diagnoses of mental retardation and/or language impairment, but there are reasons to doubt this explanation. ASD can be diagnosed as early as 2 years of age, and it is a life-long impairment in most individuals.

**Assessment.** As noted above, SLI is diagnosed largely by exclusion. If a child has a language impairment or delay that cannot be attributed to sensory disorder, cognitive limitations, social or educational deprivation, or other factors, then a diagnosis of SLI may be assigned. However, this does not mean that children diagnosed with SLI have no co-existing disorders. To the contrary, studies have shown that many children with SLI exhibit evidence of other co-occurring problems, such as motor difficulties.

A thorough assessment considers the various components of language, including grammatical ability, vocabulary (both expressive and receptive), pragmatics, and phonology. Several tasks may be employed to gauge a child’s language ability. Standardized tests are available, but some clinicians prefer nonstandardized tests for certain purposes. Table 2 lists several major milestones in language development, and these are useful as guidelines in assessing the status of a child’s language development. However, these are only crude suggestions for assessment,
and the complexities of language require intensive testing to determine the nature and severity of impairment. Formal screening instruments, which typically require no more than 10 minutes to perform, were reviewed by the United States (US) Preventive Services Task Force. The summary recommendation was that the evidence was not sufficient to recommend for or against the use of these screening instruments in primary care to identify speech and language delay in children younger than 5 years of age.

Implications for Treatment. A variety of behavioral treatments have been described. Fey and colleagues describe general principles for treatment of grammatical deficits, which are common among children classified as having SLI. It was concluded from a meta-analysis of treatments for language disorders in children that speech and language therapy may be effective for children with phonological or expressive vocabulary difficulties, but there was mixed evidence for the effectiveness of interventions for children with expressive syntax difficulties and little published evidence for the effectiveness of interventions for children with expressive vocabulary difficulties. Randomized controlled trials on children younger than 5 years were reviewed by the US Preventive Services Task Force. Although some positive outcomes were reported, the studies generally were limited by the lack of long-term outcomes, comparison data, and generalizability. One treatment that received considerable attention in the popular media is Fast ForWord, which is based on the manipulation of the acoustic properties of speech, particularly the dynamic aspects (formant transitions) that connect adjacent sounds. A randomized clinical trial did not show that this technique was associated with better outcomes than traditional language therapy or another computer-based method.

Craniofacial Anomalies

Definition and Characteristics. Craniofacial anomalies are alterations of the normal or typical structure and appearance of the craniofacial system and are linked with a number of syndromic or nonsyndromic conditions. Congenital craniofacial anomalies are discussed in Chapter 70, “Craniofacial Anomalies of the Head and Neck.” Craniofacial anomalies frequently affect the structures used in oral motor behaviors and can greatly compromise speaking and feeding abilities. Although surgery offers major benefits both functionally and aesthetically, there is clearly a need for behavioral treatments to ensure best outcomes. Craniofacial anomalies take a variety of forms, but the most common is orofacial clefting, which is discussed in more detail here.

Epidemiology. Clefting has a worldwide incidence of 1 in 700 and is the most common of the orofacial anomalies. Nonsyndromic, or isolated, clefting is distinguished from the clefting that occurs in syndromes (eg, velocardiofacial syndrome) or sequences (eg, Pierre Robin sequence). Cleft lip is associated with 171 syndromes, but only about 15% of cleft lip-cleft palate cases are syndromic. Evidence indicates that the frequency of orofacial clefting is increasing. The reasons for such an increase are not clear, but etiological factors considered next may be relevant to an eventual explanation.

Etiology. Embryologically, clefts of lip and palate almost always occur because the medial nasal process either fails to make contact, or maintain contact, with the lateral nasal and maxillary processes. Studies in developmental biology have shown that both genetics and environmental factors contribute to the etiology of clefting. Evidence points to an association between isolated clefting and genetic factors, as summarized in Table 4 (which also includes information on the genetic linkages for syndromic clefting).

Environmental factors include parental smoking, maternal alcohol consumption, maternal obesity, and parental age. Although surgery offers major benefits both functionally and aesthetically, there is clearly a need for behavioral treatments to ensure best outcomes. Craniofacial anomalies take a variety of forms, but the most common is orofacial clefting, which is discussed in more detail here.

Implications for Treatment. Within the last three decades, palatal surgery has changed both significantly and rapidly. Newer methods, such as Furlow Z-plasty, have been introduced, and surgery is now often done at 10 to 11 months (as compared to 18 to 24 months before the 1980s). Despite these advances, data indicate that the majority of preschoolers with cleft palate exhibit delays in speech sound development that require speech-language therapy. Such therapy is typically directed to improve articulation ability and hence speech intelligibility. Children with clefting often have problems associated with the ear, nose, and voice.

Childhood Fluency Disorders: Stuttering and Cluttering

Definition and Characteristics. Stuttering is a disorder of the flow of speech (fluency) and typically presents as repetitions of words or parts of words, prolongations of sounds, or blockages of speech. Although these disfluencies can occur occasionally in nearly all speakers, they become more severe in persons who stutter and can be associated with secondary characteristics (eg, facial grimacing) and avoidance or of communicative situations. Cluttering is a much less common disorder characterized by a speech pattern that is rapid, dysrhythmic, and unorganized. It is possible for stuttering and cluttering to co-exist in the same child.

Disfluencies are normal during speech development, and many children exhibit stuttering-like behaviors, such as sound repetitions, during the age interval of 2 to 4 years. Because this is a period of rapid changes in speech, language, and other behaviors, disfluencies may be the result of trying to talk at a time when many demands are placed on a child who has limited but growing cognitive, linguistic, and motor resources. If stuttering is viewed as a disruption of a skilled motor behavior, it is interesting that no other motor behavior acquired during childhood has an equivalent vulnerability to its performance.

Epidemiology. Stuttering has a worldwide prevalence of 1% and a prevalence in the pediatric population of 5%. Spontaneous and complete recovery occurs in about 60 to 80% of children who stutter, and a particular goal of research is to find ways of identifying that proportion of children who are not likely to recover spontaneously. Males are more likely to stutter than females, with a male to female ratio of 2:1 for young children and 5:1 for adults. Comorbidity with other speech disorders, language disorders, or non-speech–language disorders is estimated to be about 60%, with articulation and phonological disorders being the most frequently co-occurring disorders.

Etiology. The etiology of stuttering is controversial, but the weight of evidence points to a multifactorial origin that includes genetic factors (Table 4), probably based on interactions among multiple genes, and with a likely sex difference in gene involvement. A genetic influence has long been suspected because of familial patterns in stuttering and high rates of concordance in monozygotic twins. It appears that genetic influences interact with environmental variables to contribute to the etiology of developmental stuttering (which should be distinguished from acquired stuttering in adults, which usually has a neurogenic or psychogenic basis). Occasionally, stuttering-like behavior has been observed in connection with medications. A neurogenic basis for developmental stuttering has long been suspected, and several hypotheses have been proposed on the neural correlates of stuttering. One of the most persistent of these is that stuttering is associated with anomalous hemispheric asymmetry, such that individuals who stutter have a greater degree of right hemisphere activation for speech. Little is known about the etiology of cluttering.

Assessment. Developmental stuttering is typically identified when the child is 3 to 5 years of age, and the major presenting symptom is the repetition of individual sounds or syllables. Stuttering is identified at an age when children are making rapid advances in speech and language abilities and when there are notable changes in emotional and personality traits. Various scales have been developed to quantify stuttering behaviors, but this remains an area of some controversy. The typical procedure is to count stuttering...
events or dysfluency types. Stuttering severity tends to be reduced under conditions such as choral reading or repeated reading of a passage, and these fluency-inducing conditions are sometimes used in assessments. A particular challenge is to determine which children who demonstrate stuttering-like behaviors are at risk for the disorder of stuttering. This is not an easy determination, but some guidelines have been described, mostly pertaining to the frequency of disfluencies and the child’s reaction to these events.49

Implications for Treatment. Stuttering treatment has a long history that cannot be easily covered in any depth. The high rates of spontaneous recovery in developmental stuttering complicate efforts to demonstrate the efficacy of treatment outcome.45 A further complication is that many treatments will lead to a reduction of stuttering in the short term but the benefits may not last. Reducing stuttering is not difficult as an immediate goal, given that a number of altered speaking situations (choral reading, speaking with altered auditory feedback) lead to fairly predictable reductions in stuttering.45 A number of treatments have been introduced but few have been sufficiently examined in randomized clinical trials to formulate confident recommendations for clinical practice. The strongest evidence (in the form of randomized clinical trials) favors the Lidcombe method of stuttering therapy.46 But clinical specialists endorse a number of different interventions that have been successful in their own practices but have not been evaluated in clinical trials. One of the commonly used approaches is to encourage an easy or relaxed phonation at the initiation of an utterance. Many clinicians also will try to reduce communicative pressures within the child’s family or school, such as asking family members to reduce speaking rates.

Voice Disorders

Definition and Characteristics. A voice disorder is an abnormal voice quality, a definition that presumes an understanding of what constitutes normal voice (not an easy matter given the large variations in normal voices). Voice disorders in children are often identified perceptually and are characterized by terms such as hoarseness, roughness, and voice breaks. A perceptual assessment of voice disorders has generated a large literature, replete with arguments for and against the reliability and validity of this approach.

Epidemiology. Estimates of the prevalence of voice disorders in children range from 6% to 11%, depending on means of assessment and population under consideration.47 Estimates based on parent report are about twice as high as estimates based on clinical evaluation.47 The risk for dysphonia is greater for boys and for children with older siblings.48

Etiology. Voice disorders have several etiologies, with the most common being vocal fold nodules or polyps, laryngeal webbing, laryngitis, juvenile papilloma, vocal fold paralysis, extrinsic or intrinsic trauma to the larynx, and velopharyngeal incompetence.49 These conditions are discussed in Chapter 69, “Congenital Anomalies of the Larynx,” Chapter 75, “Benign Laryngeal Lesions,” and Chapter 80, “Laryngeal Paralysis.”

Implications for Treatment. For many of these disorders, medical treatment or voice therapy is indicated, depending on etiology, severity, and patient characteristics. Surgery may be required to remove nodules, papillomas, or webs, and surgical reconstruction may be needed in the event of trauma. Laryngoplasty is a consideration in vocal fold paralysis. Several types of behavioral voice therapy may be appropriate. These include vocal rest, laryngeal manipulation, vocal exercises, and laryngeal hydron. Medical treatments are discussed in other chapters of this section.

SPEECH AND LANGUAGE DISORDERS IN ADULTS

Adult Neurogenic Speech Disorders (Motor Speech Disorders)

Craniofacial Muscles. Because neuropathology is the basis of these disorders, it is pertinent to ask if the neurology of speech is the same as the neurology of arm or trunk movement. Although it is often assumed that the effect of neurologic disease or damage is essentially the same for the speech musculature as it is for the muscles of the trunk or limbs, recent studies show that the muscle fibers types of the craniofacial muscles are distinct from those in the limb and trunk muscles, generally showing considerable polymorphism.50 In addition to muscle-fiber isoforms, such as type I and type II variants, the craniofacial muscles often contain hybrid fibers that coexpress two or more isoforms. Muscle-fiber composition varies within and across muscles in the craniofacial muscles, and the composition in humans differs from that in homologous muscles in nonhuman species.

This paragraph summarizes information on muscle fibers within different parts of the speech production system. The vocalis muscle compartment of the thyroarytenoid muscle contains a large population of slow tonic muscle fibers that do not exhibit a twitch contraction but rather have contractions that are prolonged, stable, precisely controlled, and fatigue resistant (properties that seem highly suited to the demands of phonation in human speech). The mandibular muscles contain at least four different isoforms of myosin heavy chain, have a continuous range of contraction speeds, and have a high oxidative capacity (properties that are suited to variable dynamics and fatigue resistance). The tongue has a predominance of small type IIA fibers in its anterior portion (which has the capability for rapid movements) and a sizeable population of larger type I and type IIM/HIC fibers in its posterior region (which is responsible for slower adjustments of tongue carriage). The palatal muscles also show considerable heterogeneity in muscle-fiber composition, with palatopharyngeus and uvula containing remarkable proportions of type II fibers, and levator and tensor veli palatini possessing mostly type I fibers. Like the other speech muscles just described, the palatal muscles also are fatigue resistant. In general, it can be said that the craniofacial muscles are unique in their genetic, developmental, functional, and phenotypical properties.30

Definition and Characteristics. A adult speech disorders usually appear in adults as acquired conditions secondary to neural trauma or disease. They occur as two general types, dysarthria and apraxia of speech (also known as verbal apraxia or dyspraxia). Dysarthria is a disorder of speech production associated with lesions to the central nervous system, peripheral nervous system, or both, and generally is accompanied by motor signs of weakness, paralysis, or incoordination. As shown in Table 5, the acquired dysarthrias in adults are further classified into seven major types identified through their auditory-perceptual features and interpreted in terms of classic neurology.51,52

Apraxia of speech is an isolated disorder of speech production characterized by difficulties in the sequencing or patterning of movements, but in the absence of motoric deficiencies in non-speech movements performed by the same musculature. The responsible lesion is nearly always in the language-dominant hemisphere, especially in the frontal or parietal lobes, but occasionally in subcortical regions.53 The disorder of childhood apraxia of speech, mentioned earlier in this chapter, was given its name because it was thought to share characteristics with the acquired disorder in adults. However, loss of praxis may be fundamentally different from a failure to develop praxis in the first place. Whether or not the terminology is apt, these terms are well established clinically and probably will continue to be used.

Epidemiology. Epidemiology of these disorders tracks that of the diseases with which they are associated. Most of these diseases are those of advancing age, especially stroke and the neurodegenerative diseases. Comorbidity is high among these neurogenic disorders. An individual patient may have aphasia along with dysarthria, or aphasia along with apraxia of speech.

Etiology. Neural lesion is either known or presumed. Table 5 depicts the clinicoanatomic relationships in general terms.51-53 But it should be noted that even within a given dysarthria type, there can be quite different speech characteristics.
Aphasia is an impairment of the cognitive systems that perform language resulting from focal brain damage or disease (typically cortical lesions, but subcortical lesions are occasionally involved). This definition is intended to exclude language impairments associated with diffuse brain damage, such as that in dementia. The focal nature of the neural damage invites hypotheses on clinicoanatomic relationships, and this issue has been a major topic of the literature on aphasia. The nature and severity of the impairment varies considerably, and there is controversy over the most appropriate classification of deficits in aphasia. One of the most well-established and frequently used systems is the Boston Diagnostic Aphasia Examination, which uses the classification summarized in Table 6.

### Etiology

The primary risk factors for aphasia are advancing age and cardioembolism. A though aphasia usually is associated with stroke, it can result from other neuropathologies such as tumors or trauma. The responsible lesion is typically cortical (left hemisphere in the majority of cases), but aphasia can result from subcortical lesions, including those of the thalamus, putamen, and internal capsule.

### Assessment

Several tests or test batteries have been developed for the assessment of aphasia, with the basic goal of classifying type and severity of aphasia. The classifications shown in Table 6 are frequently, but not universally, used.

### Treatment

A number of pharmacological treatments for aphasia have been suggested, but the evidence favors only a modest benefit from amphetamine and the dopamine agonist piracetam. Indications are that drug therapies used alone are less effective than drug therapies combined with behavioral speech-language treatment. However, randomized clinical trials are needed to demonstrate the benefit of speech-language therapy.

### Structurally Based Speech Disorders

These disorders result from trauma, ablative surgery, or other factors that compromise the structural integrity of the speech production system. The effects on speech and voice depend on the extent of damage (e.g., laryngectomy, glossectomy, mandibulectomy).

### Epidemiology and Etiology

Epidemiology follows the responsible medical condition, making it difficult to offer a concise summary.

### Assessment

The main objective in assessment is to identify the effects on speech of limitations in anatomy and physiology.

### Treatment

Fortunately, a number of compensations permit adequate speech production even in individuals who have experienced serious alteration of the oral and laryngeal structures. Prosthetics can often restore a basic functionality that can be further enhanced by behavioral therapy.

### Voice Disorder

Definition and Characteristics: Epidemiology

Few studies have been reported on the prevalence...
and risk factors for voice disorders in adults. But a recent report indicated a lifetime prevalence of a voice disorder to be 29.9%, with 6.6% of respondents indicating a current voice disorder. Factors associated with chronic voice disorders were female sex, age of 40 to 59 years, patterns of voice use and demands, esophageal reflux, chemical exposures, and frequent colds or sinus infections.

Etiology. See the earlier discussion of voice disorders in Chapters 75, 76, 79, 80, and 81.

Assessment. Discussion of the assessment of vocal function is found in Chapters 73, 79, and 81.

Implications for Treatment. Medical interventions are considered in Chapters 75, 76, 79, 80, and 81. Several behavioral interventions have been described, many of which are similar to those mentioned previously with respect to voice disorders in children.

Dysphagia

Definition and Characteristics. Dysphagia is an impairment of deglutition and can affect any aspect or stage of this process. It often results from the neural and structurally based deficits considered above; and because dysphagia teams often include otolaryngologists, speech-language pathologists, and other specialists, it is mentioned in this chapter. Dysphagia is a critical concern because of the growing emphasis placed on communication for educational, vocational, and social pursuits in this digital age.

Epidemiologic and etiologic information is far from satisfactory for some of the most frequently occurring disorders. Multifactorial origins may underlie a large proportion of cases of specific language impairment, stuttering, speech sound disorders, and possibly craniofacial anomalies. As shown in Table 4, speech and language disorders are related to loci on nearly all autosomes as well as the X sex chromosome. These complex genetic influences are matched by a tangle of environmental variables that affect the development of speech and language in children. Some of these disorders persist into adulthood, either in essentially the same form (eg, stuttering) or in different forms (such as a reading disorder that may be related to an earlier language disorder). High rates of comorbidity are observed for nearly all of the disorders. Co-occurrence of disorders can complicate diagnosis and treatment, but it may also provide insights into the etiology of these conditions.

CONCLUSIONS

Disorders of speech and language are important considerations in functions of the stomatognathic, laryngeal, and auditory systems. Although prevalence estimates vary considerably, it is likely that these disorders have a prevalence of about 6 to 8% in the general population. These disorders may be of increasing concern because of the strengthening emphasis placed on communication for educational, vocational, and social pursuits in this digital age.

Benign Laryngeal Lesions

Michael M. Johns, MD
Shatul Parikh, MD

Benign laryngeal lesions are an increasingly commonly diagnosed cause of dysphonia. Modern-day advances within the subspecialty field of laryngology have allowed otolaryngologists to become increasingly precise with their ability to diagnose and treat voice disorders. Prior to the advent of sophisticated office-based imaging, most vocal-fold lesions were diagnosed in the operating room. Innovative otolaryngologists, speech language pathologists, and voice scientists have developed preventive, diagnostic, and treatment modalities to improve the quality of life of those with dysphonia.

The gold standard for the diagnosis of benign vocal-fold lesions remains a thorough history and head and neck examination, followed by a subjective assessment of the voice and detailed imaging of the vocal folds. Despite the introduction of novel methods of visualizing vocal-fold vibration including high-speed photography, videokymography, photoglottography, and ultrasonography, laryngeal videostroboscopy remains the most practical and clinically useful tool in visualizing vocal folds. The equipment is relatively inexpensive, and the examination can be performed within an office setting either with flexible transnasal or rigid transoral endoscopy. Videostroboscopy allows for detailed evaluation of vocal-fold vibratory characteristics, mucosal wave and glottal closure. This detailed evaluation of the entire vocal fold allows for visualization of even subtle benign lesions.

**PHONOTRAUMATIC VOCAL-FOLD LESIONS: NODULES, POLYPS, CYSTS**

**Etiology**

The vocal folds are subject to mechanical stress during phonation. Vocal-fold vibration during phonation leads to impact stress during the collision of the vibratory surfaces. These stress forces have been analyzed, and it has been determined that maximal impact of stress occurs in the midmembranous vocal fold, the typical location for vocal nodules. Vocal overuse in the form of excessive use, abuse, for example, yelling, and misuse, for example, vocal hyperfunction with excessive muscular tension, leads to undue mechanical stress resulting in trauma in this region. Repetitive trauma results in wound formation within the superficial layer of the lamina propria and to a lesser extent the vocal-fold epithelium. Vocal nodules are essentially calluses on the vocal fold. In contrast, a polyp is an outpouching of the epithelial cover, filled with mucoid or fibrous substance. Polyps may be pedunculated or sessile. Etiology of polyp formation is less clear, but often appears to be organization of a hematoma. When polypoid change involves the entire membranous fold, it is often referred to as Reinke edema. A cyst is an epithelial-lined mass. It is not clear whether cysts arise from trauma or from gradual enlargement of a congenital defect. A pseudocyst is an amorphous submucosal collection of fibrinoid material.

**Diagnostic Principles**

Vocal-fold nodules, polyps, and cysts can be differentiated on videostroboscopy, and the degree of dysphonia is associated with the extent of disruption of vocal-fold vibration. Vocal-fold nodules are generally symmetric and always bilateral mass lesions of the vocal folds (Figure 1). They arise at the junction of the anterior and middle third of the vocal fold and tend to appear white to opaque and firm. They result in an hourglass closure glottal configuration and will affect vocal-fold mucosal wave and vibration variability, depending on their size and the degree of associated edema. Vocal-fold polyps are more translucent to red and are more commonly unilateral, although bilateral polyps may occur (Figure 2). The mucosal wave is generally present or increased with vocal-fold polyps. Vocal-fold cysts can be divided into two types: mucous retention cysts and squamous cell inclusion cysts. Mucous retention cysts usually arise below the free margin of the glottis and are translucent collections of mucus likely arising from a plugged mucous gland duct. Squamous cell inclusion cysts appear as yellow fusiform masses within the lamina propria (Figure 3). Vocal-fold mucosal wave is affected variably depending on the size of the lesion. Small subepithelial lesions may not disrupt the mucosal wave, but larger lesions that extend to the vocal ligament distort vocal-fold pliability as they replace the superficial lamina propria (SLP). Optical coherence tomography (OCT) is a potentially new diagnostic tool for diagnosing phonotraumatic lesions. This non-contact, noninvasive technology allows detailed imaging of the vocal fold by using cross-sectional images by means of backscattered light.

**Figure 1** Vocal nodules. Generally bilateral, symmetric, midmembranous, and subepithelial vocal-fold lesions.

**Figure 2** Posthemorrhagic polyp. Peduculated mass arising at the midmembranous vocal fold.

**Figure 3** Vocal-fold cyst. Fusiform, epithelial-lined mass within vocal fold replacing the lamina propria.
Treatment Principles: Behavioral Intervention and Voice Therapy

The first-line treatment for lesions caused by phonotrauma, vocal-fold polyps, nodules, and cysts, is behavioral intervention with speaking and singing therapy. The primary goal of voice therapy is to maximize efficiency of phonation and to eliminate maladaptive vocal behaviors that exacerbate these masses. Additionally, patients should be treated for concomitant problems that contribute to mucosal friability, such as laryngopharyngeal reflux and poor vocal hygiene. Vocal nodules are responsive to voice therapy, and surgery is not often indicated. “Nodules” which persist after adequate therapy may actually prove to be cysts. In patients with vocal nodules, it has been concluded in one study that over a 4- to 6-month period of voice therapy patients experience significant perceptual improvements in voice and must have a reduction in the size of the nodules. Of note, the lesions did not disappear completely in any of the patients in this study. It must be kept in mind that adequate improvements in voice do not necessarily correlate with disappearance of the lesions.6 Vocal-fold polyps and cysts are much less responsive to voice therapy although some patients may experience adequate improvement with voice therapy.

Treatment Principles: Surgical Intervention

When maximal behavior intervention does not achieve satisfactory improvements in voice, surgical treatment may be considered. The decision to pursue surgical management, however, should take into account multiple factors, including the patient’s vocal impairment, type and location of the lesion, and willingness to accept surgical risk. Patients who do not have vocally demanding lifestyles or do not have significant functional impairment from their lesions may not warrant surgical intervention. Additionally, the probability of surgical success based on the lesion type and location should be considered. Patients with large pedunculated polyps have a high chance of significant vocal improvement with surgical resection with minimal scarring. On the contrary, vocal-fold cysts are more technically demanding to excise and have a higher probability of surgical success based on the patient’s vocal impairment, type and location of the lesion, and willingness to accept a poor postoperative outcome.

The first important operative principle is patient positioning to optimize laryngeal exposure. Direct visualization of the entire membranous vocal fold to the anterior commissure using an adequately sized laryngoscope is a fundamental element for optimizing surgical success. Patient positioning in the “sniffing position” offers optimal laryngeal exposure for endoscopic microsurgery.11 The sniffing position requires the neck to be flexed on the chest and the head being extended on the neck. A variety of suspension operating microlaryngoscopes are available that allow for binocular microscopic visualization of the larynx with the introduction simultaneously of instruments in each hand.

Once good exposure of the glottis is achieved with an appropriate laryngoscope in suspension, the surgeon should be sure to have comfortable, ergonomic seating with appropriate wrist and forearm support. A adequate arm and wrist support significantly improves microsurgical control and reduces fatigue. Specially designed operative chairs are made for this purpose, although adequate support can be achieved by stacking sheets on a Mayo stand at the patient’s head upon which the forearms can rest.

After adequate positioning, careful examination of the endolarynx is performed. Optimum examination initially includes the use of straight and angled telescopes. A 70° telescope is particularly useful for seeing the craniofacial extent of lesions and for visualizing the ventricle and subglottis. The operating microscope can then be used at the highest power magnification for binocular visualization. Careful palpation with blunt microsurgical instruments gives the surgeon a sense of the lesion’s character and helps identify the junction of normal and abnormal tissue.

An array of laryngeal microsurgical instrument sets are available that optimize surgical precision. The important principles in instrument selection are having instrument tips that are sufficiently small with a variety of functions to maintain control around small lesions and to maximize preservation of normal SLP. The surgeon should have a variety of microcannula for suction and blunt instruments for palpation. Micrograspers, microcups, and microscissors should be available in straight, up, right, and left configurations. Finally, sharp microsickle knives and blunt-angled microflap elevators are necessary.

The initial surgical incision can be made with a microsickle knife or microscissors. Placement should be at the precise junction of normal and abnormal tissue. Following the epithelial incision, blunt instruments and suction should be used to identify the junction between normal and abnormal tissue, preserving as much normal SLP deep to the lesion as possible. Human cadaver larynx investigations have determined that a natural plane of dissection occurs in the SLP of the vocal fold using semiblunt microdissectors.11 Dissection is carried out within the SLP just around the abnormal subepithelial tissue, trying to disrupt as little healthy SLP and preserve healthy mucosa medially to redrape over the surgical defect. In the case of vocal-fold cysts, care must be taken not to rupture the cyst and excise the entire cyst wall to prevent recurrence.

The CO2 laser can be a useful adjunctive tool in these procedures. Although some argue that the CO2 laser leads to excessive thermal injury in the vocal fold, it must be remembered that lasers and cold microinstrumentation are simply tools. Maximizing preservation and minimizing disruption of healthy SLP are the overriding principles, and the care, knowledge, and experience of the surgeon drive surgical outcomes. Comparison of cold dissection technique versus microspot CO2 laser-assisted dissection for surgical treatment of benign laryngeal lesions has been studied. It was found that there is no difference in clinical outcomes measured by acoustic analysis, airflow rates, videostroboscopy, and audio perceptual analysis in patients treated with either technique.12

With regard to postoperative care, voice rest is controversial. While many laryngologists advocate a period of 4 to 14 days of absolute voice rest following vocal-fold microsurgery, others feel that reduced voice use is preferable. It is difficult for patients to comply with absolute voice rest, and voice professionals may get “out of shape” without some voice use. Moreover, there may be less scarring with some vocal mobility. There are no clinical studies that can resolve this controversy.13 In a study of wound healing following vocal-fold microsurgery in a canine model, it was found that longer healing times were necessary in the vocal-fold base membrane zone in dogs that were allowed to phonate after surgery versus those on iatrogenic voice rest (recurrent laryngeal nerve resection).14 Although extrapolation of these findings to humans may be difficult, the results imply that some voice rest may be beneficial following laryngeal microsurgery. Outcomes of surgical intervention for benign laryngeal lesions have been extensively studied. Microsurgical excision has shown improved vocal function postoperatively in almost all patients as measured by patient perception, quality of life, videostroboscopy, and acoustic and aerodynamic measures.1,7

[878]
Benign Neoplasms

Recurrent Respiratory Papillomatosis

Etiology. Although recurrent respiratory papillomatosis (RRP) is a rare clinical entity, laryngeal papillomas are the most common benign laryngeal neoplasm.15–17 RRP is caused by epithelial infection with the human papilloma virus (HPV). The disease process is clinically divided into an adult-onset and juvenile-onset form. In the juvenile-onset the incidence in the United States is between 80 and 1,500 cases per 100,000 persons annually.18 The means of transmission of HPV is unknown, although exposure to the virus is clearly required combined with host susceptibility. Maternal-fetal transmission in the juvenile form and sexual transmission in the adult form have been proposed.19 While the juvenile-onset form has an equal female to male ratio, adult-onset disease has a male to female preponderance of 2:1.20 RRP is considered to be adult onset if the patient presents older than 16 to 20 years.21 In most pediatric studies, the diagnosis of RRP occurs 1 year after the start of symptoms. Most patients are firstborn, have young mothers, and come from families of low socioeconomic status. The HPV 6 and 11 viral subtypes are most commonly found in RRP, though subtypes 16 and 18 have also been found. The latter two subtypes are associated with malignant degeneration.21

Diagnostic Principles. In the adult-onset form of the disease, the most common presenting symptom is dysphonia.20 Children with RRP present with a wide spectrum of laryngeal symptoms. A though pathologically indistinct lesions, a papilloma that presents as hoarseness in one child may present with stridor in another child depending on the location and bulk of the disease. Prior to definitive diagnosis of RRP, children are often mistakenly treated for having asthma, bronchitis, croup, epiglottitis, or gastroesophageal reflux. If the onset of stridor or dysphonia is gradually progressive, a neoplastic process should be considered. Although definitive diagnosis requires pathologic confirmation, RRP has a unique appearance on laryngoscopy. Lesions are exophytic, verrucous, and have characteristic pattern of vascular stippling (Figure 4). While the extent of the neoplasm can be estimated by preoperative laryngeal imaging, careful examination in the operating room with the assistance of angled telescopes provides the most accurate assessment of disease severity.

Treatment Principles. Treatment success is determined by the ability to maintain an adequate airway and functional voice preservation. There has yet to be a surgical or medical treatment that has been shown to eradicate the disease in affected patients. Surgical treatment can occur via cold steel, CO2 laser, or microdebrider excision.22 These instruments are all simply tools, and the key to success lies in meticulous surgical technique. The preservation of voice with maintenance of the SLP is the important consideration. Additionally, resection should avoid the aposition of raw mucosal surfaces especially in the anterior commissure that may promote glottic webbing.

Traditionally, the CO2 laser has been the surgical workhorse for patients with RRP.23 These lasers are coupled to an operating microscope allowing precise vaporization of lesions. New scanning laser technology has allowed for increased precision and reduced thermal injury from the CO2 laser. Currently, the technique most commonly used among pediatric otolaryngologists for excision of gross papilloma is the powered microdebrider.24 This technique involves the use a small oscillating blade with a suction that allows papilloma to be drawn into the blade chamber and effectively sheared from its attachment. Several studies have shown improvement in operating time, patient postoperative pain, cost, and scarring when comparing microdebrider to CO2 laser excision of RRP.25 However, care must be taken to avoid injury to normal tissue, which can occur quickly and easily using this powered instrument, particularly at the glottal level.

Special precaution must be taken while treating disease at the anterior commissure to avoid raw opposing surfaces that can lead to the development of an anterior glottal web. Staging procedures several weeks apart to allow mucosalization of one side prior to surgery on the other can help prevent web formation.

Recent treatment advances in the field of RRP have emphasized the benefits of alternative technologies and medical therapies. Pulsed lasers (pulsed dye or pulsed KTP) with hemoglobin sensitivity have shown positive results in the operative and office-based treatment of RRP.26–28 These types of lasers selectively coagulate the vascular stalk feeding the papilloma, causing it to blanch and eventually slough. Reported advantages include the avoidance of general anesthesia, reduced scarring, and the ability to treat the anterior commissure.

A variety of adjuvant therapies have been reported in the treatment of RRP. These include locally injected cidofovir (an antiviral agent), intravenous interferon-α, and oral indole-3-carbinol.29–31 Varying degrees of success in treatment of RRP are reported, and use of these therapies has not been approved by the US Food and Drug Administration, and their use is therefore off-label. Reports of carcinogenesis in animal models with cidofovir use necessitate more in-depth investigation. In patients with recalcitrant RRP or with progressive disease involving the tracheobronchial tree or pulmonary involvement, the benefit that these agents may outweigh their risk to control spread of disease.

Currently, a quadrivalent (HPV types 6, 11, 16, 18) vaccine is available for reducing the risk of cervical cancer.32 The availability of this vaccine could dramatically change the incidence of RRP. However, the vaccines effect on preexisting disease is unknown.

Granular Cell Tumor (Myoblastoma)

Historically, granular cell tumors were referred to in the literature as myoblastomas. A ctually, these neoplasms arise from neural elements, more specifically Schwann cells. Granular cell tumors present in the head and neck region in 50% of cases. Approximately 10% of cases arise within the larynx. They present as a submucosal mass that most commonly arises at the junction of the vocal ligament and vocal process of the arytenoid cartilage. Surgical resection can be curative through an endoscopic or open approach. Pseudoepltheliomatous hyperplasia is a characteristic pathologic finding.33

Paraganglioma

Paragangliomas occur in the larynx infrequently. Their pathogenesis is similar to other chemodectomas that arise in the head and neck. They are the only head and neck neoplasm that shows a female preponderance. They most commonly arise from branches of the superior laryngeal nerve. They appear as a vascular submucosal mass. Diagnosis is confirmed with high-resolution computerized tomography, magnetic resonance imaging (MRI), or angiography. Characteristic salt and pepper appearance is found on MRI because of the vascular flow voids. Resection with consideration of organ preservation is important as these neoplasms are rarely malignant or metastasize. Depending on the size and extent or tumor, endoscopic or open resection can be considered. Preoperative embolization of these neoplasms has decreased intraoperative bleeding and facilitates total resection. Microscopically, these tumors show large polygonal cells with eosinophilic cytoplasm that cluster into islands or nests of cells known as Zellballen.34,35

Chondroma

The etiology of laryngeal chondroma is unclear. Cartilagenous neoplasms represent less than 1% of all laryngeal neoplasms.40 Clinically, patients present with slowly progressive dyspnea, hoarseness, dysphagia, and stridor. Because chondromas are slow-growing lesions, symptoms can be present for years prior to the diagnosis. Physical examination can show a submucosal laryngeal mass, vocal cord immobility, and a narrowed subglottis. Vocal cord immobility is almost
Laryngoceles and Saccular Cysts

Etiology

The laryngeal saccule is a mucous gland-containing appendage that lies between the false vocal fold and the thyroid cartilage. It is an outpouching of the laryngeal ventricle and extends as a sac posterolateral to the edge of the laryngeal surface of the epiglottis. The function of the saccule is unknown although it has been theorized that it may represent a vestigial air sac. Both laryngoceles and saccular cysts involve expansion of the saccule to form a mass. Laryngoceles by definition must have air contained within their lumen, while saccular cysts are strictly fluid-filled masses.

Laryngoceles contain air due to a patent communication with the laryngeal lumen. Classification of laryngoceles depends on their location. They can be defined as internal, external, or combined. Internal laryngoceles are confined within the thyroid cartilage, external laryngoceles lie outside the cartilaginous laryngeal framework, and combined laryngoceles span both the inside and outside of the thyroid cartilage.

Saccular cysts are also classified according to their location: anterior and lateral. Anterior saccular cysts appear as rounded fluid-filled masses emanating from the anterior portion of the ventricle and extend medially into the lumen of the ventricle and appear similar to interarytenoid granulomata. They are superior to the glottal level at or near the anterior commissure. They interfere with phonation or airway depending on their size. Lateral saccular cysts expand within the paraglottic space and appear similar to internal laryngoceles as a submucosal fullness in the ventricular fold.

Although the etiology of saccular masses is unclear, they result from abnormal dilation of the saccule and protruding into the laryngeal lumen. Anterior saccular cysts, a fluid-filled mass arising from the saccule and protruding into the laryngeal lumen, can be asymptomatic. The diagnosis is most commonly made by physical examination including transnasal or transoral laryngeal imaging and neck examination. In the case of anterior saccular cysts, a mass can be seen emanating from the vestibule to the laryngeal lumen while lateral saccular cysts and laryngoceles present as a submucosal mass in the false vocal fold. External and combined laryngoceles can present as a neck mass that enlarges with valsalva. Both laryngoceles and saccular cysts can become acutely infected to form a laryngopyocele or an infected saccular cyst. Superinfection can lead to rapid expansion and acute presentation with worsening symptoms, fever, and occasionally airway obstruction.

High-resolution computerized tomography (CT with 1 to 2.5 mm imaging sections) is a useful adjunctive tool diagnostically (Figure 6). The presence of air within the lesion differentiates laryngoceles from saccular cysts. The location and extent of the lesion can be accurately assessed with CT.

Treatment Principles

Although controversy exists in the literature as to the surgical management of laryngoceles and saccular cysts, most authors agree that surgery is the definitive management. Endoscopic treatment of these lesions involves either complete resection versus marsupialization. Complete resection via either an open or closed approach is the preferred methodology to prevent recurrence. Microsurgical or CO2 laser-assisted endoscopic resection has shown to be curative for both laryngoceles and saccular cysts.41,42 Open surgical management is necessary for external and large-combined laryngoceles or lateral saccular cysts that extend through the thyrohyoid membrane. Historically, it was felt that laryngofissure was necessary to remove these lesions. Internal laryngoceles and saccular cysts can be removed endoscopically with advanced instrumentation, visualization, and surgical technique. Combined laryngoceles can be removed through an external approach without performing laryngofissure. The lesion can be dissected through the often widened thyrohyoid membrane to their base and ligated without disrupting the thyroid cartilage.42,43

Contact Granulomas

Etiology

Contact granulomas are benign lesions of the posterior glottis and vocal process. Synonyms are intubation granulomas, contact ulceration, and vocal process granulomas. These lesions can be thought of as a chronic nonhealing wound. They can be attributed to precipitating, for example, mechanical causes, and exacerbating factors, for example, laryngopharyngeal reflux (LPR) or vocal trauma. Mechanical causes include vocal trauma, for example, vocal hyperfunction and chronic chough, and nonvocal laryngeal trauma, for example, intubation injury.44 Once an injury occurs to the thin mucosa and perichondrium overlaying the cartilaginous portion of the glottis, ongoing trauma or irritation, for example, LPR, exacerbates the wound and prevents complete wound healing. An exuberant tissue response occurs, and a mature mass of acute and chronic inflammatory tissue develops.

Large tube size, intralaryngeal cuff placement, and blind traumatic intubation, and injury from movement of the larynx against the endotracheal tube have been implicated in the development of postintubation contact granulomas.45 Although...
the length of intubation increases the likelihood of developing granuloma, patients incubated for periods as brief as 1 hour are found to have epithelial damage to the posterior glottis. Infectious processes such as viral and bacterial upper respiratory infections can result in edematous and infected laryngeal mucosa, that is, further traumatized by accelerated laryngeal closure from reflex coughing and swallowing.

LPR is the most common cofactor exacerbating posterior laryngeal trauma and preventing wound healing. Patients with LPR are also likely to develop vocally abusive behaviors such as chronic cough and throat clearing. In addition to LPR, speaking with excessive vocal hyperfunction is a common cofactor in development and persistence of laryngeal contact granulomas.

Objective assessments of patients with vocal hyperfunction and contact granulomas identified abnormally high vocal cord closure velocities and collision forces when compared to controls.

**Diagnostic Principles**

Patients with contact granulomas commonly present with globus sensation, throat discomfort, odynophagia, and dysphonia. Dysphonia is often mild but is described by the patient as “huskiness.” Phonation requires increased effort, and patients complain of vocal fatigue. Globus sensation and throat pain can be localized to the greater horn of the thyroid cartilage, often on the involved side. Pain can also radiate to the ipsilateral ear. Airway obstruction with stridor is a less common presenting symptom.

A thorough history should include questions detailing circumstance surrounding the onset of symptoms, for example, intubation, upper airway infection, coughing, changing vocal demands. Investigation regarding caffeine use, alcohol use, poor eating habits, and other contributing factors to LPR is warranted. Palpation of the thyrohyoid region can often elicit discomfort. Endoscopic examination of the larynx frequently reveals a depressed ulcerated area or a bilobed heaped up lesion on the vocal process of the arytenoid cartilage (Figure 7). The bilobed lesion often articulates with the contralateral noninvolved vocal process in a “cup and saucer” fashion. The granuloma may appear sessile or pedunculated.

**Treatment Principles**

Classically appearing lesions with an appropriate history do not require biopsy for diagnosis. Patients with lesions that present in an atypical location or with an appearance worrisome for malignancy should undergo biopsy for diagnosis, particularly if the patient has risk factors for carcinoma. It should be emphasized, however, that surgery is not the first-line treatment for these lesions. The treatment for laryngeal granuloma is directed at the cause. An antireflux regimen should be started on an empiric basis even for asymptomatic patients. Use of proton pump inhibitors in addition to diet and lifestyle modification for LPR has shown efficacy as a single modal-

![Figure 7 Contact granulomas. Bilateral, right larger than left, postintubation granulomas at the vocal processes.](image)

**Etiology**

Sulcus vocalis and vocal-fold scarring present similarly. Typical complaints are of dysphonia characterized by hoarseness, breathy voice quality, and vocal fatigue. Endoscopic findings for these two entities are also similar and include an asymmetric spindle-shaped glottic closure pattern, medial furrows or troughs at the glottic margin, and supraglottic hyperfunction. High-resolution videostroboscopic imaging with careful evaluation is most often necessary to identify these often subtle lesions. This examination will show disruption of mucosal wave with focal dynamic segments at the site of the lesion.

**Treatment Principles**

Treatment for sulcus vocalis and vocal-fold scarring should be directed at improving glottal efficiency and voice quality. It is essential to maximize the chance for healing by removing confounding aggravating factors. Strict control of laryngopharyngeal reflux may help to improve the overall laryngeal environment to assist in healing. Voice therapy should be instituted early to encourage optimum phonatory efficiency and cessation of maladaptive behaviors. Patients should be encouraged to avoid smoking and other instigating irritants. Surgery may be considered when patients have failed maximal medical management. Surgical techniques include medialization thyroplasty, injection thyroplasty, local corticosteroid injection, fat or fascia implantation, and mucosal elevation and redraping. The wide variety of described surgical options highlights the lack of an optimum treatment for this difficult problem.

**REINKE EDema**

**Etiology**

Reinke edema, also known as polypoid degeneration of the true vocal fold or “smokers polyps,” occurs most commonly in women. Women present complaining of a deep voice and are often mistaken to be a man on the telephone. Patients are often heavy cigarette smokers who have vocally active lifestyles. Controversy exists regarding the role of hypothyroidism in the development of Reinke edema. LPR has been proposed as an etiologic cofactor. Large lesions can lead to stridor and airway obstruction.
**Diagnostic Principles**

Diagnosis is confirmed with endoscopy, which shows severely edematous, rounded, and yellow vocal folds (Figure 8). Videostroboscopy reveals vocal folds with increased mucosal wave amplitude, lowered fundamental frequency, and vibratory aperiodicity. Inspiratory phonation is a useful technique to draw the polyoid vocal folds into the lumen of the airway revealing the true size of the lesions. A assessment of airway obstruction and degree of vocal incapacity helps direct treatment. Testing for hypothyroidism is warranted. The polyoid degeneration of the vocal folds appears histologically as the formation of excess lamina propria.

**Treatment Principles**

Smoking cessation and management of hypothyroidism, if present, are the first step in the treatment of Reinke edema. With smoking cessation alone, patients with mild edema may have some improvement over time, supporting this as first line treatment. Treatment for LPR, including lifestyle modification and pharmacotherapy, may be important in preventing disease progression as well. Surgical intervention should be reserved for patients who have airway obstruction or have failed conservative therapy. Patients wishing to undergo elective treatment for voice improvement should be counseled specifically about the risk of recurrence with ongoing smoking, vocal-fold scarring, vocal deterioration, and failure to improve the voice.

Surgical intervention follows the careful microsurgical principles described above for photodermatosis. Historically, surgical aspiration of these lesions was reported. However, the consistency of the polyoid tissue is similar to that of a grape, and subepithelial excision of redundant SLP with preservation of the vocal-fold cover for redraping is indicated. Again, vocal-fold stripping and removal of all functional SLP (overexcision) is to be avoided. Controversy exists regarding the role of staged procedures in treatment of bilateral disease to avoid the risk of a web and bilateral scarring. Reported surgical techniques include cold excision, CO2 laser excision, microdebridement, and hemoglobin-specific laser therapy (pulsed dye, pulsed KTP lasers).-Regardless of tool used, attention to careful microsurgical principles and avoiding excessive excision are likely the most important factors in successful surgery.

**SUMMARY**

Benign laryngeal lesions are interesting and diverse forms of laryngeal pathology. Patients often report hoarseness as the common presenting symptom, and occasionally, airway obstruction or dysphoria. Careful history taking, physical examination, and thorough transnasal or transoral laryngeal endoscopy usually reveal the diagnosis. Prudent medical and surgical treatment often restores laryngeal function.

Laryngopharyngeal Reflux and Laryngeal Infections and Manifestations of Systemic Diseases

Kenneth W. Altman, MD, PhD
Jamie A. Koufman, MD

Inflammatory conditions in the larynx account for the majority of causes of laryngeal symptoms in patients presenting to the otolaryngologist, particularly because of the wide spectrum of diseases that result in inflammation. The term inflammation implies a local response to tissue injury, characterized by capillary dilation and leukocyte infiltration. Consequently, the typical symptoms include hoarseness, discomfort, and pain, while typical laryngeal signs include swelling and redness. The broad differential diagnosis of the causes of laryngitis is shown in Table 1, and includes predominantly laryngopharyngeal reflux, infections, autoimmune, and systemic disease. While each of these areas can be exhaustive in its depth and signs of laryngeal inflammation may be nonspecific, it is incumbent on the clinician to determine the root causes of the inflammation to affect successful treatment.

In adults, the most common cause of laryngitis is chronic laryngopharyngeal reflux (LPR), whereas in infants and children the most common cause is acute infection. Infectious conditions in the larynx may be subdivided into (1) pediatric versus adult patients, (2) viral, bacterial, fungal, and parasitic, (3) immunocompetent versus immunocompromised hosts, and (4) nongranulomatous versus granulomatous. Similarly autoimmune and systemic diseases affecting the larynx may manifest as granulomatous and nongranulomatous. These overlapping categories make the patient with laryngeal inflammation particularly challenging.

To add to this complexity, laryngeal inflammatory disorders are unusual in that often more than one causative factor or condition can be identified. For example, tobacco smoking results in inflammation that can progress to Reinke edema but also increases the likelihood of LPR which compounds the edema; both conditions are risk factors for the development of laryngeal carcinoma. Another example is the patient with autoimmune disease who may already be immune-suppressed or require immunosuppressive therapy; such a patient is more susceptible to typical and atypical infections. Systemic disease is also associated with exacerbation of LPR. These examples pay tribute to the multifactorial nature of laryngeal disorders. As more has been learned about the larynx, environmental influences, and the effects of systemic disorders on the larynx, imprecise diagnostic terms, such as nonspecific laryngitis, have appropriately begun to disappear from the otolaryngologic literature.

LARYNGOPHARYNGEAL REFLUX

LPR and gastroesophageal reflux disease (GERD) are highly prevalent in the general population, and the impact on health systems is growing dramatically. It has been estimated that 10% of Americans have heartburn daily, 20% weekly, and an additional 30 to 60% have it occasionally. Furthermore, 10 to 50% of patients with laryngeal complaints have a GER-related underlying cause. There has also been striking growth in disease or public/physician recognition, as the number of United States ambulatory care visits to all physicians for GERD increased from a rate of 1.7/100 in 1990 to 4.7/100 in 2001.

The term reflux literally means back flow. Reflux of stomach contents into the esophagus is common, and many patients with GERD have symptoms such as heartburn and regurgitation related to inflammation of the esophagus by acid and digestive enzymes. When refluxed material escapes the esophagus and enters the pharynx and larynx, the event is termed LPR. Although the terms gastroesophageal reflux and laryngopharyngeal reflux are often used interchangeably, the latter is more specific. Laryngopharyngeal
Reflux is the preferred term for use in otolaryngology because the patterns, mechanisms, and manifestations of LPR differ from classic GERD. The symptoms and laryngeal conditions of the patient with LPR are summarized in Table 2. Laryngopharyngeal reflux is also ubiquitous and pernicious in pediatric otolaryngology patients. The diagnosis may be particularly difficult to make because infants and children almost never complain of heartburn or other reflux symptoms. Physiologic barriers against the development of reflux and its adverse effects include the lower esophageal sphincter, esophageal peristalsis, the presence of saliva that buffers the refluxed contents, and the mucus covering of the stomach—esophagus—larynx—pharynx, and the upper esophageal sphincter. A wide spectrum of diseases and medications may affect these physiologic barriers to GERD and LPR.  

The differences between the patient with typical GERD and the patient with LPR are as summarized in Table 3. Both have been associated with a wide spectrum of respiratory tract disease including chronic laryngitis, hoarseness, laryngeal carcinoma, globus sensation, cough, and paradoxical vocal fold motion, laryngeal and subglottic stenosis, laryngomalacia, sudden infant death syndrome, sleep disturbance, recurrent laryngospasm, cricoarytenoid joint fixation, chronic rhinosinusitis, and asthma, among others. The nine-item reflux symptom index (RSI) has been developed to quantify patient symptoms of LPR and evaluate treatment efficacy (Table 4). This outcome instrument has displayed excellent reproducibility and criterion-based validity.

### Laryngeal Findings in Laryngopharyngeal Reflux

The impact of reflux on the larynx is multifocal and includes both pathophysiologic and maladaptive behavioral changes. The direct effect of the acidic refluxate causes an immediate inflammatory response. Reflux contents of the stomach also includes pepsin, which is a proteolytic enzyme (digests protein) that is activated in acidic environments. As a result, there is autodigestion of the laryngeal mucosa with the effects of pepsin considered to be even more injurious than the acid. Pepsin likely persists on the mucosa with the potential for reactivation when it is exposed to alkaline conditions (e.g., mucus, saliva). Reflux also causes an immediate inflammatory response. Reflux contents of the stomach also includes pepsin, which is a proteolytic enzyme that is activated in acidic environments. As a result, there is autodigestion of the laryngeal mucosa with the effects of pepsin considered to be even more injurious than the acid. Pepsin likely persists on the mucosa with the potential for reactivation when it is exposed to subsequent episodes of reflux.  

Physical findings of LPR can range from mild, isolated edema, and/or erythema of the area of the arytenoid cartilages to diffuse laryngeal edema and hyperemia with granuloma formation and airway obstruction. The eight-item reflux finding score (RFS) has been developed to document the severity of the clinical findings of LPR (Table 5). Use of the RFS not only helps physicians identify subtle findings of reflux, it also assists in evaluating the severity of laryngeal tissue injury, as well as documenting treatment efficacy. The physical findings of LPR include edema, erythema, hypertrophy, formation of granuloma and granululation tissue, and thick mucus (Figure 1). Prominent are pseudosulcus vocalis and ventricular obliteration.

Pseudosulcus vocalis refers to a pattern of subglottic edema that extends from the anterior commissure to the posterior part of the larynx; it appears like a groove or sulcus. It can easily be differentiated from a true sulcus (sulcus verteguretum), which is the adherence of the vocal fold epithelium to the vocal ligament secondary to the absence of the superficial layer of lamina propria. True sulcus is related to scarring of the vocal fold(s) in the phonatory striking zone. Whereas true sulcus stops at the vocal process and is in the midportion of the striking zone, pseudosulcus vocalis extends all the way to the back of the larynx.

Ventricular obliteration is a frequent finding that may be identified in up to 80% of patients with LPR. Swelling of the true and false vocal folds causes this space to become obliterated and thus poorly visualized. With partial ventricular obliteration, the space is reduced, and the false vocal fold edge is indistinct. With complete ventricular obliteration, the true and false folds appear to touch, and there is no true ventricular space.

Laryngeal erythema or hyperemia is a non-specific finding that is dependent on the available endoscopic equipment. Subtle changes
in erythema are difficult to quantify and vary depending on the quality of the fiberscope, video monitor, and light source. True vocal fold edema is graded as mild (1 point) if only slight swelling exists and moderate (2 points) when it becomes more perceptible. Edema is graded as severe (3 points) when swelling of the cord becomes sessile. Finally, polypoid degeneration of the true vocal fold contributes 4 points to the RFS.

Diffuse laryngeal edema is judged by the size of the airway relative to the size of the larynx. It is graded as mild (1 point) to obstructing (4 points). Hypertrophy of the posterior commissure is another frequent finding of LPR. It is graded as mild (1 point) when there is a mustache-like appearance of the posterior commissure mucosa and moderate (2 points) when the posterior commissure mucosa is swollen enough to create a straight line across the back of the larynx. Posterior commissure hypertrophy (PCH) is graded as severe (3 points) when there is bulging of the posterior part of the larynx into the airway and obstructing (4 points) when a significant portion of the airway is obliterated. The final two items on the RFS are granuloma or granulation tissue formation and thick endolaryngeal mucus.

Ancillary Testing

A ambulatory 24-hour double-probe (simultaneous esophageal and pharyngeal) pH monitoring (pHmetry) is the current gold standard for the diagnosis of LPR. The distal probe is placed 5 cm above the lower esophageal sphincter (LES), and the proximal probe is placed in the hypopharynx 1 cm above the upper esophageal sphincter (UES), just behind the laryngeal inlet (Figure 2). The traditional technique of probe placement is to place both the proximal and distal pH probes under manometric guidance. A manometer is inserted through the nasal cavity and advanced through the esophagus into the stomach. It is then slowly withdrawn, and the locations of the LES and UES are determined. The correct pH catheter is then chosen based on these measurements. An alternative technique involves placing the proximal probe just above the UES under direct fiberoptic visualization. The distance between the proximal and distal pH probes is fixed at 15 cm. This technique is easier, less time consuming, and less costly than using manometric guidance. Placement of the proximal probe above the UES can be performed accurately using this method. This technique, however, is unable to estimate precisely interprobe distances. Thus, the exact

location of the distal probe is uncertain, and the esophageal data are often grossly inaccurate using this technique.

pH-metry has been available for many years, and standards (normal values) have been established in many laboratories.11 In general, the most important parameter used to evaluate the presence of GERD at the distal probe is the percentage of time that the pH is less than 4. This measurement is usually recorded for time in the upright position, time in the supine position, and the total time of the study. For the upright period, the upper limit of normal is approximately 8.0%, and for the supine period, approximately 2.5%.11 The proximal pharyngeal probe is placed behind the larynx just above the criophraryngeus where it may accurately document episodes of LPR that may otherwise be missed in as many as 30 to 50% of patients (Figure 3).

Esophagitis has been demonstrated in 12% of patients with LPR, and Barrett metaplasia in an additional 7%.12 While a barium esophagram may be informative, the preferred adjunctive procedure is transnasal esophagoscopy (TNE).13 This may be conveniently performed in an unsedated patient in the office setting as a diagnostic tool in the evaluation of reflux, globus, and dysphagia.

**Treatment**

There are three levels of antireflux treatment: level I—dietary and lifestyle modification plus antacids, level II—level I plus use of a histamine H2-receptor antagonist, for example, cimetidine, ranitidine, or famotidine, and level III—antireflux surgery, for example, fundoplication, or proton pump inhibitor (PPI) therapy, for example, omeprazole, esomeprazole, lansoprazole, pantoprazole, or rabeprazole. The details of each of the three levels are listed in Table 6.

Clinical experience with LPR suggests that treatment must be individualized, with the level of treatment depending on the severity of the patient’s condition. For many patients with LPR, level I or level II treatment is appropriate initial therapy, but both forms will fail in up to 35% of patients. If level II treatment fails, level III treatment with a PPI is indicated. In patients who present with severe LPR or complications of LPR (laryngospasm, obstructing granuloma, subglottic stenosis, etc), initial treatment with twice-daily PPI is indicated.

While there is not a generally accepted “clinical pathway” for severe or complicated LPR patients, most laryngologists consider aggressive therapy with twice-daily PPI until resolution of symptoms to ensure complete resolution of tissue injury to the larynx and then scaling back to a lower maintenance dose by the time patients can make suitable lifestyle changes. Laryngeal reflux symptoms resolve sooner than the findings which may take 6 months or longer to reverse. If patients are still symptomatic at 2 months or if the laryngeal findings have not significantly improved by 6 months, repeat pH testing is indicated to ensure reasonably complete acid suppression (efficacy study). The failure of adequate acid suppression on twice-daily PPIs is significant, and a low threshold for obtaining an efficacy study on medication should be maintained. In some patients who face a lifetime of antireflux treatment or in patients who fail medical therapy, referral for a fundoplication is warranted.

**Controversies in Laryngopharyngeal Reflux**

There are many remaining controversies surrounding LPR that warrant further study of the etiology and pathophysiology, particularly as they pertain to the larynx. These controversies include variable correlation between pH probe findings in patients with substantial LPR symptoms,16 abnormal laryngeal seromucous secretions and decreased MUC5AC mucin gene expression seen in patients with chronic laryngitis associated with LPR,17 the presence of pachyderma as a nonspecific finding associated with LPR,17 some degree of a possible placebo effect with medical therapy,18 and a high rate of failed endoscopic Nissen fundoplication surgery for symptoms of LPR.19 One of the more recent and controversial discoveries pertaining to LPR is the demonstration of the H+/K+-ATPase (proton pump) in laryngeal glands.20 This proton pump has been previously noted only in the stomach as the source of hydrogen ions that form hydrochloric acid. The presence of the proton pump in the larynx may be an adaptive change to protect mucosal cells from an acidic environment, such as that from LPR and be an additional site of action of PPI pharmacotherapy. These controversies are playing an important role in our understanding of the LPR effects on the larynx, as well as appreciating the spectrum of treatment options.

**VIRAL LARYNGEAL INFECTIONS**

**Viral Laryngotracheitis (Croup)**

Viral laryngotracheitis is the most common laryngeal inflammatory disorder of childhood. Usually, this condition is self-limited, occurs in children under the age of 3 years, and has a seasonal peak, with most cases occurring during the winter. Typically, the child has a several day history of a viral upper respiratory infection with rhinitis, cough, and low-grade fever. Laryngotracheitis may be diagnosed as symptoms progress to include hoarseness, dyspnea, stridor, and a barking cough. The characteristic cough gives laryngotracheitis its common name, croup. Parainfluenza viruses (types 1, 2, and 3) account for more than half of croup cases. Other viruses frequently implicated in the disorder include rhinovirus, respiratory syncytial virus, and adenovirus. Less common causes of laryngotracheitis are influenza, measles, mumps, pertussis, and chickenpox.21

When airway obstruction is caused by laryngotracheitis, the stridor is characteristically

**Figure 3** Example of an abnormal double-probe pH study. The blue tracing is the esophageal pH, and the red tracing is the pharyngeal pH. A combined esophageal and pharyngeal reflux event (pH <4) is demonstrated at 9:26. An isolated esophageal reflux event is demonstrated at 9:28.
inspiratory or biphasic. Although the diagnosis of laryngotracheitis is generally based on the history, examination of the larynx shows erythematous and edematous mucosa with normal vocal fold mobility. Radiographs reveal a narrowing of the subglottic lumen, the “steeple sign,” and may be used to differentiate this condition from supraglottitis. Airway obstruction from inflammatory laryngeal edema is more common in children than in adults owing to the small size of the pediatric larynx. Equivalent amounts of mucosal swelling may result in critical narrowing and obstruction in a child, while causing only minimal symptoms in an adult. Table 7 demonstrates the more severe effect of glottic and subglottic inflammation in the pediatric population, showing the effects of 1 mm of edema on the cross-sectional (subglottic) area of a small neonate, an average child, and an adult male.

The need for inpatient hospitalization depends on the degree of airway obstruction. Treatment is aimed at decreasing laryngeal edema and preventing stasis and crusting of secretions within the airway. Therapy usually includes hydration, humidification of inspired air, and treatments with nebulized racemic epinephrine. Antipyretics, decongestants, and parenteral corticosteroids are often empirically administered to decrease airway inflammation. Artificial airway support, that is, intubation, is necessary in a relatively small proportion of patients with laryngotracheitis. When needed, however, intubation should be carried out by experienced personnel, preferably in the operating room, where maximum airway control can be achieved.

Secondary bacterial infection of the airway (membranous croup) may subsequently occur and is more serious and usually suspected when the patient experiences high temperature spikes and exudative, purulent drainage. The microorganisms most commonly involved are Haemophilus influenzae, Staphylococcus aureus, Streptococcus pneumoniae, Moraxella catarrhalis, and hemolytic streptococci. A nontoxic therapy is then indicated and is directed at the causative microorganisms.

Pediatric viral laryngotracheitis should be distinguished from spasmodic croup, or “false croup,” which is a noninfectious form of laryngeal inflammation associated with a mild, chronic intermittent, croup-like pattern. Spasmodic croup generally affects children 1 to 4 years of age and the afebrile child generally awakes at night with a barking cough, stridor, and mild dyspnea of sudden onset. Nocturnal attacks may occur as isolated events or recur over 2 to 3 nights, but generally the child is asymptomatic during the day and the episode subsides spontaneously. Although the cause of spasmodic croup remains uncertain, evidence suggests that extraesophageal reflux may frequently be the cause, so appropriate testing with 24-hour pH monitoring and anti-reflux therapy are often indicated.

A dult infectious croup is uncommon; when it does occur, it is quite similar to the laryngotracheitis seen in children. The viral prodrome lasts 1 to 7 days, followed by the development of a barking cough and sometimes inspiratory stridor. Throat cultures are usually negative. It has been reported that a relatively large proportion of adults with this syndrome require airway intervention.21

Viral Laryngitis

A cute viral laryngitis in adults is common and is generally less serious than in children because of the larger adult airway. Influenza and parainfluenza viruses, rhinoviruses, and adenoviruses are the most common causative agents although many other viruses have been implicated. Adult patients with viral laryngitis do not usually seek medical attention unless they are professional voice users, in which case, the laryngitis may be of great significance to the patient’s ability to earn a living. Such patients present with symptoms of a generalized viral syndrome (low-grade fever, malaise, rhinitis) and hoarseness with voice breaks, episodic aphasis, and a lowering of pitch.23

Characteristically, the laryngeal mucosa is diffusely erythematous and edematous, especially over the true vocal folds. While newer antiviral medications may have some utility in reducing the duration and severity when administered in the first 24 hours of clinical infection, the disease is self-limited and treatment is usually centered on supportive care. In the professional vocalist, corticosteroids are sometimes used to reduce the vocal fold edema, particularly during the recovery phase. However, the physician’s administration of such anti-inflammatory medications does not imply that the vocalist with laryngitis can or should perform.

Herpes Simplex Virus

Herpes simplex infection is ubiquitous, may affect any age group, and, uncommonly, may infect the larynx. Most cases of herpetic laryngitis have been reported in young or debilitated patients. At the time of delivery, a neonate passing through the birth canal may contract genital herpes from a mother with active disease. Subsequent herpes infection in the infant may involve the upper airway and, if the larynx is involved, may cause acute airway obstruction. A dult laryngeal herpes is most commonly seen in the immunocompromised patient, although herpetic epiglottitis causing airway obstruction in otherwise healthy adults has been reported.24

Herpes infection should be suspected whenever a patient presents with a painful vesicular mucosal eruption. After the vesicles rupture, ulceration and tissue necrosis may occur, and the surrounding inflammatory response may be intense. The diagnosis of a primary herpetic infection may be made by serologic testing; however, swab, culture, and polymerase chain reaction detection of viral deoxyribonucleic acid (DNA) are the most reliable diagnostic tests. Symptomatic treatment depends on the site of involvement: topical or systemic acyclovir or another specific antiviral medication may hasten recovery.

Human Papillomavirus

Human papillomavirus (HPV) results in epithelial changes and neoplastic growth in the upper aerodigestive tract; but, unlike most other viral infections, it does not present as an acute infection typified by a self-limited clinical course. It also may result in genital condyloma accuminatum. The predominant strains of HPV affecting the larynx are types 6 and 11, while more virulent types 16 and 18 have been implicated in higher risk of malignant degeneration.25 Papillomatosis has also been implicated in immunocompromised and autoimmune disorders. Typical appearance of the papillomavirus lesion includes vascular ingrowth (stippling) and a cauliflower-like exophytic mass. This infection results in a neoplastic disease and is discussed in Chapter 75, “Benign Laryngeal Lesions.”

Bacterial Laryngeal Infections

Bacterial Supraglottitis (Epiglottitis)

A cute supraglottitis is a life-threatening infection that is traditionally more common in children than adults. Since childhood immunization against type B H. influenzae has become commonplace, the disease is significantly less prevalent; and epidemiologic data suggest that nontype B H. influenzae is more frequent among vaccinated children.26 Other microorganisms causing supraglottitis include Streptococcus pyogenes, S. pneumoniae, and S. aureus. The infection is

| Table 7 Effect of 1 mm of Edema on the Cross-Sectional Area of the Subglottic Larynx in the Neonate, Child, and Adult (Area = πr²) |
|-----------------|----------|----------|---|
|                  | Neonate  | Child    | Adult  |
| Subglottic diameter (mm) | 4        | 8        | 14     |
| Subglottic radius (mm)     | 2        | 4        | 7      |
| Subglottic area (mm²)       | 12       | 48       | 147    |
| Effect of 1 mm of edema    | 2        | 6        | 12     |
| Subglottic diameter (mm)   | 1        | 3        | 6      |
| Subglottic area (mm²)       | 3        | 27       | 108    |
| Percent reduction of airway area | 75   | 44       | 27     |

*For the sake of simplicity, for these calculations π = 3.
a true medical emergency. Children aged 2 to 4 years are the most frequently affected group, and cases are more frequent in the winter and spring months. The illness begins rapidly over 2 to 6 hours with the onset of fever, sore throat, and inspiratory stridor. The voice tends to be muffled, and there is no barking cough, as in croup. As the supraglottic structures become more edematous, airway obstruction develops.

The child is generally ill appearing, stridulous, sitting upright, and drooling because swallowing is painful. The diagnosis is usually based purely on the history and clinical findings. Examination of the epiglottis (in the emergency room) may precipitate airway obstruction and thus is not recommended. Lateral soft tissue radiographs may reveal the classic “thumb sign” of the edematous epiglottis with a dilated hypopharynx. Occasionally, the epiglottis itself is not enlarged, but the supraglottic region still appears hazy and indistinct owing to edema of other supraglottic structures. In severe cases, treatment should not be delayed to obtain radiographs.

The child should be transported to the operating room by the parents, an otolaryngologist, and an anesthesiologist to establish the diagnosis and secure an airway. Direct laryngoscopy usually will show the epiglottis to be swollen and cherry red, as are the aryepiglottic folds and the false vocal folds. The true vocal folds and subglottis typically appear to be normal or to be only minimally involved.

Treatment is directed at airway maintenance and then toward providing antimicrobial and supportive care. Drawing blood, starting intravenous lines, obtaining a rectal temperature, or otherwise disturbing the patient should be postponed until the airway is secured. In institutions without a highly skilled pediatric intensive care staff, a tracheostomy may be preferable to endotracheal intubation. Cultures of the epiglottis and blood are obtained after the airway is secured. Antibacterial therapy is initiated against H. influenzae and group A streptococcus, and extubation is usually possible after 48 to 72 hours, at which time the edema has subsided sufficiently to allow an air leak around the endotracheal tube. Transnasal fiberoptic laryngoscopy is the most reliable and most commonly employed technique to ensure resolution of the edema before extubation. Differentiating acute epiglottitis from laryngotracheitis is not always easy, but it is of paramount importance. Some of the differentiating signs and symptoms are shown in Table 8.

In adults, supraglottitis is manifest by fever, sore throat, a muffled voice, dysphagia, and odynophagia. The onset of symptoms prior to presentation is typically longer than that seen in children (usually more than 24 hours). The diagnosis of supraglottitis is made by observing the swollen, bright-red epiglottis and/or supraglottic structures with fiberoptic laryngoscopy or a swollen epiglottis and dilated hypopharynx on a lateral neck radiograph.

In adults, the infectious cause is more likely group A streptococcus. The clinical course appears less severe, with less seasonal variation and airway compromise. Although one must never be complacent with management of the airway, conservative airway management in an intensive care setting is often successful, and tracheostomy is rarely required. Conservative measures include oxygenation, humidification, hydration, corticosteroids, and intravenous antibiotics. Bacterial supraglottitis should be distinguished from bacterial laryngeal seeding secondary to purulent rhinosinusitis (“rhinogenic laryngitis”) or tracheobronchitis, as the latter are often far less severe than supraglottitis and rarely result in airway compromise.

In adults, there appear to be two relatively useful clinical predictors of the need to establish an airway. Patients who present to the emergency department less than 8 hours after the onset of a sore throat and patients who are drooling at presentation (in preference to swallowing because of severe odynophagia) almost always require airway intervention.

**Laryngeal Abscess**

Laryngeal abscess is a complication of perichondritis and a recognized sequela of bacterial laryngeal infection. Often the adult patient who develops a laryngeal abscess has a preexisting, predisposing laryngeal condition, such as prior irradiation for cancer. In the preantibiotic era, typhoid fever was a frequent cause and was usually fatal. Other less frequently associated infections include measles, scarlet fever, erysipelas, gonorrhea, syphilis, tuberculosis, and diphtheria. Laryngeal abscess may also be a complication of prolonged nasogastric or endotracheal intubation.

The symptoms of laryngeal abscess are similar to those of supraglottitis. Localizing tenderness to palpation over the laryngeal framework is its hallmark. Fluuctose in the anterior neck, although uncommon, denotes necrosis of the thyroid cartilage. The diagnosis of laryngeal abscess may be made by computed tomographic scanning of the larynx and by fiberoptic or direct laryngoscopy.

When abscess is suspected and the patient’s airway is marginal, a tracheostomy should be performed under local anesthesia prior to direct laryngoscopy. If the airway is not compromised, direct laryngoscopy, with laser-assisted incision and drainage of the abscess, may suffice as initial treatment. Granular mucosa should be removed, and an attempt should be made to determine if necrotic cartilage is exposed within the endolarynx. Infection of the laryngeal framework can lead to severe laryngeal stenosis.

Gram stain and bacteriologic cultures of the abscess contents or necrotic debris should be obtained routinely, and the results should influence the choice of antibiotic. When necrotic cartilage is present, the combination of surgical debridement, prolonged parenteral antibiotic therapy, and hyperbaric oxygen therapy may enhance recovery and preserve laryngeal function. When all other alternatives have failed, laryngectomy may be considered.

**Diphtheria**

Worldwide, diphtheria is an uncommon laryngeal infection, although a report from India suggests that outbreaks still occur. Laryngeal diphtheria is caused by Corynebacterium diphtheriae and generally affects children over the age of 5 years. A febrile illness of slow onset associated with sore throat and hoarseness is then followed by an inflammatory response in the mucous membranes, which results in a thick, grayish-green, plaque-like membranous exudate over the tonsils, pharynx, and laryngeal structures. This pseudomembrane may result in airway compromise, requiring establishment of a safe airway via a tracheostomy. A additional treatment consists of administering diphtheria antitoxin and penicillin or erythromycin to eradicate the microorganisms. Mortality results largely from the neuropathies that develop secondary to the diphtheria toxin. Even in the patient immunized against diphtheria, the disease may still occur but will tend to be mild.

**Neisseria Gonorrhoea**

Gonorrhea is a sexually transmitted genital and sometimes oropharyngeal infection caused by the bacterium Neisseria gonorrhoeae. The genital infection may be asymptomatic, so carriers can unknowingly infect their sexual partners. Pharyngeal gonorrhea is transmitted by orogenital contact and is manifested as a diffuse and severe exudative pharyngitis that may directly or indirectly involve the larynx. The infection may produce a pseudomembranous inflammation, which may be confused with diphtheria or streptococcal pharyngitis. Diagnosis is made by culture and identification of the N. gonorrhoeae microorganism from swabs of the pharynx. Today, most cases

of laryngopharyngeal gonorrhea are treated with a single intramuscular dose of ceftriaxone or a course of oral cefixime.

**Tularemia**

Tularemia, also called “rabbit fever” and “deer fly fever,” is caused by the bacterium Francisella tularensis. It is found only in the northern hemisphere (Europe, Asia, and North America). Most cases occur from contact with rabbits or squirrels, but many other wild and domesticated animals have been reported to carry the disease. Transmission to humans can also occur by a bite from a tick or a deer fly, which are the intermediate hosts and insect vectors.

In humans, the most common portal of entry is through the skin or mucous membranes. Headache, myalgia, and malaise are common symptoms. Oropharyngeal tularemia, which occurs in approximately 1% of cases, produces an intense exudative pharyngitis associated with lymphadenopathy. Diagnosis is made by serologic tests since the microorganisms are difficult to identify on culture or histologic examination. Treatment is with streptomycin or gentamicin for 7 to 10 days.

**Glanders**

At one time in history, glanders was “the plague of horses,” and, secondarily, it affected humans. Today, glanders is rare around the world but still occurs in Asia, Africa, and South America. The disease is caused by infection through the skin or mucous membranes. Headache, myalgia, and malaise are common symptoms. Oropharyngeal glanders, which occurs in approximately 1% of cases, produces an intense exudative pharyngitis associated with lymphadenopathy. Diagnosis is made by serologic tests since the microorganisms are difficult to identify on culture or histologic examination. Treatment is with streptomycin or gentamicin for 7 to 10 days.

**Tuberculosis**

In 1900, laryngeal tuberculosis was very common, occurring in approximately half of patients with advanced pulmonary disease. With the discovery of effective antituberculous drugs, the incidence of both pulmonary and laryngeal tuberculosis rapidly declined. Nevertheless, tuberculous laryngitis remains one of the most common granulomatous diseases of the larynx, and, today, it is frequently unassociated with advanced active pulmonary disease. Because persons with laryngeal tuberculosis often have no simultaneous or previous pulmonary involvement, the clinical presentation may often be similar to that of a neoplastic process. A biopsy is necessary to obtain an accurate diagnosis. Some of the distinguishing features of the most frequent laryngeal granulomatous conditions are shown in Table 9.

<tbody>
<tr>
<td>Tuberculosis</td>
<td>Posterior third of larynx involved</td>
</tr>
<tr>
<td>Leprosy (Hansen Disease)</td>
<td>Leprosy is caused by infection with the bacillus Mycobacterium leprae. The disease usually affects the skin and peripheral nerves but may affect other organ systems. Cutaneous nodules may become disfiguring and will eventually cause peripheral neural damage and muscular weakness. In 2000, 738,284 cases of leprosy were identified worldwide. In 1999, 108 cases were reported in the United States. Over one-third of the global cases are limited to India. The larynx is involved in approximately one-half of patients with leprosy, and it most consistently involves the epiglottis. As the disease progresses, inflammation of the larynx may develop, and later destruction of the cartilaginous framework may occur, as well as lepromatous nerve involvement, which may cause laryngeal paralysis and oedynophagia. Direct laryngoscopy typically reveals a nodular, edematous supraglottis with ulceration, and biopsy reveals a chronic inflammatory cell infiltrate with foamy leprous cells that contain the bacillus M. leprae (Hansen bacillus). Nasal smears for the intracellular microorganisms may be diagnostic. Treatment consists of the long-term use of dapsone. Tracheostomy may be required if laryngeal stenosis develops.</td>
</tr>
<tr>
<td>Scleroma</td>
<td>The disease has three distinct stages: (1) the catarhal stage, characterized by persistent purulent rhinorrhea, with nasal crusting and obstruction; (2) the granulomatous stage, characterized by small, painless granulomatous nodules within the upper respiratory tract, including the larynx; and (3) the sclerotic stage, in which the glottis and subglottis are usually involved, and hoarseness and respiratory obstruction may develop. The progression through these three stages usually takes many years. The disease is caused by infection by the bacterium Mycobacterium leprae. Initial involvement of the cervical or mandibular region leads first to paralaryngeal and then to laryngeal disease. Pain is the most common initial manifestation, followed by hoarseness, cough, and, eventually, airway obstruction. The larynx appears diffusely erythematous and swollen with draining sinuses; its consistency is firm and woody. Diagnosis is made by identifying the typical &quot;sulfur granules&quot; in biopsy material and by culturing the microorganism. Long-term therapy with penicillin or tetracycline is effective. Stenosis and laryngeal fixation secondary to deep ulcerations and chondritis may develop if the disease is left untreated. Laryngeal...</td>

dilatation, arytenoideectomy, or tracheostomy may be required.

Nocardia species of the Actinomyces family are soil saprophytes that are widely distributed throughout the world. Like other Actinomyces, Nocardia may infect humans by inhalation or through a break in the skin. Nocardiosis is characterized by diffuse microabscesses that, on histologic examination, show a neutrophilic predominance; sulfur granules are atypical. Aerodigestive tract involvement is common. The diagnosis is made by culture and isolation of the Nocardia microorganism, and treatment is with systemic sulfisoxazole.

**Syphilis**

Syphilis is a sexually transmitted spirochetal infection caused by Treponema pallidum. Syphilitic chancres do not usually involve the larynx, and, most commonly, the larynx becomes involved during the secondary and tertiary stages. However, tertiary syphilis may not develop until years after the initial infection. Diffuse erythematous papules, painless superficial ulcers, and cervical lymphadenopathy are seen during the secondary stage and generally clear without treatment within several weeks. Gumma formation during the tertiary stage can lead to laryngeal fibrosis, chondritis, and stenosis. Serologic tests for syphilis are diagnostic, and a lumbar puncture should be performed to rule out central nervous system involvement. Penicillin is still the treatment of choice. Although rare, congenital syphilitic laryngitis can occur in infants born to mothers with syphilis. This diagnosis should be considered in the differential diagnosis of neonates with laryngeal stenosis.

**Fungal Laryngeal Infections**

**Candidiasis**

Among the risk factors for development of laryngeal candidiasis (usually infection by the species Candida albicans) are the use of corticosteroids and broad-spectrum antibiotics, diabetes, burns, alcoholism, endotracheal intubation, previous (viral or bacterial) laryngeal infection, and in patients who use corticosteroid inhalers. In addition, inhaled corticosteroids in particular form often used to treat pulmonary disease are increasingly recognized to cause laryngeal inflammation, leukoplakia and predispose to laryngeal candidiasis. This form of isolated laryngeal candidiasis has a distinctive appearance: intense, diffuse laryngeal erythema with an irregular, friable, white exudate (occurring most notably on the true vocal folds). The infection is superficial, and no ulceration or necrosis is seen (Figure 4). Oral nystatin suspension is often effective. More advanced laryngeal disease is associated with biofilm formation, encasing the Candida within a polysaccharide-rich extracellular matrix, so an oral antifungal agent such as ketoconazole or flucconazole is sometimes necessary (in some cases for as long as several weeks).

Figure 4 Candidiasis. (A) Oral thrush showing white patchy plaques surrounded by erythematous mucosa. (B) Laryngeal candidiasis in patient who had been using corticosteroid inhalers.

**Histoplasmosis**

Histoplasmosis is a systemic granulomatous mycotic disease caused by Histoplasma capsulatum and may involve the larynx (Figure 5). Nodular superficial granulomas that may ulcerate and become painful involve the anterior portions of the larynx and epiglottis. Esophageal involvement may occur (Figure 6). Histologic examination shows granulation tissue composed of plasma cells, microorganism-laden macrophages, lymphocytes, and giant cells, which may be confused with the granuloma of tuberculosis. Diagnosis is made by culture and the complement fixation test. Amphotericin B is the treatment of choice.

**Blastomycosis**

North American blastomycosis is a granulomatous chronic pulmonary infection caused by the fungus Blastomyces dermatitidis. Laryngeal involvement occurs in 2 to 5% of cases, although primary laryngeal blastomycosis has been reported. The microorganism is generally found in damp areas where decaying wood is present. Its distribution in the United States and Canada is concentrated around the Great Lakes and along the Mississippi, Ohio, and St. Lawrence rivers.

Patients typically present with multiorgan systemic involvement and severe hoarseness and cough when the larynx is involved. The microorganism produces erythematous, granular, mucosal lesions in the larynx, which progress to painless abscesses and ulcerations. Histologically, caseous necrosis with abundant acute inflammatory cells and microabscesses are seen, as well as giant cells in the surrounding tissue. Pseudoepitheliomatous hyperplasia is a characteristic change seen in the epithelial layer. The fungus in yeast form may be seen in the region of the microabscesses and is periodic acid–Schiff positive. Treatment is with long-term oral itraconazole, with amphotericin B being reserved for severe or recalcitrant cases. In the absence of treatment, progressive fibrosis with vocal fold fixation develops, as do pharyngocutaneous fistulae.

Figure 5 Histoplasmosis of the larynx. Note pedunculated lesion of the left true vocal fold.
Laryngeal stenosis may develop when extensive ulceration leads to chondritis. In this instance, laryngeal dilatation, arytenoidectomy, or tracheostomy may be required to provide a safe airway.

**Coccidioidomycosis**

Coccidioidomycosis, also called "desert fever" (or "San Joaquin Valley fever" in the United States), is caused by the microorganism *Coccidioides immitis* which is found in desert soil. It is primarily a granulomatous pulmonary fungal infection that is endemic to the southwestern United States, Mexico, and central South America. Reportedly, 60% of people with this infection are asymptomatic; 40% develop a flu-like illness, and among those, 0.5% develop a systemic, disseminated, more severe form of the disease. Patients with the disseminated form may develop hoarseness, cough, and airway obstruction owing to laryngeal coccidioidomycosis.

Laryngeal disease usually develops during the acute phase of the primary infection. Laryngeal involvement can, however, develop in patients who have had granulomatous lung disease for months or years. In addition to the laryngeal findings of intense, diffuse laryngeal erythema (with or without focal ulceration), most patients with *C. immitis* have cervical lymphadenopathy. Histology reveals caseating granulomas with multinucleated giant cells and pathognomonic, double-walled endospores. The diagnosis is made by serologic testing and biopsy of affected tissue. Treatment is with amphotericin B. When death occurs, it is usually owing to meningeal involvement.

**Aspergillosis**

Aspergillosis is generally an infection of immunocompromised patients, and respiratory tract involvement is common. When the larynx is involved, patients complain of hoarseness, dysphagia, and sometimes symptoms of airway obstruction. In the immunocompromised patient, Aspergillus infection is usually necrotizing, invasive, and associated with a poor prognosis. Despite aggressive antifungal treatment with amphotericin B and attempted wide surgical excision (including laryngectomy), most such patients with this infection die of progressive disease.

**Sporotrichosis**

Sporotrichosis, an uncommon fungal infection of the skin or airway, is caused by *Sporothrix schenkii* and occurs worldwide. The causative fungus is most commonly found in sphagnum moss and wood. People who work with wood usually get the cutaneous form of sporotrichosis, whereas most cases of laryngeal sporotrichosis occur in people working with the moss.

The more common cutaneous form of sporotrichosis causes granulomas in the subcutaneous layer of the skin and in regional lymph nodes. If the mucous membranes of the upper airway are damaged or abraded for any reason, inhalation of the fungus may result in laryngopharyngeal infection. Hoarseness and cough are the most common symptoms, and the lesions appear granulomatous. Diagnosis is made by biopsy and by culturing the microorganism. Oral potassium iodide is sufficient treatment for cases with superficial involvement; deep tissue involvement requires a course of amphotericin B therapy.

**PARASITIC LARYNGEAL INFECTIONS**

**Trichinosis**

Trichinosis in humans is caused by ingesting meat contaminated with the helminthic roundworm *Trichinella spiralis*. Trichinosis is relatively common worldwide. About 30 cases occur each year in the United States. In the past, contaminated pork was the most common source of infection, but today, most cases are caused by eating feral meat, such as bear or wild boar. Humans are particularly susceptible to trichinosis infection. Soon after ingestion, the larvae penetrate the intestinal wall, where copulation and multiplication occur. The next generation of larvae enters the bloodstream and is distributed throughout the body, and finally enters and grows in skeletal muscle. The muscles of the diaphragm, eyes, tongue, chest, shoulders, and calves are often affected. Laryngeal involvement is uncommon.

In tissue, the larvae elicit an eosinophilic and lymphocytic inflammatory response. The severity of the clinical manifestations depends on the location and density of the larvae. The first symptoms occur within 2 days of ingestion. During the initial stage of infection, diarrhea, nausea, and malaise are common. During the muscle invasion stage (lasting 1 to 6 weeks), fever, weakness, skin rash, myalgia, muscle tenderness, and facial and periorbital edema are usually present. Some cases are complicated by urticaria, splinter hemorrhages, and angioedema. The primary symptom of laryngeal involvement is hoarseness. Trichinosis should be suspected by the history and eosinophilia. Diagnosis can be made by serologic testing and muscle biopsy. Treatment is with a 7-day course of thiabendazole. The disease can be prevented by cooking meat products to an internal temperature of 170°F.

**Leishmaniasis**

Leishmaniasis, although uncommon in the United States, is indigenous throughout the rest of the world. It is estimated that there are 1.5 to 2 million cases each year worldwide. The vast majority of the world’s cases occur in India, Bangladesh, Nepal, Sudan, and Brazil. The organism infects rodents and dogs, and transmission to humans is usually from an animal, although the bite of an intermediate host, the sandfly, may cause the disease as well. Although there are several clinical forms of the disease, the mucocutaneous form, caused by *Leishmania braziliensis* and *Leishmania mexicana*, is the one that most commonly involves the airway. Espondia, the form caused by *L. mexicana*, is endemic in south-central Texas.

Usually, one or more skin lesions on the lower extremity begin as sores that slowly enlarge and ulcerate over a period of months. These untreated lesions seldom heal. Months or years later, metastatic lesions appear on the lips, nose, and pharynx. Leishmaniasis involves the larynx in approximately one-third of cases.

Fever, anemia, weight loss, and hoarseness are common symptoms. As time passes, extensive soft tissue destruction may lead to grotesque facial disfigurement, as well as progression of the laryngeal disease. Examination of the larynx may reveal a localized, polypoid, inflammatory lesion or diffuse, granular, spongy mucosa. The lesions may be ulcerated, and airway obstruction may occur. These lesions are often mistaken for laryngeal cancer, tuberculosis, histoplasmosis, or blastomycosis.

Biopsy reveals a chronic granulomatous pattern, with a predominance of lymphocytic and histiocytic cells. The diagnosis can be made by identification of the parasite in biopsy specimens, but, in some cases, the parasites may be difficult to find. A specific agglutination test for leishmaniasis and the leishmaniasis skin test are diagnostic. The mucocutaneous form of leishmaniasis should be treated with antimonials for at least 30 days.

**Schistosomiasis**

Endemic in the tropics and subtropics, schistosomiasis (“bilharziasis” in Egypt) is widespread in 72 countries of the world and infects an estimated 5% of the world's population. It is the most prevalent helminthic infection in the world. There are three Schistosoma species parasitic in man: *S. mansoni*, *S. japonicum*, and *S. haematobium*. Schistosoma mansoni and *S. japonicum* inhabit the mesenteric veins; the eggs are found along the wall of the intestine and in the liver and are passed in the feces. Schistosoma haematobium invades the veins of the pelvic plexus, and the eggs are passed in the urine. Ectopic lesions occur in 18% of cases and may be found in any part of the body.

Humans contract schistosomiasis from water infested by cercariae, the microscopic infective stage. Cercariae penetrate the intact skin, and schistosomules form in the skin. After several
days, the schistosomules migrate to the lungs and portal veins, where the male and female species mate. Weeks later, depending on the species and the time of transit, eggs are deposited in the infected organs. To complete the life cycle, organisms excreted by humans must contaminate water because the snail is the intermediate host. The cercariae grow in the soft tissue of the snail, and after 1 to 2 months, they are released back into the water, where they can again enter the human body.

Schistosomiasis in the aerodigestive tract is characterized by intense inflammatory granulomas around deposits of schistosome eggs. Granulomas may be as small as a pinhead or as large as an orange. Histologically, coagulation necrosis occurs around the egg deposits, and eosinophils, plasma cells, and lymphocytes predominate in the cellular response. Patients with laryngeal schistosome granulomas present with hoarseness. The laryngeal lesion has the appearance of a pink–gray, cauliflower-like granuloma, with surrounding inflammation. The degree of surrounding fibrosis is determined by the egg density and the duration of the infection. Confirmation of the diagnosis is made by identification of parasitic ova in the urine or feces. Treatment is with antihelminthics.

Syngamiosis

Syngamus laryngeus is a unique gapeworm indigenous to Brazil, Puerto Rico, Martinique, Trinidad, British Guyana, the West Indies, and the Philippines. It invades the upper respiratory tract of cattle, water buffalo, and (rarely) humans. Transmission to humans is believed to be through consumption of contaminated vegetables. Once ingested, the adult worms migrate to the larynx and upper trachea and firmly attach themselves to those mucosal surfaces. The primary symptoms of syngamiosis are cough, a foreign body sensation in the throat, and, occasionally, hemoptysis. The diagnosis may be suspected if the patient coughs up worms in copula or if they are seen on laryngoscopy. Removal of the worms by direct laryngoscopy is the only known treatment.

Infections of the Immunocompromised Host

Immunocompromised patients, whether immunocompromised from diabetes, long-term corticosteroid therapy, chemotherapy, or AIDS, are at risk of developing opportunistic infections of the aerodigestive tract. The most commonly reported opportunistic infections that affect the larynx are shown in Table 10. Of those listed, laryngeal candidiasis, tuberculosis, and herpes infections are the most commonly encountered in patients with AIDS.

Autoimmune, Allergic, and Idiopathic Disorders

Sarcoidosis

Sarcoidosis is a slowly progressive, rarely fatal, systemic granulomatous disease of unknown cause. The disease afflicts African Americans 10 times more commonly than whites. The lungs and skin are most commonly involved, and laryngeal sarcoidosis occurs in 1 to 5% of cases (with or without lung involvement). When the skin of the nasal rim is affected, upper respiratory sarcoidosis involvement is seen in approximately 75% of cases.

Laryngeal sarcoid usually involves the supraglottic larynx and sometimes the subglottis but typically spares the true vocal folds (Figure 7). Characteristically, the entire supraglottis appears pale pink and massively edematous, sometimes obscuring visualization of the vocal folds. The turban-like appearance of the epiglottis is virtually pathognomonic. Less commonly, some laryngeal sarcoidosis patients present with a few discrete, sometimes hemorrhagic, nodules (up to 1 cm in diameter) on the epiglottis or other supraglottic structures.

Laryngeal sarcoidosis is a diagnosis of exclusion based primarily on finding noncaseating granulomas and diffuse edema with milliary nodules involving mainly the supraglottic structures and on excluding tuberculosis and fungal diseases. An elevated serum angiotensin converting enzyme (ACE) level may be found. The use of systemic and intralesional corticosteroids generally results in improvement or apparent resolution of the lesions. In severe cases, however, endoscopic dilatation and laser resection of involved supraglottic tissues, or tracheostomy, may be necessary for those patients with airway obstruction.

Wegener Granulomatosis

Wegener granulomatosis is characterized by necrotizing granuloma with vasculitis involving the upper respiratory tract, lungs, and kidneys. On presentation, its laryngeal involvement may resemble acute laryngitis, but the eventual development of granulomatous ulcers throughout the larynx may lead the clinician to suspect the diagnosis. Subglottic stenosis occurs in approximately 20% of cases and can lead to significant airway obstruction, requiring tracheotomy and surgical correction of the stenosis. Diagnosis is based on typical histologic findings of necrotizing granulomas and vasculitis. The anticytoplasmic autoantibody test (C-ANCA) is highly specific for Wegener granulomatosis but may have low sensitivity in early disease. Recommended treatment includes cyclophosphamide with corticosteroids.

Hypersensitivity Reactions

The term hypersensitivity implies an overzealous response of the immune system to an antigenic stimulus. Hypersensitivity reactions include conditions such as allergic rhinitis, contact dermatitis, and urticaria, but these conditions do not produce life-threatening, obstructive edema within the airway. Anaphylaxis, an acute and profoundly life-threatening immune-mediated allergic response, is made up of a triad of clinical manifestations: (1) flushing, pruritus, and/or urticaria; (2) airway obstruction, for example, angioedema, laryngospasm, and/or bronchospasm; and (3) circulatory collapse, for example, shock.

Angioedema

Angioedema is an acute, allergic, histamine-mediated, inflammatory reaction characterized by acute vascular dilation and capillary permeability. In susceptible patients, angioedema can be precipitated by medications, food additives and preservatives, and by blood transfusions, infections, or insect bites. In addition, the condition may be associated with a coexisting connective tissue disorder. The hereditary form of angioedema is an autosomally dominant deficiency of C1 esterase inhibitor that leads to recurrent attacks of mucocutaneous edema. An acquired form of C1 esterase deficiency has also been reported in patients with angioedema who have occult lymphoma.

Oral and laryngopharyngeal structures are frequently affected and with localized or general edema that may lead to airway obstruction, but it can also occur in other parts of the body. Diagnosis is made primarily from the history, although the offending agent may not be readily apparent. Treatment of both types of angioedema must
Chronic inflammation of the cartilage of the ears, nose, and larynx. Most patients who eventually die of the disease, most of whom have other systemic inflammatory diseases, such as systemic lupus erythematosus, and other connective tissue diseases, often have arthritis, malar rash, photosensitivity, and other manifestations of systemic lupus erythematosus. Treatment is with the anti-inflammatory medication dapsone, with systemic corticosteroids and/or immunosuppressive therapy being reserved for dapsone treatment failures. Intralesional corticosteroids are ineffective. Stenosis of the larynx and/or ear canals occurs in up to 30% of patients with rheumatoid arthritis and sometimes occurs in patients with other autoimmune diseases, such as Sjögren syndrome, systemic lupus erythematosus, and psoriatic and rheumatoid arthritis.

Relapsing Polychondritis

Relapsing polychondritis is a rare, idiopathic, generally progressive, autoimmune disease that causes inflammation of cartilage. It can mimic rheumatoid arthritis and sometimes occurs in patients with other autoimmune diseases, such as Sjögren syndrome, systemic lupus erythematosus, and psoriatic and rheumatoid arthritis.

Relapsing polychondritis occurs in all age groups, having a bell-shaped distribution and a peak incidence in the fourth decade. Although only 10% of patients present with respiratory tract involvement (larynx and trachea), more than 50% eventually develop such involvement, and 20% require tracheostomy. Of the 20 to 30% of patients who eventually die of the disease, most do so from respiratory complications.

This disease is characterized by episodes of inflammation with subsequent destruction of the cartilage of the ears, nose, and larynx. Most patients present with bilateral involvement of the ear cartilage, becoming red, swollen, and tender. With or without treatment, the condition may subside within 5 to 10 days. The next most common sites of involvement are the nose and the costal cartilages. Arthritis involving the large joints is also common. Laryngeal involvement is manifested by hoarseness, dyspnea, stridor, cough, and sometimes, pain and hemoptysis. A clinical diagnosis is confirmed by cartilage biopsy although most patients with this disorder also have autoantibodies to type II collagen.

Histologically, the normal cartilage is replaced by an eosinophilic material, and acute and chronic
infiltrates of lymphocytes and plasma cells are present. The usual basophilic appearance of the cartilage matrix is lost; lacunae are interrupted, and fibrous tissue replaces cartilage. As the disease progresses, fibrosis and chondrocnecrosis become marked.

Treatment includes corticosteroids and anti-inflammatory medications such as dapsone. Corticosteroid and immunosuppressive medications are used for patients with severe, relapsing, or rapidly progressive disease, especially when the larynx or other airway structures are involved. Tracheostomy may be necessary in the later stages of the disease.

**Sjögren Syndrome**

Sjögren syndrome is an idiopathic autoimmune disorder characterized by the clinical triad of xerostomia, that is, dry mouth, conjunctivitis sicca, that is, dry eyes, and rheumatoid arthritis. Patients with Sjögren syndrome have a relatively high incidence of developing lymphoma. There is also a “limited” form of the disease, occurring without the arthritis, called “sicca syndrome.” Although the cause (or causes) of these syndromes is unknown, both the limited and the full-blown forms have in common autoantibodies to glandular tissue in the eyes, nose, oral cavity, and laryngopharynx. In addition to the lacrimal glands and the major salivary glands, minor salivary and seromucinous glands are usually affected throughout the aerodigestive tract.

The diagnosis is made clinically using a Schirmer test to document the dryness of the eyes and by salivary gland biopsy. In the major salivary glands, the histologic picture demonstrates: (1) an intense lymphoid infiltrate, especially in periductal areas; (2) glandular atrophy; and (3) myoepithelial hyperplasia. Although the salivary glands are virtually always affected, biopsy of minor salivary gland tissue (lip biopsy) is usually sufficient to make the diagnosis. The histopathologic features seen in minor salivary glands are similar to those seen in the major salivary glands, although the myoepithelial hyperplasia is absent.

The seromucinous glands of the larynx may be involved, leading to inflammation of the larynx similar to that seen in the salivary glands. Clinically, this involvement produces edema, erythema, dryness, crusting, and, hence, chronic hoarseness. Patients with Sjögren syndrome have other manifestations of the disease.51

**Amyloidosis**

Amyloidosis is a dysproteinemia in which a characteristic, amorphous, eosinophilic substance is deposited in the tissues of various organs. Amyloidosis is classified as being either “systemic” or “localized.” The systemic types are familial, primary (with or without myeloma), and secondary (usually associated with chronic inflammatory disease). Primary amyloidosis has a 5-year survival of only 20%, with the patients dying of renal, central nervous system, or cardiac involvement.52 The “localized” type of amyloidosis is almost never fatal and is the type that most commonly involves the larynx. Most cases of laryngeal amyloidosis occur in isolation, although simultaneous involvement of the trachea and, to a lesser extent, the bronchi occurs in about one-third of those cases.

On laryngoscopy, amyloidosis appears as diffuse mucosal thickening or subepithelial nodules, localized mainly to the anterior part of the subglottis. Patients are usually asymptomatic until the deposits involve the vocal folds or critically narrow the airway. When amyloidosis is suspected, biopsy specimens should be stained with Congo red, which, when viewed with polarized light, shows a pathognomonic apple green birefringence.

Laryngeal amyloidosis usually has a benign course. Symptomatic cases are best treated by endoscopic carbon dioxide laser excision of the lesions; laryngeal dilatation and tracheostomy are rarely necessary.

**Inhalant Laryngeal Trauma and the Effects of Radiation**

It is prudent to briefly discuss the effects of inhalant laryngeal trauma, as well as the effects of radiation. These conditions are often seen in otolaryngology practice and can predispose to edema, stasis of mucus secretions, and bacterial suprainfection. When nebulized radiolabeled acidic fog is inhaled and scanned, the density of aerosol deposit in the larynx is greater than in any other site in the aerodigestive tract. The size and anatomic configuration of the larynx (having the narrowest and most convoluted lumen of the upper airway) may explain this phenomenon. Perhaps for this reason, the larynx is especially susceptible to the effects of inhaled corticosteroids for treatment of asthma, tobacco smoke, dust, and other airborne environmental contaminants. Table 1 lists some of the commonly reported substances associated with acute and chronic inhalation injuries of the larynx.

Radiation therapy for laryngeal carcinoma, as well as for tumors in other head and neck sites, may deliver significant radiation doses to normal laryngeal tissue. The initial effects produce an intense inflammatory response, characterized by increased capillary permeability, edema, neutrophilic infiltration, vascular thrombosis, and obliteration of lymphatic channels. Patients undergoing radiation treatment complain of a globus sensation, dysphagia, odynophagia, dysphonia, and odynophonia, and are more likely to have exacerbation by LPR based on laryngeal sicca. Late tissue sequelae consist of degenerative changes and fibrosis in adipose, connective, and glandular tissues and a pronounced obliterative endarteritis of small blood vessels. Both the acute and chronic changes associated with radiation also predispose to bacterial suprainfection and LPR.

**CONCLUSIONS**

Laryngeal inflammation is the common theme linking the effects of LPR, infections and autoimmune-inflammatory diseases in the larynx. While it is imperative to identify the underlying causative diseases, these conditions tend to be further complicated by suprainfection and immune susceptibility.

Trauma to the Larynx

Ricardo L. Carrau, MD
Bridget C. Hathaway, MD

BLUNT AND PENETRATING LARYNGEAL TRAUMA

A acute external trauma to the larynx is a rare occurrence because of the protection provided by the reflexive flexion of the neck along with the bony protection offered by the arch of the mandible and sternum anteriorly and the rigid cervical spine posteriorly. The reported incidence of acute laryngeal trauma is 1 per 5,000 to 137,000 emergency department visits per year in the United States, with an increased prevalence in younger populations.1,2 Although the incidence of laryngotracheal trauma is low, <1% of blunt trauma and <5% of penetrating trauma, the consequences of mistreatment are severe. With its proximity to vital vascular, neural, and skeletal structures, a laryngeal injury can be overlooked.

A high clinical suspicion is necessary in the setting of any neck trauma. Additionally, due to the increased incidence of long-term endotracheal intubation, iatrogenic laryngeal injury is becoming more common.

The larynx has multiple physiologic and mechanical functions that depend upon the integrity of the rigid and highly functional architecture of its framework.3 Its rigid apparatus consists of the hyoid bone and the major cartilages of the larynx: the thyroid, cricoid, epiglottic, and paired arytenoid cartilages. Its soft tissue architecture comprises three important folds: the arypepiglottic fold, the vestibular fold, and the true vocal fold. These three folds, in association with their muscles, form a three-tiered sphincter allowing air exchange, while preventing passage of saliva and ingested material into the lower airway. Other laryngeal functions such as vocalization, although important, are secondary to respiration and airway protection from an evolutionary standpoint. Laryngeal fractures that heal improperly can result in chronic airway stenosis and deterioration of the sphincteric and phona
tory functions of the larynx.

Historically, the surgical repair of laryngeal fractures has involved the use of stitches or wire fixation of fragments, along with autologous cartilage grafts for large defects. Internal stents have been advocated as a technique to preserve the proper size and shape of the airway when extraluminal repair cannot ensure immediate restoration of a stable laryngeal framework.4-6 Although these techniques may adequately align fracture fragments, they do not always restore the functional architecture of the larynx. The resulting asymmetry or loss of anteroposterior or lateral dimension of the larynx can lead to posttraumatic dysphonia, dysphagia, or inadequate airway. Even minimally displaced fractures cause changes in glottal resistance and sound pressure levels, resulting in phonatory alterations. Mechanical loads applied by the extralaryngeal and intralaryngeal muscles during swallowing and neck movements may bend wire fixation, causing angulation of fragments with subsequent loss of the reduction. Midline or paramedian fractures stabilized with wire fixation tend to heal in a flattened position with loss of the anteroposterior dimensions.5 Metal alloy plating techniques, commonly used for the fixation of maxillofacial fractures, have been adapted to treat fractures of the laryngeal framework. The advantages of plate fixation for maxillofacial trauma equally apply to laryngeal trauma, and include stabilization across fracture lines and restoration of the premorbid architectural framework with immediate or accelerated restoration of function.

The mechanisms of external laryngeal injury are conceptually divided into blunt and penetrating trauma. Blunt injuries are most commonly the result of motor vehicle accidents, sports and assaults and include “clotheslining,” crushing, and strangulation injuries. In the United States, the incidence of this type of injury is decreasing. This may be due to increased use of seat belts and front seat air bags. In the absence of a secured chest restraining belt, the driver is thrust forward during rapid deceleration while the neck is hyperextended. In this position, the bony protection afforded by the mandible is lost, exposing the larynx to crushing forces in an anterioposterior axis. In this situation the larynx may be compressed between a blunt object and the cervical spine.

Clothesline injuries occur when a patient encounters a fixed horizontal object, such as a line, rope, cable, or tree branch at high speed at neck level. This type of injury imparts a large amount of energy over a relatively small area, resulting in severe trauma.7,8 Many of these injuries lead to immediate death due to laryngeal crush injury or separation of the cricoid cartilage from the larynx or trachea.

Strangulation injuries result from manual compression, garroting, or by hanging. Clinical findings may initially include hoarseness or abrasions on the neck skin. Later, within 12 to 24 hours, the injury may progress to marked edema of the larynx and subsequent loss of the airway. To avoid this progression in airway complications, initial management decisions are largely based on the magnitude of the force sustained to the anterior neck.

Unfortunately, in the United States and other countries, the incidence of penetrating trauma is increasing due to the rise in personal assaults. Penetrating trauma to the larynx includes such injuries as stab wounds, gunshot wounds, and impalements. Severity of injury from a gunshot wound depends on the firing range and the type of weapon used. Gunshots at close range are often fatal due to the intense energy imparted to the soft tissues. From a long range, the damage may be less critical. Low-velocity handguns impart a moderate blast effect injury on surrounding tissue. The bullet’s erratic course in soft tissues makes initial assessment of the wound difficult. On the other hand, high-velocity weapons impart a significant amount of kinetic energy. In high-velocity injuries, the total extent of the injured area may not be clinically evident initially. Judicious debridement of surrounding tissue is advisable at the time of surgical repair. Knife injuries do not destroy tissue distant to the path of injury, and the course may be accurately estimated from the entrance and exit wounds.

Diagnosis

Otolaryngologic evaluation is essential for any patient suspected of suffering a laryngeal trauma. The signs and symptoms of external laryngeal trauma vary from obvious open fractures to subtle aberrations of laryngeal function. Clinical findings may include any subtle alterations in voice, dysphagia, odynophagia, subcutaneous crepitus, saliva leaking through an open wound, bruising of the anterior neck, loss of the thyroid cartilage prominence, and tenderness to palpation. Findings may help to elucidate the mechanism of injury when an adequate history is unavailable.

External examination of the neck may reveal loss of the thyroid prominence, an open fracture or laryngocutaneous fistula. The larynx should be palpated for any crepitance. Tenderness to palpation, although not specific, is often present
Management

A comprehensive clinical and radiologic examination determines the need for surgical or medical management of laryngeal trauma. Medical management is reserved for patients with a stable airway such as those who present with minor mucosal lacerations, minor nonexpanding hematoma or a single nondisplaced fracture of the thyroid cartilage with intact overlying mucosa. Noninvasive management includes close observation with continuous pulse oximetry, administration of humidified air, and head of bed elevation over 45°. The use of heliox (mixture of helium and 30 to 40% oxygen) is controversial because it may mask stridor, an important clinical sign of airway deterioration. Heliox, however, may be of use as a temporizing measure while securing the airway. Early administration of systemic corticosteroids may be advantageous although their onset of action may take hours. Further injury or compromised healing caused by laryngopharyngeal acid reflux can be minimized with proton pump inhibitors or high-dose H2 blockers.

Indications for an open repair of a laryngeal fracture include the presence of comminuted or displaced fractures, fracture of the median or paramedian parts of the thyroid alae, and cartilage fracture. Any fracture of the median or paramedian thyroid cartilage may result in loss of the anterioposterior dimension of the larynx; thus, an open repair is indicated. Any injury resulting in vocal fold paralysis, airway compromise requiring intubation or tracheostomy, or associated with an important injury to other areas of the neck is also best managed with surgical exploration.

Rationale for Plate Fixation

Injury to cartilage results in bleeding and inflammation, with activation of the wound-healing cascade. Cytokine release and the chemotaxis of inflammatory cells lead to deposition of scar tissue, which is primarily composed of type II collagen. Regeneration of cartilage tissue (primarily type I collagen and proteoglycans) by native chondrocytes commences simultaneously, but this process that can take up to 3 months. Motion of fracture fragments increases bleeding, hematoma formation, inflammation, and the likelihood of infection, all of which promote scar formation as opposed to organized cartilage repair. Applying the principles of adaptation fixation, previously validated in craniomaxillofacial surgery, to laryngeal fractures optimizes the repair and regeneration of normal laryngeal cartilage. Plating techniques are fundamentally different from wire or suture fixation. Traditionally, wire or sutures have been used to approximate the fracture fragments, whereas no attempt is made to prevent motion across the fracture line. Plated fragments are held in place by the interactions between the screw, the bone or cartilage, and the plate. Therefore, plates fix the fragments, leading to deposition of new cartilage or bone. The interface of the screw and the bone or cartilage should be able to resist pullout and lateral torque forces. Ideally, two-point fixation should be used for fractures of the thyroid cartilage (either two straight plates or a box-shaped plate). The height of the cricoid cartilage does not allow for two-point fixation.

Surgical Technique

General anesthesia is induced after the airway is stabilized via endotracheal intubation or tracheostomy. Local anesthesia and sedation can be used in patients with no intraluminal injury and minimally displaced fractures (class II). The cervical incision is made in a transverse skin crease approximating the level of the cricoid cartilage. Subplatysmal skin flaps are raised to the level of the hyoid bone superiorly and to the sternum inferiorly, thus exposing the entire larynx. The strap muscles are separated in the midline, revealing the thyroid and cricoid cartilages (Figures 1 and 2). The periosteum is incised in the midline, and perichondral flaps are raised to expose 1 to 2 cm of cartilage at both sides of the fracture lines. The surgical technique for the fixation of laryngeal fractures with adaptation plates is similar to the techniques used for fixation of the maxillofacial skeleton. The most significant difference is the lack of rigidity of the laryngeal skeleton when the thyroid and cricoid cartilages are not completely ossified. To increase the screw-cartilage contact and pull out strength, a drill bit that is one size smaller than the bit appropriate for the screw size can be used. For example, it is customary to use a 1.1 mm drill bit for a 1.5 mm screw. Noncemented laryngeal cartilage, however, should be drilled with a 0.76 mm drill bit. Alternatively, an “emergency” screw may be used after drilling with the customary-sized drill bit. Emergency screws should only be used in patients in whom the drill hole has already been stripped. Currently, an integrated self-drilling, self-tapping screw, and plating system that does not require a drill hole is preferred and may be used regardless of the degree of calcification of the laryngeal framework. Obviating the need for a drill hole produces a tighter screw-tissue interface. One drawback is that the screwdriver has been designed to retain the screws; therefore, it requires significant lateral torque to disengage it from the screw after insertion. Any lateral torque applied to a screw in a noncemented cartilage may disrupt the screw-tissue interface; thus, to avoid stripping the screw hole, the surgeon must stabilize the screw head with an instrument before applying the lateral torque to disengage the screwdriver.

Fixation Techniques in Laryngeal Trauma

Paramedian fractures of the thyroid cartilage are best fixed with a four-hole “box-type” plate across the fracture (Figures 3 and 4). Midline fractures require additional attention because the plate must be conformed to
the original curvature and angle of the thyroid cartilage (Figure 5–7). A four-point fixation of thyroid cartilage fractures is optimal; however, the height of the cricoid cartilage does not usually allow the application of more than a single straight plate. A single horizontal plate is generally adequate to preserve the structural integrity of the subglottic airway, the primary function of the cricoid cartilage. If significant mucosal injury exists, a thyrotomy which can be preplated should be performed, preferably through a midline or paramedian fracture line; and the intralaryngeal mucosa repaired primarily. Alternatively, if adequate visualization may be obtained with a rigid laryngoscope and a cervical spine injury has been elevated “en bloc” with the ipsilateral strap muscle. Before closure of the thyrotomy, it is critical to reattach the vocal folds at the anterior commissure. After the fracture has been stabilized, the wound is closed in layers, a suction drain is placed, and a pressure dressing is applied. Patients who have not undergone tracheostomy are observed overnight and may be discharged the next day.

IATROGENIC LARYNGEAL TRAUMA

Intubation

The incidence of laryngeal stenosis after prolonged or repeated intubation has been estimated to range from 3 to 8% for both adults and children. Figures as high as 37% have been cited for low-birthweight neonates and those with respiratory distress syndrome.

The causes of laryngeal stenosis after intubation are multifactorial. The mechanisms of injury most commonly associated with laryngotracheal intubation include, but are not limited to, duration of intubation, size of the tube, pressure and rubbing of the shaft against the larynx, repeated intubation, foreign body reaction to the tube, release of toxic substances used for sterilization, use of a stylet, route of intubation, nursing care, and anatomic differences between the genders.

Animal and clinical studies have correlated different intubation methods with clinical and histologic injury patterns. Nordin and Linholm, using a rabbit model, correlated the degree of damage with duration of intubation and cuff characteristics. They concluded that the pressure of the cuff over the tracheal surface is more important than the duration of intubation. Since the microcirculation of the laryngeal mucosa stops at 30 mm Hg pressure, low-volume, high-pressure cuffs are more likely to cause ischemic injury than high-volume, low-pressure cuffs. Whited, using a dog model, studied how the biomechanics of endotracheal tubes produce ulceration of the posterior glottis and circumferential injury of the subglottis and trachea. He demonstrated that the inflammatory reaction progresses even after the tube is removed. Whited confirmed the findings of his animal study in a clinical prospective study that correlated the degree of injury with patterns and duration of intubation. He found that patients intubated for 2 to 5 days had 0% to 2% incidence of chronic stenosis, those intubated for 5 to 10 days had a 4% to 5% incidence, and those with an indwelling tube for more than 10 days had a 12% to 14% incidence. He suggested that a tracheostomy may prevent laryngotracheal stenosis in patients who need endotracheal intubation for more than 10 days. Bryce also correlated duration of intubation with laryngeal injuries. Lesions caused by repeated intubation were the most severe. This study suggested that perichondritis is the most significant factor for the development of stenosis.
Lesions. Nevertheless, combined stenoses are more prone to posterior commissure stenosis than has tracheostomy. The cricothyroid membrane ranges from 8 to 13 mm (average 9 mm) in adults. Damage to the cricoid cartilage may lead to cricoid chondronecrosis. Tracheostomy tubes are poorly tolerated through the third or fourth tracheal ring. A high tracheostomy through the first tracheal ring or the cricoid cartilage may lead to cricoid chondronecrosis with resultant fibrosis and stenosis.

Similarly, cricothyroidotomy has been associated with a higher incidence of laryngeal stenosis than has tracheostomy. The cricothyroid membrane ranges from 8 to 13 mm (average 9 mm) in adults. Damage to the cricoid cartilage owing to introduction of microorganisms or direct trauma to the cartilage may lead to chondronecrosis. Tracheostomy tubes are poorly suited to intubate the subglottic larynx because of the lack of overlying soft tissue. In addition, the outer diameter of a number 6 Shiley tracheostomy tube is 10 mm, which is larger than the height of the cricothyroid membrane for a significant portion of the population.

**Nasogastric Intubation**

Nasogastric tubes are often an unrecognized source of trauma. Nasogastric intubation produces inflammation owing to foreign body reaction to the tube, swallowing impairment with pooling of secretions, pressure necrosis, and gastrostrophic reflux. All these factors play a role in the development of a postcricoid ulceration with resultant perichondritis. Healing leads to fibrosis and contracture. Trauma associated with the nasogastric tube may be synergistic with the trauma induced by an endotracheal tube.

**Hyoid Fracture**

The hyoid is a U-shaped bone located in the superior part of the neck, well protected by the mandible. Given this location, fracture of the hyoid is relatively rare and usually associated with other cervical injuries. Hyoid fracture is often the result of a strangulation injury; however, other common mechanisms of blunt and penetrating trauma may be causative as well. Presenting symptoms may include dysphagia, odynophagia, or dyspnea. Physical examination may reveal swelling, neck crepitus, tenderness, or pain with movement of the neck. Diagnosis of hyoid fracture requires a high degree of clinical suspicion since the signs and symptoms are not unique to this injury. Diagnosis is confirmed with CT. Laryngoscopy is also indicated to assess associated mucosal injuries and airway swelling. Treatment is based on the severity of symptoms and clinical findings. Asymptomatic hyoid fractures may be observed. Significant soft tissue injuries, such as pharyngeal lacerations or skin lacerations, are sutured. Care is taken to remove small fragments of bone, and the remaining bone fragments may be fixed with wires.

**REFERENCES**

The successful management of the airway is of paramount importance. Airway control requires a logical and systematic approach guided by the principles of basic and advanced life support techniques and a working knowledge of relevant pharmacology. Most importantly, the physicians must possess a mastery of the anatomy and physiology of the upper aerodigestive tract. The airway surgeon is also uniquely responsible for the diagnosis and treatment of airway lesions such as laryngotracheal stenosis and arytenoid fixation.

ANATOMY

Successful airway intervention necessitates an understanding of the anatomy of the laryngotracheal complex. A detailed discussion of the anatomy of the larynx can be found in Chapter 72, "Development Anatomy and Physiology of the Larynx." The major cartilages of the larynx include the thyroid, cricoid, and paired arytenoids (Figure 1). The thyroid cartilage is a shield-shaped structure whose central prominence tends to be more acutely angled in men than in women. The position of the larynx varies between infants and adults. In infants, the cricoid cartilage is positioned at the level of the fourth cervical vertebra. The thyroid cartilage is often behind the hyoid and impalpable. The tip of the epiglottis then lies at the level of the dorsal surface of the soft palate. As the infant matures, the larynx gradually descends to its adulthood position with the cricoid cartilage at the level of the sixth vertebra.

The cricoid cartilage is the only complete ring of the airway, which accounts for the association between prolonged or traumatic endotracheal intubation and subglottic stenosis. The cricoid cartilage is often behind the hyoid and impalpable. The tip of the epiglottis then lies at the level of the dorsal surface of the soft palate. As the infant matures, the larynx gradually descends to its adulthood position with the cricoid cartilage at the level of the sixth vertebra.

The trachea begins at the lower border of the cricoid cartilage at the level of the sixth vertebra and extends to the upper border of the fifth thoracic vertebra, where it divides into the two bronchi. The trachea is composed of incomplete, C-shaped “rings” of hyaline cartilage that are open posteriorly (pars membranosa) and connected here by fibroareolar connective tissue and smooth muscle fibers. The larynx and trachea are lined by pseudostratified, ciliated columnar epithelium interspersed with mucus-secreting cells, except at the glottis, which is lined with a stratified squamous cell epithelium. The trachea bifurcates at approximately the sternal angle. The right bronchus is wider, shorter, and more vertically oriented than the left bronchus. When using an open bronchoscope, one may most easily examine both bronchi by passing the instrument through the right side of the mouth, thus allowing the best view of the obliquely angled right bronchus while preserving visualization into the left bronchus.1

CLINICAL EVALUATION OF THE AIRWAY

The clinical evaluation of the airway must begin with a rapid assessment of the patient’s ventilatory and respiratory status. A systematic evaluation of the patient based on advanced cardiac life support (ACLS) protocols should be used for each patient. Understanding the basic evaluation of the airway and using a diagnostic and therapeutic algorithm to secure an airway are necessary for treating these patients. Symptoms that indicate upper airway obstruction include hoarseness, dyspnea, stridor, restlessness, and drooling. Physical signs of a damaged airway include bloody sputum, subcutaneous emphysema, palpable laryngeal fractures, cyanosis, and suprasternal or intercostal retractions.

In evaluation of the nonemergent airway, a complete history, including prior history of trauma, previous intubations, and voice and swallowing complaints, should be obtained. The physician may then proceed with a diagnostic assessment of the upper aerodigestive tract. If the patient is seen in the clinic setting, a mirror indirect laryngoscopy may be performed to assess vocal fold mobility and possible lesions of the glottis and supraglottis. Perhaps the most
valuable study is an indirect fiberoptic examina-
tion via nasopharyngoscopy. This technique
allows unparalleled visualization of the upper
airway and larynx and may allow for video
documentation in the clinic setting (Figure 2).
A blood gas evaluation, chest X-ray, and airway
radiographic evaluation via X-ray or computer-
ized tomography (CT) may also be indicated.

MANAGEMENT OF THE EMERGENT
AIRWAY

While management of the airway in the con-
trolled environment of the operating room is usu-
ally straightforward, patients presenting in the
emergency room pose unique problems such as
cervical spine injuries, closed head injuries with
the possibility of increased intracranial pressure,
laryngotracheal disruption, airway hemorrhage,
and facial injury. Supplemental oxygen is the sim-
est means of additional support and should be
given almost universally to patients with air-
way distress. After this intervention, the clinician
should evaluate for airway obstruction from for-
eign bodies such as displaced teeth or tongue and
soft tissues collapse into the pharynx. Because
of its efficacy and lack of cervical movement,
jaw thrust is the most appropriate positioning.2
Placement of an oropharyngeal airway or nasal
trumpet may also aide in relieving soft tissue
obstruction of the airway (Figure 3). An orophar-
yngeal airway displaces the tongue anteriorly,
preventing soft tissue obstruction. A nasal trum-
pet is placed transnasally into the oropharynx
relieving soft tissue obstruction at the level of
the pharynx. Nasopharyngeal airways tend to be
less stimulating than oral airways in the awake
patient, but there is a small risk of epistaxis.
Nasal airways should not be used in patients with
known or suspected basilar skull fractures due to
the risk of intracranial placement.3

The delivery of positive pressure ventilation
may be achieved noninvasively using a facemask.
Successful ventilation requires both an airtight
mask and a patent airway. Without an airtight
seal between the skin of the patient’s face and
the mask, sufficient pressure to inflate the lungs
cannot be developed. Air leak is the most com-
mon problem in delivering facemask ventilation.

An airtight seal may be achieved by using the
thumb and index finger of one hand to secure the
mask, that is, by pushing downward. The middle
and ring finger are then used to grasp the mandi-
ble (and not the soft tissue of the chin) to extend
the neck. The little finger is positioned under the
angle of the jaw and thrusts it anteriorly. If an
assistant is available to squeeze the ventilation
bag, two hands may be used to secure an airtight
seal. Signs of a successful seal and ventilation
include a foggy mask, the rising of the chest with
delivery of positive pressure, breath sounds on
auscultation, a firm, full bag, and return of carbon
dioxide on exhalation capnography.

A laryngeal mask airway (LMA) is a nonde-
finitive technique that may be employed to obtain
a temporary airway for positive pressure ventila-
tion. This device forms a seal over the larynx and
provides a route for oxygen flow into the trachea.
The LMA may also serve as a conduit for fibero-
ptic intubation. If a definitive airway is required,
endotracheal intubation is the quickest and most
successful option whenever possible. Endo-
tracheal intubation allows ventilatory control with
the ability to deliver high levels of oxygen as well
as protecting against aspiration. Endotracheal
intubation can be achieved though both oral and
transnasal routes. In the case of head and neck
trauma, oral intubation may be achieved while
holding in-line cervical traction. Manual in-line
immobilization is the optimal method of stabi-
lization and results in significantly less cervical
spine movement than stabilization in a cervical
spine collar.4

The most common technique employed for
oral intubation in the emergent setting is rapid
sequence intubation (RSI). The first
step is preoxygenation in which patients are
administered 100% oxygen to produce a nitrogen
washout. Preoxygenation is followed by adminis-
tration of an induction agent to produce sedation
and amnesia. A paralytic agent is also usually
administered to provide muscle relaxation. In
many situations, spontaneous ventilation may be
of benefit; because once a patient’s muscle tone
is relaxed, the patient must be artificially venti-
lated. In the case that intubation is not success-
ful, the medical professional must be prepared
to establish a surgical airway. An assistant may
hold cricoid pressure to prevent aspiration if the
patient is unconscious. If a cervical spine injury
is suspected, a second assistant maintains in-line
stabilization during the procedure. If this tech-
nique is accomplished transnasally, a fiberoptic
endoscope may also be placed inside an endotra-
cheal tube to facilitate localization of the airway.
The endotracheal tube can then be passed over the
endoscope after the airway has been identi-
fied. Visualization of the airway with a fiberoptic
endoscope may be obscured by the presence of
blood and secretions.

A more invasive method of providing oxy-
genation to a patient who cannot be adequately
ventilated or intubated is the technique of percutan-
eous transtracheal ventilation. This technique
involves a caudally directed puncture of the cricothyroid
membrane with a 14-gauge intravenous catheter.
Accidental placement of the catheter within the
subcutaneous tissue will result in subcutaneous
emphysema making further attempts at endotra-
cheal intubation more difficult. After the catheter
has been accurately placed into the trachea,
the needle is removed and oxygen is provided via a
jet ventilator, ventilating bag, or gas outlet of an
anesthesia machine. It is important to realize that
an adult cannot breathe through such a catheter.
and thus requires one of the above means of providing oxygen under pressure. Oxygen delivered under high pressures also poses the risk of pneumothorax. If there is an obstruction preventing the egress of air, a second catheter is necessary to prevent overinflation of the lungs and pneumothorax. Percutaneous tracheal ventilation is merely a temporizing measure until a definitive surgical airway can be obtained, and there is little to recommend transtracheal puncture over cricothyroidotomy in adults.

**Cricothyroidotomy**

If the airway cannot be controlled through endotracheal intubation or other medical maneuvers, a surgical airway must be obtained. Cricothyroidotomy is considered the preferred method of obtaining an emergent surgical airway. Chevalier Jackson condemned the procedure in 1921 because of the high rate of glottic and subglottic stenosis; however, over the past quarter century, multiple articles have reported the efficacy of the technique. Indications for cricothyroidotomy include patients requiring emergent airway management that cannot be obtained through the oral or nasal route, for example, patients where manipulation of the neck is contraindicated, severe maxillofacial trauma, edema with inability to visualize the vocal cords, severe oropharyngeal or tracheobronchial hemorrhage, fracture of the base of skull, and supraglottic foreign body obstruction. Cricothyrotomy should not be performed when the landmarks cannot be palpated, as in the presence of tumor, hematoma, or other mechanical barrier, or before the age of 5 years, as the cartilaginous landmarks are not sufficiently distinct. The technique is also contraindicated in the presence of acute laryngeal pathology. Cricothyrotomy will not establish an airway when the trachea has been transected with retraction of the distal end into the mediastinum.

The technique involves creation of an opening in the cricothyroid membrane followed by placement of a stenting tube. The procedure begins with identification of the cricothyroid space between the thyroid and cricoid prominences (Figure 4). Local anesthesia may be infiltrated if time permits. The trachea is stabilized with the surgeon’s nondominant hand. A horizontal incision is made over the middle third of the membrane and carried directly into the airway. The scalpel handle is inserted and rotated 90° or a dilating instrument may be inserted next to the scalpel to secure the airway opening. Mayo scissors may be used to enlarge the opening. Every effort is made not to damage the cricoid or thyroid cartilages. An endotracheal tube is then placed through the cricothyrotomy and directed distally into the trachea. It is best to have several sizes of endotracheal tubes available. Once the cuff has been inflated and the tube secured, ventilation is begun. Auscultation, bilateral chest rise, and the presence of end-tidal CO₂ should be utilized to confirm accurate placement. After the airway has been secured, the patient should be taken to the operating room as soon as possible to convert the cricothyrotomy to a formal tracheostomy because the endotracheal tube is not a stable airway.

While cricothyrotomy has been utilized for long-term airway management, it is most useful in the emergency setting where an urgent surgical airway is needed. Cricothyrotomy is usually faster and easier to perform than tracheostomy, especially in the hands of a nonsurgeon, as it requires little surgical skill other than knowledge of anatomy. Complications of cricothyrotomy include hemorrhage, tube displacement, infection, vocal cord damage, subcutaneous emphysema, and the development of subglottic or tracheal stenosis.

In 1995, Hawkins and colleagues reported a series of 5,603 consecutive adult trauma patients, of whom 66 required cricothyrotomy. Three major complications, including hemorrhage, failure to obtain a surgical airway, and thyroid cartilage laceration, occurred in 2 patients. No patient had significant clinical morbidity from the cricothyrotomy. Cricothyrotomy remains an important technique with low morbidity in patients needing emergent airway control.

**Tracheostomy**

Tracheostomies have been performed for over 2,000 years. Until a century ago, however, the procedure was essentially reserved for moribund patients due to high rates of morbidity and mortality. Attitudes toward tracheostomy changed in 1909, when Chevalier Jackson described the modern tracheostomy. Jackson addressed the high rate of laryngeal and tracheal damage previously associated with tracheostomy in his landmark paper of 1921, “High Tracheostomy and Other Errors: The Chief Cause of Chronic Laryngeal Stenosis.” In this paper, Jackson hypothesized that the unacceptably high rates of laryngeal and tracheal stenosis associated with tracheostomies were secondary to damage to the thyroid and cricoid cartilages incurred during the performance of “high” tracheostomies. Jackson instructed that tracheotomies be performed below the second tracheal ring, thereby avoiding these dreaded complications. These teachings have been followed to the present day.

The relative indications for tracheostomy as outlined by the American Academy of Otolaryngology—Head and Neck Surgery include upper airway obstruction with stridor, air hunger, retractions, documented obstructive sleep apnea, bilateral vocal fold paralysis, previous neck surgery, throat trauma or irradiation to the neck, as well as, prolonged or expected prolonged intubation, inability of the patient to manage secretions, facilitation of ventilation support, inability to intubate, and as an adjunct to manage head and neck surgery or significant head and neck trauma.

**Technique**

A tracheostomy is generally begun with a horizontal skin incision approximately midway between the thyroid and cricoid prominences (Figure 4). Local anesthesia may be infiltrated if time permits. The trachea is stabilized with the surgeon’s nondominant hand. A horizontal incision is made over the middle third of the membrane and carried directly into the airway. The scalpel handle is inserted and rotated 90° or a dilating instrument may be inserted next to the scalpel to secure the airway opening. Mayo scissors may be used to enlarge the opening. Every effort is made not to damage the cricoid or thyroid cartilages. An endotracheal tube is then placed through the cricothyrotomy and directed distally into the trachea. It is best to have several sizes of endotracheal tubes available. Once the cuff has been inflated and the tube secured, ventilation is begun. Auscultation, bilateral chest rise, and the presence of end-tidal CO₂ should be utilized to confirm accurate placement.
between the sternal notch and the cricoid cartilage. The incision is carried down through the skin, subcutaneous tissue, and platysma to the level of the strap muscles. A more inferiorly based Bjork flap consisting of the second and third tracheal rings is a superior option for adults. Following Jackson’s principles, a horizontal incision is made above either the second or third tracheal ring and then carried inferiorly on the lateral aspects with Mayo scissors to fashion an inferiorly based flap. The space between the rings may be calcified in older patients. The Bjork flap is sewn to the subcutaneous tissue of the inferior skin margin with absorbable suture (Figure 5). The Bjork flap makes recannulation easier in the event of accidental extubation but does lead to a slightly increased risk of tracheocutaneous fistula. For this reason, a horizontal incision based on the second or third tracheal ring or the removal of an anterior section of a single tracheal ring may be preferable in patients who are expected to require a tracheostomy for only a short period of time. The Bjork flap is contraindicated in children because it results in high rates of tracheocutaneous fistula and subglottic stenosis. A vertical incision of the trachea is preferred, along with carefully labeled and secured stay sutures on either side of the tracheal incision.

When a tracheostomy is to be permanent or of long duration, the surrounding skin may be surgically defatted and sutured to create a tracheostomy tract facilitating removal and reininsertion of the tracheostomy tube. A reinforced endotracheal tube may be inserted while the operation is finished or the desired tracheostomy tube may be placed. Correct placement of the tube should be verified using end-tidal CO₂ measurement, the presence of bilateral breath sounds and chest rise. Finally, the tracheostomy incision should never be tightly closed because leakage of air around the tube will be trapped below the skin, leading to subcutaneous emphysema, pneumomediastinum, pneumothorax, or infection. Instead, the incision should be loose around the tube to allow passive egress of air from the trachea. A post-tracheostomy chest X-ray is often advisable to detect possible complications of trapped air, and in children, such X-ray is mandatory.  

For a patient who is intubated and in the intensive care unit, tracheostomy may be performed as an open procedure at the bedside. This avoids the costs associated with the operating room, and equipment is less expensive than that required for percutaneous tracheostomy. Disadvantages of performing an open bedside tracheostomy may include lack of adequate lighting, surgical assistance, and inferior equipment. Just as with percutaneous tracheostomy, patients with unfavorable anatomy are not candidates for open bedside tracheostomy.

Complications of Tracheostomy

Complications of tracheostomy are often divided into early and late complications. Early complications include hemorrhage, pneumothorax, subcutaneous emphysema, tube obstruction, and tube displacement. Late complications include infection, aspiration, granuloma formation, laryngeal or subglottic stenosis, and tracheo-innominate artery fistula.

Early Complications. Mild bleeding is the most common early complication of tracheostomy, occurring in about 5% of cases. The hemorrhage usually results from venous oozing from either the soft tissues or the incised thyroid tissue. Mild bleeding can generally be controlled by raising the head of the patient to decrease venous pressure or by placing hemostatic gauze over oozing areas. Major hemorrhage is unusual and most often involves a branch of the superior thyroid artery. Arterial bleeding is an indication for immediate surgical exploration.

Tube obstruction is the most common cause of ventilatory insufficiency in a post-tracheostomy patient and most often results from a mucous plug. Dried mucus and secretions in and around the tracheostomy tube can form crusts that may become large enough to obstruct the lumen of the tube. Audible airflow and difficulty passing a suction catheter are signs of impending tube obstruction. A dequate humidification, irrigation, frequent suctioning, and cleaning of the inner cannula help to reduce the risk of plugging and tube obstruction. If the tracheostomy tube becomes obstructed, first the inner cannula should be removed. If removal of the inner cannula fails to relieve the obstruction, the patient and care staff should be instructed to remove the entire tube. It is mandatory to have a same size and the next smaller size tracheostomy tubes available at the bedside.

Displacement of the tracheostomy tube or dislocation of the tube from the tracheal lumen poses a considerable risk in the postoperative period. Displacement of the tracheostomy tube is most likely to occur in the early postoperative period before a stable tract has matured between the tracheal lumen and the skin. Displacement most often occurs due to the tube being inadequately secured. Excessive tension applied to the tube from the ventilatory apparatus also poses a risk of tube dislodgement.

Tracheostomy tube replacement in the early postoperative period and during the first tube change should be done under direct vision. Blind reinsertion poses the risk of creating a false passage for the tube. If reinsertion cannot be accomplished, the airway may be reestablished by oral endotracheal intubation.

Subcutaneous emphysema results from the forced entrance of air into the fascial planes of the neck, usually resulting from closing the tracheostomy incision too tightly. Tube obstruction or displacement can also lead to escape of air into the fascial planes. Crepitus and soft tissue swelling can involve the neck, face, and upper torso. Minor amounts of subcutaneous emphysema usually resolve spontaneously without significant sequelae, while massive amounts may progress to pneumomediastinum and pose increased risk of infection through bacterial contamination. A flexible scope inserted through the tracheostomy tube is a valuable means of confirming that the tube is actually in the lumen of the trachea.

Pneumothorax occurs in less than 5% of tracheostomies and can result from damage to the pleural spaces during dissection that veers away from the midline. Pneumothorax may also be caused by excessively forceful ventilation that prevents passive exhalation of air, leading to alveolar rupture and the entrance of air into the pleural space. Air can also enter the pleural space or mediastinum via a misplaced tracheostomy tube. A pneumothorax may become apparent due to respiratory distress or be detected by decreased breath sounds on auscultation of the chest, but this complication is usually asymptomatic and noted incidentally on the postoperative chest X-ray. A small pneumothorax can be expectantly observed with serial chest radiographs, while a large or symptomatic pneumothorax may require a chest tube for lung re-expansion.

Late Complications. Innominate artery erosion is perhaps the most dreaded post-tracheostomy complication and, although rare, results in only a 10 to 25% survival rate. Tracheo-innominate fistula most commonly occurs at the tip of the
tracheostomy tube, and causes include inappropriately low tracheostomy, erosion from a high-pressure cuff, movement of the tube, and infection. Innominate artery erosion is often heralded by a sentinel bleed. Rapid peristomial bleeding, even when it resolves, should trigger a fiberoptic examination of the tracheostoma, with the tracheostomy tube removed to rule out innominate artery involvement. When massive bleeding does occur, the tracheostomy tube should be rapidly replaced with a longer endotracheal tube in order to allow oxygenation while digital pressure is applied between the anterior trachea and the manubrium to compress the innominate artery. Placement of an orotracheal tube allows better access through the stoma for digital pressure. The patient must be taken immediately to the operating room for median sternotomy and innominate artery ligation, with a coordinated thoracic surgery-otolaryngology team. Any surgeons feel the Bjork flap technique lessens the risk of this potentially fatal complication.

While bacterial colonization of the trachea and peristomal area is unavoidable, significant infections occur rarely. Local cellulitis can generally be managed with local cleansing measures and topical antibiotics. Uncontrolled local infection can lead to such serious complications as mediastinitis, peristomal tissue loss, or tracheo-innominate fistula. Local infection that does not respond to aggressive wound care should be treated with systemic antibiotics. Dysphagia and aspiration following tracheostomy is often overlooked. Tracheostomies have been shown to decrease the protective glottic closure reflexes of both the true and false vocal cords. Loss of this protective mechanism predisposes the tracheostomized patient to aspiration and concomitant pneumonia. Prophylactic measures include a soft, solid diet and a somewhat upright position during feeding. While inflating the tracheostomy tube cuff can afford temporary airway protection, hyperinflation of the cuff actually causes exacerbated aspiration due to compression of the esophagus. Consultation with a speech and swallowing therapist is advisable for any patient who requires a tracheostomy.

Granulation tissue may form in the peristomal area due to chronic mucosal and skin irritation, which may be exacerbated by an inadequately fixed or improperly sized tracheostomy tube. Granulation tissue may also form inside the tracheal lumen. Early and small granulomas may be managed with local debridement. M ature, fibrotic lesions generally require endoscopic laser excision.

Tracheostomies may contribute to subglottic stenosis by causing chronic irritation to the tracheal mucosa while also providing a route of bacterial contamination that causes increased inflammation in the damaged area. This inflammation may result in the formation of scar tissue and subsequent subglottic or tracheal stenosis. Gastroesophageal reflux is also felt to increase the risk of subglottic stenosis by providing additional mucosal irritation that contributes to granulation and scar tissue formation. When a patient requires mechanical ventilation, tracheostomy tube cuff pressure must be checked at regular intervals. If the cuff pressure is higher than the tracheal mucosal capillary filling pressure, the mucosa will slough leading to chondritis and stenosis. The risk of subglottic stenosis underscores the importance of minimizing extraneous motion of the tracheostomy tube, managing gastroesophageal reflux, and decannulation when the tracheostomy is no longer required for airway support.

**Percutaneous Tracheostomy**

While percutaneous tracheostomy was first described in 1955, it has experienced a resurgence in popularity after its reintroduction by Ciaglia and colleagues in 1985. The technique involves the transcervical insertion of a guidewire into the airway followed by blunt dilation of the guidewire tract. The tracheostomy tube is then inserted over the guidewire using a modified Seldinger technique. The advantage of percutaneous tracheostomy is that it can be performed at the bedside in the intensive care unit eliminating the potential risks associated with transport of a critically ill patient to the operating room. Relative advantages also include the time- and cost-saving aspects of the procedure.

Initial concern over the safety of the technique has been tempered by increased use of bronchoscopy, allowing direct visualization of airway entry, and newer commercially available kits using a single dilator, lessening manipulation of the trachea, and allowing the procedure to be performed more quickly. Visualization of the guidewire insertion, dilation, and tracheostomy tube placement may be achieved using a flexible bronchoscope inserted through the endotracheal tube at the time of the procedure. Improved visualization with bronchoscopy decreases airway complications by preventing improper placement of the guidewire into the subcutaneous tissue or the esophagus. The proper level of tracheostomy placement may also be confirmed with airway visualization at the time of the procedure.

Percutaneous dilational tracheostomy is an elective procedure and should not be performed in an emergency setting. Proper patient selection is crucial to successful outcomes. Patients undergoing percutaneous tracheostomy should have easily palpable surgical landmarks to avoid damage to the thyroid or cricoid cartilage. Patients who are difficult to intubate or obese have documented or suspected cervical spine injury and have a neck mass or infection, and those with an inability to extend the neck are not generally considered candidates for the procedure. Additionally, patients requiring high positive end expiratory pressures should be considered carefully. Percutaneous tracheostomy is contraindicated in pediatric patients.

**Technique.** Percutaneous tracheostomy is most often performed in the intensive care unit (ICU) setting under deep intravenous sedation. The patient should have continuous monitoring with nursing and respiratory staff at the bedside. Additionally, since a percutaneous tracheostomy must sometimes be converted to a standard open tracheostomy, a surgical tracheostomy tray should be present at the time of the procedure, and the operator should be able to perform a standard tracheostomy.

After placing a shoulder roll to extend the patient’s neck, the thyroid and cricoid cartilages, as well as the hyoid and suprasternal notch, are palpated. Local anesthesia with epinephrine is infiltrated into the surgical area, and an approximately 2 cm horizontal incision is made midway between the cricoid cartilage and suprasternal notch. Using blunt dissection, the pretracheal plane is identified and the thyroid isthmus is swept inferiorly or superiorly. A bronchoscope is then passed through the endotracheal tube. After the cuff is deflated, the endotracheal tube is withdrawn to the level of the subglottis taking care not to extubate the patient. The light from the bronchoscope serves as an additional guide for placement of the tracheostomy.

Next, the surgeon passes the needle through the anterior tracheal wall under direct visualization. The guidewire is inserted, the needle withdrawn, and the tract dilated. The tracheostomy tube is inserted over an introducer. The tube should be sutured and secured with tracheostomy ties. A filter securing the tracheostomy tube and verifying placement, the bronchoscope and endotracheal tube are withdrawn.

**Advantages, Disadvantages, and Complications.** As the popularity of percutaneous tracheostomy has increased over the last two decades, debates on the precise indications for percutaneous tracheostomy and the possible advantages over conventional surgical tracheostomy have ensued. A meta-analysis of prospective trials comparing percutaneous and open tracheostomy in critically ill patients performed by Freeman and colleagues found no difference with respect to the overall complication rate between the two techniques. Percutaneous tracheostomy was, however, found to have a lower incidence of peristomal bleeding and postoperative infection. Antonelli and colleagues performed a prospective, randomized trial with 1-year double-blind follow-up comparing the two techniques. The study found no difference in the complication rates between the two procedures at the time of 1-year follow-up.

Percutaneous dilational tracheostomy is most often performed at the bedside in the ICU, decreasing complications associated with transport of a critically ill patient to the operating room. Although percutaneous tracheostomy has been shown to save an average of 5 to 10 minutes, the clinical implications of this time savings are likely limited. More importantly, because the procedure is performed in the ICU, operating room personnel and facilities are not necessary and patient charges are reduced.

Comparison to open tracheostomy, percutaneous tracheostomy results in a narrow, dilated
tract rather than a formal stoma. The narrow tract results in an increased rate of tube displacement and difficult tube reinsertion with percutaneous tracheostomy as compared to an open tracheostomy. An additional disadvantage of percutaneous tracheostomy is the risk of tracheal or subglottic stenosis due to cartilage damage incurred during the procedure. Unlike soft tissue, cartilage is rigid and incapable of conforming to the shape of the dilator. The progressive dilations performed during percutaneous tracheostomy put the tracheal cartilages at high risk for crush injury during the procedure. Damaged cartilage poses a risk of scar tissue formation and subsequent tracheal or subglottic stenosis. The risk of cartilage damage is minimized by bronchoscopic guidance during the procedure ensuring proper placement of the tracheostomy. Overall, with proper patient selection and adequate training, percutaneous tracheostomy is a safe and efficient alternative to open tracheostomy.

LARYNGEAL AND TRACHEAL STENOSIS IN THE ADULT

Laryngotracheal stenosis (LTS) is, in adults, challenging to manage. The diagnosis and evaluation of these lesions requires a complete mastery of the anatomy and function of the upper aerodigestive tract. The multiplicity of stenotic lesions in the adult larynx and trachea requires unique strategies for management and careful individualization of treatment. LTS is an unfortunate complication of diseases and therapies.

Etiology

The list of causes of laryngotracheal stenosis is extensive. Historically, the majority of adult LTSs result either from external trauma or prolonged endotracheal intubation; however, sequelae of intubation has become the number one cause. External trauma causes cartilage damage and mucosal disruption with hematoma formation. The resulting hematoma organizes and leads to collagen deposition and scar tissue formation through the healing process. This scar may eventually contract leading to the development of stenosis. Endotracheal intubations can cause mucosal damage through pressure necrosis and direct injury resulting from the pressure of the endotracheal tube or cuff. Mucosal ulceration also leads to chondritis and healing with collagen deposition and fibrosis, leading to eventual scar formation. Lesions from endotracheal intubation are usually located in the posterior glottis where the tube most often contacts mucosa or in the trachea where the cuff or tube tip may cause mucosal damage. Damage related to the cuff has been significantly reduced by the development of low-pressure, high-volume cuffs. The duration of intubation, amount of tube movement, the tube size, and the presence of gastroesophageal reflux all may contribute to the development of LTS. Patients specific disease processes may also contribute to the development of LTS. Patients with diabetes mellitus, congestive heart failure, and a history of stroke or tuberculosis have an increased incidence of laryngeal injury from intubation. Benign and malignant neoplasms, collagen vascular infections, fungal disease, and inflammatory conditions all may cause LTS without a history of trauma or previous intubation.

Classification

Since areas of LTS are so variable in their size, consistency, and location, a rigid classification scheme is essentially impossible; and, for this reason, multiple staging systems exist. Although introduced as a staging system for subglottic stenosis, the Myer-Cotton system remains the most widespread classification system in use. The classification system separates obstruction into four categories: Grade I, less than 50% lumen obstruction; Grade II, 50 to 70% obstruction; Grade III, 71 to 99% obstruction; and Grade IV, complete obstruction without a detectable lumen. Regardless of the classification system used, it is important for the surgeon to describe and document the lesion in a way that is widely understandable and reproducible. Photodocumentation when available aids in documenting the lesion and preparing for future surgical intervention.

In 1992, McCaffrey developed a classification system based on 72 cases of LTS. In this system, Stage 1 lesions are confined to the subglottis or trachea and are less than 1 cm long. Stage 2 lesions are subglottic and longer than 1 cm but do not extend into the glottis or trachea. Stage 3 lesions involve the upper trachea but do not involve the glottis. Stage 4 lesions involve the glottis with fixation or paralysis of one or both vocal folds. McCaffrey found the above system to be highly predictive for successful decannulation, with 90% of Stages 1 and 2 patients, 70% of Stage 3 patients, and 40% of Stage 4 patients achieving successful decannulation.

The general description of LTS in adults begins with the anatomic location of the lesion. Stenotic areas are first described by their origin in the glottis, subglottis, trachea, or a combination of the above areas. Stenotic segments may be further described as anterior, posterior, or circumferential in nature. Posterior glottic stenosis always involves impaired vocal fold abduction, due to soft tissue contracture or actual fixation of the cricoarytenoid joints. The size and length of the stenotic area are critical in classifying the lesion as well. The quality of the lesion, soft versus fibrous, and any associated vocal fold motion impairment should also be noted. This quantitative, reproducible method offers the most consistent technique for describing laryngotracheal stenosis.

Diagnostic Assessment

The evaluation of the patient with LTS must begin with a meticulous history and physical examination. Since most cases of LTS result from laryngotracheal trauma or endotracheal intubation, the timing of the predisposing incident should be recorded. Any previous airway evaluations or attempts at repair should also be noted. The patient should be questioned regarding the onset, duration, and severity of symptoms such as exercise intolerance, disruption of lifestyle, and tracheostomy dependence. Patients who require a tracheostomy should be questioned as to how often and the duration that the tracheostomy tube can be plugged. Symptoms of aspiration, voice change, or dysphagia may indicate glottic involvement.

The entire upper aerodigestive tract must be carefully examined in a patient with suspected LTS. Indirect laryngoscopy and flexible fiberoptic laryngoscopy provide critical information regarding the supraglottic airway and mobility of the true vocal folds. In extreme abductions, areas of subglottic stenosis may be visible using these techniques. Video documentation offers a valuable method of treatment planning and patient education. Although imaging studies such as airway radiographs, computerized tomography, and magnetic resonance imaging occasionally provide useful information, the most valuable diagnostic assessment stems from examination of the patient endoscopically.

After the patient has been examined by indirect laryngoscopy and flexible fiberoptic techniques, open endoscopy evaluation under general anesthesia should be performed in all patients with symptomatic airway abnormalities. Direct objective measurement and documentation of the diameter and length of the stenotic areas are critical steps in the management of patients with these lesions. Measurement of the diameter of stenotic segments is best evaluated by passing a telescope, with a known diameter, that just fits through the stenotic area. Alternatively, an uncuffed endotracheal tube may be used. It should be noted, however, that the endoscope or tube will compress soft tissue and can temporarily dilate the lumen, so that the actual dimensions are usually overestimated. Measurement of stenosis length may be performed by placing the endoscope at the distal end of the stenotic segment and marking the instrument at the incisors. The endoscope is then withdrawn to the proximal aspect of the stenosis and marked. The length of the stenosis may then be directly measured on the endoscope.

Treatment of Laryngotracheal Stenosis

The goal of treating the patient with LTS is to reconstruct an adequate airway, while preserving phonation and airway protection. Operative intervention ranges from outpatient endoscopic procedures to major open airway reconstruction, including laryngotracheoplasty, cricotracheal resection, and tracheal resection. Many patients require multiple procedures to treat this severe and challenging disease process.

Medical Treatment. Most surgeons who treat LTS recommend the use of antibiotics, local or systemic corticosteroids, and H2 antagonists or proton pump inhibitors when treating mild or
acute subglottic injuries. Treatment of underlying disease processes such as inflammation, infection, and autoimmune processes may lessen the degree of stenosis in appropriate cases. In mature areas of laryngotracheal scarring, these medical treatments are unlikely to result in significant clinical improvement. In the treatment of glottic stenosis, static enlargement of the glottis impairs vocal function, to varying degrees.

**Endoscopic Treatment.** Some areas of LTS are amenable to endoscopic treatment techniques such as laser vaporization and dilation, excision using a microtrapdoor technique, or serial dilation with radial incisions of the stenotic segment. Regardless of the technique used, the most common cause of failure is restenosis. A corticosteroid may be injected into the stenotic area, or mitomycin-C may be applied to the lesion under endoscopic guidance to inhibit recurrent scar formation. Lasers allow the precise treatment of tissue throughout the airway while avoiding external incisions and provide an excellent method of cutting, coagulating, or vaporizing tissue. Hemostasis may be achieved and perioperative edema is often less with the use of lasers due to smaller amounts of tissue thermal damage compared to electrocautery.

The ideal laser for any particular patient depends on the type of tissue and lesion that requires treatment. Due to the precision, that is, the small spot size of the carbon dioxide (CO₂) laser, it remains the instrument of choice in the endoscopic management of LTS. While the CO₂ laser is precise, it is not a good instrument for coagulation and can only be used to coagulate vessels up to 0.5 mm in size. If the area of stenosis is felt to be particularly vascular, a laser with better hemoglobin absorption, such as KTP or Nd:YAG, would be recommended. One further disadvantage of the CO₂ laser is that it lacks a good fiberoptic delivery system and must generally be controlled via a micromanipulator system mounted on a microscope.

Laser ablation of areas of LTS is a useful technique that may be combined with dilation of the stenotic segment or placement of an intraluminal stent. Laser ablation is most successful in the management of early lesions composed mostly of granulation tissue that have not yet evolved into a mature scar. Stenotic segments less than 1 cm in length may also be addressed with this method. The microtrapdoor technique is used to debulk stenotic areas confined to a single quadrant of the airway. This technique is somewhat more technically demanding than simple ablation of the stenosis. The procedure begins by performing an incision on the superior aspect of the stenotic shelf (Figure 6). Once the incision has been made, a microelevator is used to elevate a mucosal flap over the area of scar tissue. The laser may be used to vaporize the underlying scar tissue forming the stenosis. Once the scar tissue has been adequately ablated, the flap is repositioned into its correct anatomic location. The laser may be defocused and milli-
Open Surgical Treatment. Severe areas of laryngotracheal stenosis that do not respond to endoscopic techniques require an open surgical procedure. Open techniques attempt either to excise the stenotic segment and anastomose the airway or to augment the circumference of the stenotic segment with transplanted tissue. Stenoses that are longer than 1 cm have glottic or extensive tracheal involvement, or have no improved with endoscopic treatment, as well as near-complete stenoses are candidates for open surgical repair. In patients with diabetes or severe systemic illnesses, for example, systemic lupus erythematosus, rheumatoid arthritis, open approaches must be considered with great care. Such patients suffer from poor wound healing, have a high incidence of perioperative complications, and have a lower success rate. In these high-risk patients, a tracheostomy may be the most prudent choice of management.

Mitomycin-C is an antineoplastic antibiotic that acts as an alkylating agent inhibiting cell division, protein synthesis, and fibroblast proliferation. Mitomycin-C has been used successfully in ophthalmologic procedures to decrease scar formation and restenosis; however, at this time the local use of mitomycin-C in LTS is still controversial. Rahbar and colleagues published the results of a multicenter prospective trial aiming to evaluate the efficacy and safety of the topical application of mitomycin-C in the prevention and treatment of airway stenosis. Over an average follow-up period of 18 months, 14 of 15 patients (93%), ranging in age from 2 to 78 years, showed a significant improvement in their airway.27 A retrospective review of 55 patients by Ubell and colleagues showed only 1 suspected complication in 93 applications. The patient in question suffered from diffuse inflammation and possible fungal infection, ultimately requiring a tracheostomy.28 Although many trials point to promising initial results for application of mitomycin-C, ultimately additional studies are needed to estimate better the risks and benefits of its use.

Laryngotracheoplasty. Laryngotracheoplasty is often used to repair segments of subglottic stenosis more than 1 cm in length.30 The procedure begins with a transverse cervical incision in a natural skin crease at the level of the cricoid cartilage. Subplatysmal flaps are elevated superiorly to the thyroid notch and inferiorly to the sternum. The strap muscles are separated in the midline and retracted laterally. The thyroid isthmus is divided and ligated. The anterior cricoid ring is divided vertically with a knife or saw. The incision is extended superiorly and inferiorly based on the exact location and extent of the stenosis (Figure 8). The goal is to open the entire stenotic segment. To prevent voice damage, the incision is not extended to the anterior commissure unless this area is involved by the stenosis. If the cricoid cannot be opened sufficiently due to calcification or extensive scarring, a posterior cricoid split may be performed to gain the mobility needed. If a posterior cricoid split is performed, the surgeon must be careful not to damage the underlying esophagus. While it is tempting to remove scar tissue at this point in the procedure, the surgeon must remember that the goal of the procedure is to open the area of stenosis widely rather than to remove tissue. Resection of scar tissue and mucosa risks scar regeneration and recurrent stenosis in the postoperative period. Submucosal resection of scar tissue, however, is generally safe and does not increase the risk of restenosis. A posterior graft, if it must be used, is placed next. Posterior grafts usually contain a flange that is tucked behind the posterior lamina of the cricoid cartilage bilaterally to prevent extrusion into the airway. An airway stent, if one is to be placed, is inserted after placement of the posterior cricoid graft. Placing an airway stent requires one to leave a tracheostomy in place while healing occurs. The anterior cartilage graft is generally cut in a fusiform or boat-shaped fashion with beveled edges to prevent the graft from slipping into the airway. The graft is sutured into place while taking great care to ensure the sutures remain extraluminal. The strap muscles are reapproximated in the midline, and the platysma and skin are closed over a passive drain to allow air egress. The success rate of primary laryngotracheal reconstruction in adults is in the 60 to 70% range.

Cartilage grafts for laryngotracheoplasty may be harvested from the costal cartilage or from nasal septal cartilage. Costal cartilage is the most commonly used source for grafts. The fifth or sixth costal cartilage is harvested with the anterior perichondrium intact. The grafts are carved to the appropriate shape with the perichondrium facing the airway lumen. The hyoid bone may also be harvested through the existing cervical incision and used as an interposition graft, which offers the advantage of avoiding a second operative area. The central portion of the hyoid bone between the lesser cornua may be used as a free graft and fixed into place. The hyoid bone has also been used as a pedicled graft based inferiorly on the sternohyoid muscle.31 In children, the outer table of the thyroid cartilage taken from the lateral edge may be used as a graft.

Tracheal Resection and Anastomosis. Areas of cervical tracheal stenosis up to about 5 cm can generally be excised and the trachea reanastomosed primarily, providing that it is not in close proximity to the carina. Sternotomy may be needed if the lesion is intrathoracic. A supraharyngeal laryngeal release may be required to allow for closure under minimal tension. When performing this procedure, the surgeon must keep in mind the age and body habitus of the patient. Older patients tend to have calcifications between tracheal rings, resulting in decreased tracheal elasticity. Patients with large, thick necks and older patients with cervical kyphosis also tend to lack tracheal mobility.

Prior to the procedure, the patient is positioned with the neck hyperextended on a shoulder roll. If a tracheostomy is present, the skin of the tracheostomy site is included in the incision.
planning and is excised. After a transverse skin incision has been made, subplatysmal flaps are raised superiorly to the thyroid cartilage and inferiorly to the manubrium. The strap muscles are separated in the midline and retracted laterally. The thyroid isthmus is divided and ligated if necessary. The area of stenosis is located and can be confirmed endoscopically. Care is taken to preserve the lateral blood supply to the trachea proximal and distal to the site of stenosis. The dissection around the area of stenosis must proceed directly on the trachea to prevent injury to the recurrent laryngeal nerves. The esophagus is identified and carefully dissected away from the membranous trachea. The trachea may then be incised above and below the stenotic segment. The endotracheal tube is placed transorally into the distal tracheal segment. The closure always begins posteriorly. Vicryl sutures are placed in an extraluminal fashion through the perichondrium of the proximal and distal tracheal segments (Figure 9). The neck is flexed prior to tying the sutures. Additional sutures may be placed around a tracheal ring above and below the site of anastomosis to decrease tension on the closure. The strap muscles are reapproximated in the midline. The platysma and skin are closed after placement of a passive drain to allow the egress of air.

It is essential to minimize the tension on the closure after tracheal reanastomosis. Surgical techniques that decrease tension include mobilization of the trachea through blunt anterior and posterior dissection and release of the suprahyoid muscular attachments. A cardiothoracic surgeon may also perform a division and reattachment of a bronchus, which allows further superior mobility of the distal trachea, although this is rarely necessary. Positioning maneuvers such as neck flexion also decrease tension on the site of anastomosis. Some surgeons place a stitch between the chin and manubrium (Grillo stitch) to prevent patients from extending the neck during the postoperative period. The patient may be extubated at the conclusion of the procedure or remain intubated overnight and extubated on the first postoperative day at the discretion of the surgeon. Multiple studies show operative success, defined by decannulation, in excess of 90%. Complications of laryngotracheal resection and anastomosis include subcutaneous emphysema, pneumomediastinum, mediastinitis, hematoma formation, abscess, wound dehiscence, cellulitis, reintubation or prolonged intubation, tracheitis, pleural effusion or pneumonia, and tracheocutaneous fistula, in addition to anastomotic complications including granulation tissue formation, stenosis, and separation. In a review by Wright and colleagues of 901 patients undergoing tracheal resection, predictors of anastomotic complications were reoperation, diabetes, resections greater than or equal to 4 cm, laryngotracheal resection, need for tracheostomy before the operation, and age 17 years or younger. Aesthetic complications, while uncommon, may require multiple additional airway procedures including multiple dilations, temporary tracheostomy, permanent T-tube, and reoperation. Overall, tracheal resection in the hands of a skilled surgeon has a high success rate with low mortality.

Additional Open Techniques. Several new techniques have recently been described and applied in the treatment of segmental tracheal stenosis. Cryopreserved, irradiated tracheal homograft transplantation has been used to treat patients with tracheal stenosis. This technique requires the harvest of tracheal tissue from donor cadavers within 24 hours of death. The grafts are placed in a –70°C chamber prior to irradiation to 25,000 Gy and then stored at –70°C until transplantation. Kunachak and colleagues reported that three of four patients treated with this technique were successfully decannulated and display a near-normal tracheal lumen with histologic evidence of normal respiratory epithelium at the graft site.

The technique of microvascular-free tissue transfer has been applied to the challenging problem of laryngotracheal stenosis. Escamado and Carroll reported the use of a fibular osseocutaneous-free flap in the reconstruction of a complex LTS. At this point, the usefulness of free tissue transfer appears to be limited to a subset of complex cases not amenable to more conventional surgical techniques.

CRICOARYTENOID JOINT FIXATION

The cricoarytenoid joint is a synovial joint formed by the articulation of the arytenoid cartilages with the posterosuperior aspect of the cricoid cartilage. The vocal process of the arytenoid cartilage is usually free to rotate in three dimensions to allow proper apposition of the true vocal folds. This normal mobility of the arytenoids can be impaired by several factors. First, dislocation of the arytenoid cartilage may occur due to external trauma or intubation. The arytenoids may be dislocated either anteriorly or posteriorly, with anterior dislocation being slightly more common due to the force vector exerted by the blade of a laryngoscope. Several inflammatory disorders such as rheumatoid arthritis and gout may also involve the cricoarytenoid joint and result in fixation of the joint. With cricoarytenoid arthritis, the patient generally presents with symptoms of stridor and dyspnea with a variable degree of dysphonia. The dysfunction results from a fixed position of the vocal folds in a paramedian position and the inability to create normal apposition or abduction of the vocal folds. Other causes include denervation of the larynx, Wegener granulomatosis, previous laryngeal operations, and caustic ingestion.

In the patient with suspected cricoarytenoid joint dysfunction, the differential diagnosis includes denervation, dislocation, or fixation due to an inflammatory condition. A history of trauma should always be carefully elicited in this group of patients. The proper location and mobility of the cricoarytenoid joint is best assessed under general anesthesia by gently rocking the arytenoid cartilage. An electromyogram of the intrinsic laryngeal musculature can determine if the immobility is due to denervation or is secondary to fixation of the joint. Bilateral arytenoid cartilage fixation bears resemblance to bilateral recurrent laryngeal nerve paralysis, and the two conditions may be difficult to distinguish clinically.

The treatment of cricoarytenoid joint dysfunction must be carefully individualized to the patient and the disease process. A patient with an inflammatory disorder should be treated medically with the aid of a rheumatologist. Stable patients that are able to phonate, breathe, and swallow without aspiration may be safely observed. Unstable patients or patients who are not improved with medical and rehabilitative strategies must be treated surgically. Patients with inadequate ventilation may undergo a tracheostomy, which would likely result in an excellent voice due to the paramedian position of the vocal folds. Patients that wish to be decannulated can be offered a cordotomy or arytenoidectomy; however, the patient must be counseled that this will result in an inferior voice.

A CO2 laser endoscopic posterior partial transverse cordotomy can sometimes provide an adequate airway and allow decannulation in a patient whose true vocal folds are in a paramedian position, cannot be abducted, and prevent adequate airflow through the glottis. The cause of the medialized vocal folds may be either bilateral cricoarytenoid joint fixation or bilateral vocal fold paralysis. The procedure of laser cordotomy involves excising a transverse wedge of tissue from the posterior portion of the vocal fold just anterior to the vocal process of the arytenoid cartilage. The technique may also be performed bilaterally. Sequelae of the procedure include granulation or scar tissue formation at the site of the cordotomy, possible need for a repeat procedure, and decreased voice quality.

Excision or lateralization of the arytenoid cartilage is a second option for providing for improved patency of the airway when the vocal folds are adducted and airflow through the glottis is inadequate. The arytenoid cartilage may be removed surgically, and the true vocal fold sutured laterally to improve the airway. Likewise, an endoscopic laser partial arytenoidectomy may...
be performed. The goal of both techniques, as with posterior transverse laser cordotomy, is to improve airflow through the posterior part of the glottis while minimally affecting the anterior two-thirds of the glottis, which is largely responsible for phonation. A another option is to split the posterior cricoid plate and interpose a cartilage plate to increase the diameter of the posterior glottis. This is particularly useful in patients with concomitant subglottic stenosis. None of these techniques are ideal, and the choice of technique used should be tailored to the individual patient.

CONCLUSIONS

The successful management of the airway requires a complete understanding of the anatomy and function of the upper aerodigestive tract. A systematic and progressive algorithm must be employed in cases of airway distress. Several options exist for the management of patients that require a surgical airway, and the correct technique must be individually matched to the clinical situation.

LTS poses a formidable challenge to the airway surgeon due to variability in both the location and degree of stenosis. Stenosis segments must be carefully evaluated prior to treatment planning. Treatment must be individualized to the patient taking into account the cause and structure of the lesion as well as the health status of the patient.

Neurogenic Disorders of the Larynx

Christy L. Ludlow, PhD
Steven A. Bielamowicz, MD

Normal speech requires the complex integration of peripheral and central motor control mechanisms. The voice component of speech requires (1) neural control of the intrinsic and extrinsic laryngeal muscles to shape the glottis, and (2) a steady stream of airflow from the respiratory system to support regular, symmetric, and synchronous vibration of the vocal folds. Speech production requires the coordination of laryngeal function with pharyngeal shape as well as tongue, lip and jaw position, and articulation. Thus, the central nervous system must coordinate the respiratory, phonatory, and speech mechanisms to produce normal phonation during speech.

EFFECTS OF SPEECH ON LARYNGEAL VIEW DURING ENDOSCOPY

The larynx does not function in isolation from other structures in the vocal tract. Muscles shaping the pharynx and oral cavity, particularly those controlling the tongue, lip, and jaw, alter laryngeal tension as they change vocal tract posture. In normal speech, the vocal tract moves rapidly between different target shapes for specific speech sounds.

Valing at the glottis, velum, tongue, lips, and jaw amplifies certain harmonics of the fundamental frequency of vocal fold vibration, based on the posture and shape of the vocal tract. Depending upon the shape of the vocal tract, harmonics of certain resonant frequencies are amplified resulting in sound energy in formants. The frequency regions of the formants are responsible for the vowel sounds. In high vowel sounds such as /i/ or “ee,” the posture of the tongue is high and forward exerting tension from the tip to the base of tongue. Coupling between the hyoid bone and suspended thyroid cartilage distributes tension to extrinsic and intrinsic laryngeal musculature that may tilt the thyroid cartilage. During /i/, the pharyngeal cavity is large, making conditions for airflow different than for production of /a/ or “ah” which is characterized by a constricted pharyngeal cavity because of the low and posterior placement of the tongue.

These differences in pharyngeal constriction also affect videendoscopy; the vowel /i/ allows a better view of the larynx because the tongue is forward and high, opening the pharynx and bringing the epiglottis forward. In contrast, during /a/ the larynx is much less visible because the tongue is back and consequently the epiglottis covers the larynx, providing a more obstructed view of the larynx.

MULTIDIMENSIONAL ASPECTS OF VOICE FUNCTION AND DISORDERS

Pharyngeal and/or laryngeal constriction can produce turbulence in airflow, in the case of neurogenic disorders. In these disorders, reduced vocal fold adduction can produce glottal insufficiency and inefficient voice production leading to a disturbance in vocal quality and durability of sound production. The acoustic product is thus affected by changes in constriction and air pressures in the pharynx and oral cavity. Both peripheral and central neurogenic disorders may alter the voice by changing the configuration of the larynx and vocal tract. In functional voice disorders, changes in vocal tract tension can also alter voice to a similar degree as in neurogenic voice disorders. Abnormalities in vocal tract tension due to voluntary or involuntary muscle contractions occur in neurogenic and/or functional voice disorders. The origins of these disorders may be traumatic, neoplastic, vascular, infectious, degenerative, or idiopathic. They are often present in conjunction with disease processes that alter not only the laryngeal musculature but also lip, tongue, and jaw control and other motor systems such as respiration.

In addition to the degree of motor impairment, the diagnostic process must also take into account the body’s capacity for reorganization and compensation that may alter the perceived severity of speech disturbance. Perceptual voice parameters such as pitch, loudness, voice quality, and their variability, may help to characterize neurogenic and functional voice disorders. Quantification of acoustic and perceptual characteristics of voice and speech may be useful based on a variety of instrumental techniques. Computer-assisted quantification of the acoustic product may be a valuable adjunct to the perceptual parameterization of voice, however the two are not synonymous. Measures based on pressure and flow transduction during phonation provide information about the functional relationship between the respiratory and phonatory systems. Further, the use of diagnostic imaging techniques, including rigid and flexible fiberoptic videoendoscopy, allows observation of laryngeal and pharyngeal movement. Flexible fiberoptic examination is required when the voice disorder occurs more during connected speech, such as in spasmodic dysphonia (SD). Stroboscopic examination is useful in assessing the vibratory characteristics of the vocal folds. High-speed photography, ultrasound, videofluoroscopy, and magnetic resonance (MR) are other imaging tools that have value in the diagnostic protocol.

Use of electromyography (EMG) accompanied by magnetic stimulation of the laryngeal nerve may be valuable in differentiating peripheral and central neurogenic dysfunction. The goal of instrumental and perceptual techniques has been to characterize vocal fold movement control in terms of timing, speed, and accuracy of movement of vocal tract structures and to quantify these parameters for the documentation of the status and progression of disease for therapeutic purposes.

NEUROGENIC DISORDERS

Dysphonia can appear as the first sign of neurogenic disease while the other speech symptoms (dysarthria) may only become evident as the disease progresses. Therefore, caution should be used in treatment of neurogenic voice symptoms until it can be assured that the laryngeal disorder is focal and not part of a progressive neurodegenerative disease. For example, what may initially appear to be a unilateral idiopathic vocal fold paralysis might later progress to become a vocal fold paralysis as part of a peripheral neuropathy; early unilateral effects of Parkinson disease with bowing in one vocal fold or multiple systems atrophy. A unilateral thyroplasty could be detrimental if bilateral vocal fold paralysis developed due to a peripheral neuropathy or neurological disease subsequently resulting in airway compromise. For this reason, a complete neurological examination is important before planning intervention in these disorders.

Functionally, neurogenic disorders resulting in dysphonia may be divided into the following categories:

1. Consistent neurogenic voice disorders are characterized by constant vocal quality,
louderness or pitch deviations during speech, and sustained vowels. Examples include flaccid dysarthria, due to lower motor neuron disease such as amyotrophic lateral sclerosis, progressive supranuclear palsy, a peripheral neuropathy or laryngeal nerve injury. These can produce paralysis or paresis of the adductor and/or abductor muscles, causing asymmetries in movement. On the other hand, tension in the vocal fold may be altered when either the cricothyroid muscle or the thyroarytenoid muscles are affected as both contribute to vocal fold tension.

2. Spastic dysarthria, including dysphonia, is associated with upper motor neuron disease involving the corticobulbar tracts. For example, spasticity of the vocal tract, including the vocal folds, may be seen in multiple sclerosis.

3. Nonrhythmically fluctuating neurogenic voice disorders are most common. These are characterized by unpredictable, irregular variations in quality, loudness, and pitch during speech. Sustained vowel production may accentuate irregularities in some cases. A tachic, choreic, and dystonic dysphonia, including spasmodic dysphonia, display this type of irregularity.

4. Rhythmically, fluctuating neurogenic voice disorders include palatopharyngolaryngeal myoclonus and essential voice tremor. These dysphonias are marked by regular or rhythmic fluctuations in voice, pitch, and loudness.

5. Neurogenic voice disorders associated with loss of volitional control of voice production, including apraxia of phonation, respiration or speech, and akinetic mutism, usually follow a cerebrovascular accident or cortical injury. In addition, paroxysmal neurogenic voice disorders exhibit bursts of dysphonic voice, as in Gilles de la Tourette syndrome.

6. Fluctuating vocal fold paralysis can occur in myasthenia gravis mimicking a vocal fold paralysis.

Upper Motor Neuron Disorders

Upper motor neuron diseases which affect the voice include Parkinson disease and related syndromes. Parkinsonism is a pathophysiological state reflecting failure of the nigrostriatal dopaminergic neuronal system due to degeneration or destruction of the substantia nigra. This can occur by depleting neuronal dopamine, inhibiting its synthesis, or blocking the striatal dopamine receptors. The basal ganglia modulate cortical control via the thalamus. Neural activity at the cortex, in turn, controls the lower motor neurons. Hence, damage to the basal ganglia can release inhibition of nerve impulses affecting the lower motor neurons, resulting in rigidity and reduced rate of movement (bradykinesia).

Hypophonia in Parkinson Disease. Although parkinsonism can be described as a syndrome of diverse origins, distinct syndromes are identified by specific clinical features, although differentiation is often difficult. Parkinson disease occasionally can be familial, and genetic predisposition can be both Mendelian or a complex interaction of a genetic predisposition with environmental factors. Onset is typically in the sixties or later, but the disease may appear as early as the mid-thirties. Rare cases have been reported as early as 15 years of age.

Reduced loudness and breathy vocal quality, referred to as hypophonia, are the hallmark of voice disorders in early Parkinson disease. An essential feature is a voice quality that fades into breathiness in contextual speech. The patient may have difficulty with production of glottal stops or voice onset after voiceless consonants such as /s/. For this reason, persons with early onset of Parkinson disorder may have similar voice symptoms to abductor spasmodic dysphonia. A reduced range and speed of vocal fold movement, particularly on the more affected side, is often identified. Distinctions between voiceless and voice sounds become reduced due to impaired ability to produce glottal stops to mark word boundaries. In later stages of the disease, the patient may be unable to produce phonation even with instruction. In advanced disease, severe "on-off" drug-related phenomena may occur, during which patients may experience breathy voice followed by periods of propulsive voice with strained quality. Vocal fold imaging studies in Parkinson disease often illustrate incomplete glottic closure during voicing along with bowing of the vocal folds. Asymmetries have also been demonstrated in vocal fold closure as well as thinning of the vocal fold mucosa and vocal fold bowing.

Patients can increase voice intensity on demand, and voice therapy aimed at increasing vocal intensity can improve speech intelligibility and voice when combined with dopaminergic enhancement therapy. Focus on upper articulators (lip, tongue, and jaw) movement produces little in the way of increased intelligibility for this population. Percutaneous collagen has been used to improve the breathy hypophonia of Parkinson disease in persons with vocal fold bowing and glottic insufficiency, especially in the patient with early symptoms. Collagen therapy does not, however, improve overall speech intelligibility in patients with preexisting dysarthria producing speech intelligibility and articulatory precision problems.

Progressive Supranuclear Palsy. Progressive supranuclear palsy (PSP) is a rare degenerative neurological disorder characterized by supranuclear ophthalmoplegia, complaints of falling backward, nuchal dystonia in extension, moderate axial dystonia, pseudobulbar palsy, difficulty in swallowing, dysarthria, bradykinesia, masked facies, nonspecific changes in personality, lability, sleep disturbance, and performance decrements on various neuropsychological tasks. PSP may be differentiated from Parkinson disease in that supranuclear ophthalmoplegia is characteristic of PSP and the tremor present in parkinsonism is typically absent in PSP. Patients with PSP may have voice symptoms similar to those in parkinsonism, with the possible exception of vocal tremor. Dysphagia is a major problem for these patients. Hypophonia is present, with unilaterally reduced vocal fold range and speed of movement. The associated dysarthria may include palilalia (uncontrolled syllable repetition) and oral motor rigidity.

Multiple Systems Atrophy. Multiple systems atrophy is another disease which is included as a Parkinson plus syndrome. This is a rare degenerative movement disorder with lesions in the cerebellum, brainstem, and basal ganglia. Three clinical variants are recognized: (1) spinocerebellar degeneration (olivopontocerebellar atrophy or OPCA); (2) progressive autonomic failure (Shy-Drager syndrome); and (3) atypical Parkinsonism (striatongral degeneration). OPCA is characterized by progressive cerebellar ataxia, and coordination of the laryngeal muscles is affected as in ataxic dysarthria. One sees loss of muscle coordination (dyssynergia), loss of ability to gauge range of motion (dysmetria), and tremor during voluntary movement (intention tremor). The degree of laryngeal impairment depends upon the severity of the ataxia. Dysphonia may take one of several forms: sudden bursts of loudness, irregular increases in pitch and loudness, or coarse voice tremor.

In Shy-Drager syndrome, voice symptoms typical of Parkinson disease are present, along with progressive autonomic dysfunction. The principal distinguishing features of this disease is autonomic dysfunction, including loss of bowel and bladder control as well as erectile dysfunction. Voice may be more severely affected due to reduced range and speed of adduction and abduc tion of the vocal folds. Speech is slowed with a reduction in vocal intensity, an absence of glottal stops and poor voicing contrasts. Patients may also be predisposed to laryngospasm. The most prominent laryngeal feature is airway compromise secondary to bilateral abductor paresis, and patients often require tracheostomy in the late stages of the disease. Voice treatment for these syndromes largely depends on the stage of disease and may include compensatory strategies as well as supportive nonverbal communication alternatives in end stages.

Pseudobulbar Palsy. Pseudobulbar palsy results from neuronal loss above the level of the nucleus ambiguus involving the corticobulbar tracts bilaterally. It can occur with vascular and degenerative lesions involving the cortical motor areas bilaterally, vascular lesions and tumors of the internal capsule or brainstem, degenerative lesions involving the entire corticobulbar tract system, or infections. Dysphonia associated with these types of lesions is characterized by strained, strangled, harsh voice, likely the result of hyperadduction of true and false vocal folds. This is thought to occur from inhibition of excitation of vagal nuclei. Some persons have a breathy voice with vocal fold asymmetry.

Multiple Sclerosis. Multiple sclerosis (MS) is a progressive demyelinating disorder, having sensory and motor impairments, some cognitive problems, spasticity, and tremor. Although one
of the most common causes of ataxia, patients with MS usually have evidence of central nervous system disease outside the cerebellum and its pathways. For example, optic nerve and corticospinal tract involvement are usually present. Dysarthria, tremor, and decomposition of movement are frequently associated with gait and limb ataxia in MS.

Essential features include staccato speech and harsh voice quality with intermittent hyperadduction of the vocal folds. Spasticity and tremor may affect all or some regions of the vocal tract, thereby reducing speech intelligibility and making speech effortful. Breathy voice and vocal fold movement asymmetry are common findings. Depending on the systems involved, voicing may or may not be affected in some stages of this disease. Given the predominant ataxia that may influence speech motor systems, voicing is characteristic of other ataxic dysarthrias (due to cerebellar degeneration). A principal feature of the natural history of MS is repeated acute neurological deficits with recovery in the relapsing-remitting phase followed by chronic progressive loss in the secondary progressive stage.

Myoclonus. Myoclonus is a sudden, brief, jerking involuntary movement of the involved muscles that occurs in a rhythmic fashion. The distribution may be focal, multifocal, or generalized, with the presentation spontaneous, active, and stimulus-sensitive. The source of the neural discharge may be cortical, brainstem, or spinal. Four main pathophysiologic categories of myoclonus have been described: cortical, subcortical, cortical-subcortical and spinal. These differ in the location of neurons involved in producing myoclonus. Sometimes these jerks are produced in response to external stimuli but most occur both at rest and during purposeful movements. In some patients, the symptoms can be voluntarily suppressed for short time periods.

Palatal myoclonus is focal affecting the movements of the palate either unilaterally or bilaterally at 1.5 to 3 Hz. It is frequently accompanied by synchronous movements of adjacent muscles such as the pharynx, tongue, larynx and occasionally by synchronous movement of the extraocular muscles, face, neck, or diaphragm. When the soft palate is involved, abrupt, rhythmic, anteroposterior, and vertical movements are present. This rhythmic activity can open and close the eustachian tubes, thereby producing a clicking sound transmitted to the middle ear. The clicking sound is the most disturbing feature of this illness and can result in a severe inability to initiate sleep. The constant clicking sounds can be treated by injection of the tensor veli palatini muscles with small dosages of botulinum toxin A. Movements are often present during sleep and may occur without the patient’s knowledge. Myoclonus may be idiopathic or may be seen in close head injury, or metabolic encephalopathy. Myoclonus may be idiopathic or may be seen in and may occur without the patient’s knowledge.

Lower Motor Neuron Disorders: Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), a motor neuron disease, may produce a mixed dysarthria because of both upper motor neuron involvement and some lower motor neuron involvement, particularly in the late stages of the disease (flaccid-spastic paralysis). ALS is a degenerative disease of the corticobulbar tracts and lower motor neuron nuclei. The speech and voice symptoms may vary depending on the predominance of spastic or flaccid components. Flaccid symptoms present as hypoaudation of one or both vocal folds and pooling of saliva in the pyriform sinuses on laryngeal examination. Voicing is characterized by breathy, hypernasal quality with reduced intensity range. A “wet” phonation is the result of poor management of secretions due to flaccidity. Dysphagia is common. If spastic components prevail, voicing will be strained and harsh because of hyperadduction of the true and false vocal folds. A mixed form of dysphonia may result in voicing characterized by both flaccid and spastic components. ALS occurs in the fifth to seventh decade of life and may present with primarily pyramidal tract signs or lower motor neuron signs of progressive muscular atrophy. Fasciculations are more common in the pyramidal tract form. When the disease affects the brainstem rather than the spinal cord, it may progress more rapidly. Speech symptoms may be the first signs in the bulbar type. Facial muscle weakness, palatal weakness, lip, tongue, and jaw weakness with tongue fasciculations are predominant and cause poor speech intelligibility. Voicing is weak and breathy because of flaccidity of the vocal folds.

Myasthenia Gravis. Myasthenia gravis is a disorder of acetylcholine transfer at the neuromuscular junction, characterized by weakness and fatigability of striated muscle. Muscle contraction, dependent on stimulation of the motor end plate by acetylcholine, is weakened or reduced by the reduction of acetylcholine receptors. This disorder causes a flaccid dysphonia, characterized by breathy, weak phonation. Sometimes stridor can develop with bilateral abductor muscle weakness. The voice intensity range is reduced, and sustained effort causes progressive weakness. This disorder may affect phonation (larynx), resonance (velum), and articulation (lip, tongue, and jaw), and these systems may be affected separately or serially as the disease progresses. The larynx is less frequently affected, whereas the extraocular muscles are usually the first affected. Dysphagia can be severe. This and other early disorders of neurogenic origin may present with reduced movement range and speed of the vocal folds on laryngoscopic examination and are often mistaken for psychogenic voice disorders. Flaccid dysphonia may be an early symptom of neurogenic disease.

Wallenberg Syndrome. Occlusion of the posterior-inferior cerebellar artery may produce infarction of the lateral medulla, resulting in Wallenberg syndrome, also known as lateral medullary syndrome. The medial and descending vestibular nuclei are usually included in the zone of infarction consisting of a wedge of the dorsolateral medulla just posterior to the olive. This syndrome is marked by dysarthria and dysphagia, ipsilateral impairment of pain and temperature sensation on the face, and contralateral loss of pain and temperature in the trunk and extremities. Major symptoms include vertigo, nausea, vomiting, intractable hiccuping, ipsilateral facial pain, and diplopia. Unilateral vocal fold paralysis and flaccid dysphonia occur when the nucleus ambiguous or corticobulbar tracts leading to the nucleus ambiguous are affected. If the paralysis does not completely resolve, a medialization laryngoplasty can provide improvement in both voice and some of the swallowing difficulties. However, many of these patients also have a central loss of swallowing patterning because of their brainstem lesions.

Postpolio Syndrome. Of the 250,000 survivors of the poliomyelitis epidemics, approximately 25% experience progressive muscle weakness known as postpolio syndrome (PPS). Patients with PPS who complain of swallowing difficulties are at risk for laryngeal dysfunction. This syndrome is characterized by the new onset of progressive muscle weakness, fatigue, and pain. This may occur 30 to 40 years after the initial infection with polio. Electrodiagnosis of neuronal dropout or axonal loss in these patients is consistent with neurogenic change. Patients with previous bulbar symptoms show evidence of neuronal degeneration. The course of this disease is variable. In some cases, patients may develop progressive vocal fold involvement leading to bilateral vocal fold paralysis and acute respiratory distress. Polio patients with swallowing complaints require a thorough laryngeal and voice assessment to evaluate for coexistent laryngeal pathology in addition to identifying appropriate therapy for dysphagia.

Disorders of the Peripheral Nervous System

The recurrent laryngeal nerves (RLNs) and external branches of the superior laryngeal nerves (SLNs) supply motor innervation to the laryngeal muscles, providing support for fine laryngeal control, as described in Table 1. The conduction velocity is high, estimated to be 50 m/s. Although the innervation ratio of fibers per motor unit in the human larynx is unknown, the laryngeal muscles are somewhat unique in that single muscle fibers have multiple neuromuscular junctions from the same nerve fiber. Multiple innervations per fiber would support an ability to control precisely the laryngeal muscles during phonation for parameters such as fundamental frequency.
Legan of the tenth cranial nerve at any point along its pathway from the nucleus ambiguous in the brainstem to the musculature cause paresis or paralysis of the laryngeal muscles resulting in dysphonia or even aphonia. The extent of vocal fold weakness and the degree of dysphonia depend upon the degree of neural injury and the location of the lesion along this pathway.

EVALUATION OF VOICE FUNCTION

Clinical evaluation of dysphonia includes diagnostic procedures to determine the cause of the voice disorder, the degree of phonatory deficit, and the prognosis for recovery of function. Based on these assessments, therapeutic recommendations may involve behavioral, medical, or surgical treatment. The most effective treatment plan often includes a multidisciplinary approach, using complementary techniques. For example, patients who present with vocal fold polyp may require microflap removal. To optimize outcomes, complementary care is often used to provide education on vocal hygiene and resonant voice techniques. Some diagnostic parameters measure the degree and nature of vocal impairment to determine appropriate intervention. Monitoring the patient’s progress throughout treatment is essential to achieve a successful outcome. Because phonosurgery does not always result in a normal voice, the speech-language pathologist or laryngologist must decide whether difficulties in ease of phonation are strictly or behaviorally based. This is best accomplished with a combination of instrumental and perceptual tests.

Videostroscopy

The importance of adequate visualization of the larynx during phonation and respiration cannot be overstated. These observations are usually made using laryngeal videostroscopy, which allows viewing of the vibratory characteristics of the vocal folds, as well as opening and closing gestures. A description of vibratory characteristics of the vocal folds should include basic information about the (1) symmetry of bilateral movements, (2) regularity of vibration, (3) degree of glottal closure, (4) mucosal wave amplitude, (5) mucosal wave excursion, (6) arytenoid regions, and (7) the opening-closing pattern of the glottis during the most closed phase.

Acoustic and Perceptual Measures

Perceptual assessment and acoustic objective measures are also useful in documenting progress and success of treatment. Measures of frequency and intensity characteristics of phonation should include fundamental frequency mean, vocal range, measures of vocal intensity, and vibration periodicity. Fundamental frequency is the acoustic correlate of pitch, measured in Hertz (Hz). Intensity, measured in decibels (dB), is the acoustic correlate of loudness. The range in each of these parameters reflects the flexibility of laryngeal dynamics available to the subject. Instrumental assessment of these factors as well as noise and harmonic structure in the voice signal is now available in a variety of computer-based systems designed specifically for voice analysis. Measures of the irregularity in frequency and intensity of the voice signal, also known as perturbation measures, may be useful in monitoring vocal performance in normal voices but often cannot be accurately used in dysphonia because of tracking difficulties for an abnormal signal. Jitter refers to cycle-to-cycle variation in time or period of vibration (frequency). Shimmer refers to variation in amplitude from cycle to cycle (intensity). Harmonics-to-noise ratio is often used to assess the degree of energy contained in harmonics of the fundamental frequency compared to turbulent noise between harmonics present during phonation. These values are thought to reflect abnormalities or asymmetries in mass, neural control, tension, and biomechanical characteristics of the vocal folds.

Aerodynamic Measures

Some measure of airflow or volume velocity is useful in determining how rapidly the air passes through the glottis. Mean airflow may be obtained from averaged measures over several glottal cycles. Mean airflow rates are useful in documenting change following phonosurgery, especially in surgical management of vocal fold paresis. Preoperative airflow is high and may return to normal after surgery. These measures are made using a pneumotachograph connected to a facemask placed over the face during voice production. Therefore, provide indirect measures of laryngeal airflow.

Subglottal pressure is important for vocal fold vibration and for modulation of vocal intensity. Subglottal pressure may be measured indirectly by a pressure transducer placed in the oral cavity. During production of sound “p” requiring lip closure, the vocal tract is a closed tube with equal pressure throughout. Pressure measured in the oral cavity reflects pressure beneath the glottis. In a related measure, glottal resistance is calculated by dividing subglottal pressure by mean airflow. Glottal resistance increases with vocal intensity and is thought to be low in cases of RLN paralysis. Phonation threshold pressure is the lowest subglottal pressure that a person can use to achieve phonation, and as such can be used as a measure of vocal fold stiffness. These and other quantifiable measures are currently routinely used in the evaluation of voice deficits including vocal fold paralysis. The acquisition of self-perceptual and objective data is key in the treatment program of patients with neurogenic voice disorders.

Neurophysiological Measures of Voice and Laryngeal Function

Electromyographic (EMG) evaluation is a useful adjunct in the assessment of neuromuscular disorders and is often used in prognostic judgments about patients with those disorders. Electrical silence, fibrillation potentials, polyphasic potentials, high-amplitude potentials, and percentage of normal potentials are the basis for interpretation of such examinations. EMG may be useful in differentiating a variety of voice disorders: peripheral and central vocal fold paralysis, functional disorders and arytenoid joint fixation. Otho
er have suggested the use of neuromyographic assessment that involves the direct stimulation of a laryngeal nerve in conjunction with the use of EMG to monitor resulting muscle activity. During this examination, the contraction of laryngeal muscles is monitored with EMG while the skin surface is stimulated in the area of the SLN. Transcranial magnetic stimulation over the mastoid can produce an action potential in the RLN as it emits from the skull, allowing measurement of the muscles response latency in the thyroarytenoid muscle. This technique can also induce a response in the efferent branch of the superior laryngeal nerve producing a response in the cricothyroid muscle. This is one means of obtaining an early estimate of the type and degree of laryngeal nerve injury. Compared with standard EMG, this technique may offer some advantage in monitoring the reinnervation of paralyzed laryngeal muscles following different reinnervation techniques.

LARYNGEAL PARALYSIS AND ASPIRATION

Vocal fold paralysis alone, rarely, results in aspiration unless the patient has a wide glottal gap. When vocal fold paralysis occurs in conjunction with other motor or sensory dysfunction, the combination may significantly impair the protective function of the larynx, leading to aspiration. Neurogenic causes of aspiration may include cerebrovascular accidents, degenerative...
diseases, neuromuscular disorders, peripheral nerve disorders, intracranial neoplasms, and anoxic or traumatic brain injury.

Evaluation of the patient with aspiration begins with a thorough history and physical examination and requires a multidisciplinary evaluation. The history should elicit information about associated neurological symptoms. These may suggest a generalized neurogenic disorder. In addition, information regarding baseline pulmonary status is critical, as this will dictate a patient’s tolerance of minor or moderate aspiration. Physical examination should include a general physical examination, a detailed neurological examination, as well as a thorough evaluation of cranial nerve function. Other testing should include a modified barium swallow to evaluate the oral and pharyngeal phase of swallowing using contrast material of different consistencies (thin liquids, semi-solids, and solid food) performed with the guidance of a speech-language pathologist.

Nonsurgical management of the patient with aspiration usually consists of discontinuing oral intake and providing alternative methods of alimentation. Enteral alimentation is preferable and short-term feeding is usually provided by a nasogastric feeding tube. For long-term feeding, however, a gastrostomy or jejunostomy is usually preferred. Attention should also be given to pulmonary toilet. Tracheostomy may be helpful in caring for patients with copious secretions; however, the presence of a tracheostomy may also contribute to problems with aspiration.

Specific surgical treatment of the patient with significant aspiration and vocal fold paralysis includes a variety of procedures to medialize the vocal fold discussed in Chapter 80, “Laryngeal Paralysis.” Patients in whom recovery of function is expected, procedures that are temporary or reversible are indicated, such as Cymetra or collagen injections.

For permanent difficulties with severe aspiration, other surgical techniques aim to separate the upper digestive tract from the upper respiratory tract. Unfortunately, patients undergoing such procedures frequently lose the ability to phonate and may also require a permanent tracheostomy. Such procedures can be performed with low morbidity, and some of these procedures are at least theoretically reversible should function return.

Narrow-field laryngectomy remains the oldest and one of the most effective surgical treatments of aspiration. Tracheoesophageal puncture can be used to restore phonation. Reluctance by the patient to sacrifice the larynx has led to the development of other procedures to close the larynx. Montgomery described a glottic closure technique in which the true and false vocal cords were approximated. Closure was improved by Sasaki and associates with the interposition of a sternohyoid muscle flap. This procedure was extremely effective but did not permit phonation, which was sometimes possible with supraglottic laryngeal closure methods. Since first being described in 1972, the epiglottic flap closure technique has undergone certain modifications, including intentionally leaving an opening posteriorly to permit phonation. Successful reversal of this procedure with an endoscopic approach and ease of reversibility. However, successful control of aspiration has not been uniform and long-term use of stents carries the risk of endolaryngeal injury, limiting their utility.

Tracheoesophageal diversion was developed by Lindeman with the goal of controlling aspiration definitively while preserving the larynx and RLNs and thus the potential for reversal. In this procedure, the trachea is divided at the level of the fourth or fifth ring. The proximal trachea is anastomosed to the esophagus; whereas the distal trachea is anastomosed to the skin. Thus, aspirated secretions are diverted back into the gastrointestinal tract. In the modified laryngotracheal separation procedure, the proximal segment is instead closed as a blind pouch. Both techniques have provided good control of aspiration, and both have been successfully reversed. Because no current method is completely satisfactory, investigations continue in an attempt to find a safe, effective means of controlling aspiration without disrupting respiratory or phonatory function. One possibility for the future may be implantable electronic systems now being developed in animals that can produce tight glottic closure or hyolaryngeal elevation during swallowing.

### SPASMODIC DYSPHONIAS

The spasmotic dysphonias (SDs) include adductor SD (uncontrolled closing of the vocal folds), abductor SD (prolonged vocal fold opening after voiceless sounds extending into vowels), or vocal fold tremor (modulations in phonatory pitch and loudness most evident during prolonged vowels). These disorders are characterized by involuntary changes in the ability to maintain voicing during speech either because of intermittent glottal catches (voice breaks) in the adductor type or breathy breaks due to prolonged vocal fold abductions in the abductor type. Only speech is affected; singing is less affected, and emotional expression (laughter and cry) and shout are unaffected. As the disorder progresses during the first 2 years, it may progress from only affecting vowel production during speech to interfering with other tasks or postures such as singing and speaking using falsetto. In mild to moderate forms of SD, patients may have uncontrolled spasms affecting only the speaking voice, with normal singing and falsetto phonation.

Onset often follows an upper respiratory infection, laryngeal injury or inflammation, a period of excessive voice use, or occupational or emotional stress. Increased effort is one of the major patient complaints along with loss of control and an increased difficulty with prolonged voice use or stress. Onset is characterized between 30 and 50 years of age, and 60 to 80% of those affected are women. Characteristics include
1. Symptoms are specific to a particular task, gesture, or posture of the larynx (vowels and glottal stops in adductor SD and voice onset after voiceless consonants in abductor SD);
2. Symptoms are action induced, that is, they appear only with voluntary movement and are not usually apparent at rest;
3. Symptoms become worse with prolonged speaking, practice, or performance;
4. Onset is usually gradual, often following an upper respiratory infection, laryngeal inflammation or injury, or a stressful period;
5. Reflexive and emotional aspects of vocal function are unaffected, such as coughing, crying, shouting, and laughing;
6. In professional voice users, the symptoms may appear with heavy professional schedules or following injury.

In some patients, particularly those with abductor SD, some degree of vocal fold asymmetry may be apparent only during speech. Movement abnormalities occur when the patient attempts specific gestures such as phonation of vowels or voice initiation after glottal stops in adductor SD, or for initiation of voice after voiceless consonants (such as s, h, t, k) in abductor SD, or on prolonged vowels in a speaking voice in vocal tremor. The etiology of these disorders is unclear at this time. In some individuals, these disorders occur in persons with a family history of dystonia; however, this occurrence is rare.

Diagnosis and Assessment
Diagnosis and management of patients with SDs is best accomplished by a voice team including an otolaryngologist, a speech pathologist, a neurologist, and, in some cases, a psychiatrist. Because these movement disorders affect the larynx, diagnosis depends upon observing the vocal folds during speech and nonspeech gestures. In addition, the larynx must be visualized to rule out other disorders which could account for the symptoms. The laryngologist rules out vocal fold nodules, polyps, carcinoma, cysts, contact ulcers, inflammation (laryngitis), vocal fold pariesis, or paralysis using fiberoptic laryngoscopy. A neurological examination is necessary to rule out amyotrophic lateral sclerosis, Parkinson disease, or supranuclear palsy, which can all produce vocal fold movement abnormalities. Some patients may also have concomitant focal dystonias such as writer’s cramp or blepharospasm. Many patients may have some degree of laryngeal tremor in addition to spasmodic hyperadduction or hyperabduction. These patients are usually included as a subtype of the spasmodic dysphonias and may have a more severe disorder.

An extensive history, a trial of voice therapy, and a psychosocial interview may be needed to rule out psychogenic dysphonia. Patients may have psychosocial reactions as a result of their voice disorder, confounding the ability to differentiate idiopathic SD from psychogenic disorders through history and interview. For example, many patients will no longer use the telephone and avoid social gatherings as a result of having a speech disorder. Voice disorders have not been found to produce mental illness, however.

Tasks to Be Examined during Fiberoptic Laryngoscopy
Both speech and nonspeech tasks must be sampled to identify (1) movement control abnormalities during vocal fold abduction (opening) and adduction (closing) in speech and (2) movement during nonspeech items such as respiration, sniffling, throat clearing, whistling, and singing. This is in contrast to paradoxical vocal fold movement disorder (PVFMD) where vocal fold abnormalities may only appear during inspiratory breathing but not speaking.

Fiberoptic laryngoscopy is useful in evaluating patients with dysphonia associated with neurological disorders for vocal fold movement during speech. Usually, stroboscopy is less helpful because patients with tremor or spasms do not have regular phonatory cycles that can be tracked from the contact microphone or electroglottographic signal. Further, in patients with other functional voice disorders, such as muscular tension dysphonia, the severe signal periodicity similarly interferes with tracking of the stroboscopy light source, rendering stroboscopic interpretation meaningless. The emerging use of kymography and eventually high-speed video will be particularly useful for examining vocal fold vibration in such patients, as these techniques do not rely on signal periodicity.

Speech Testing
Voice symptoms should be compared during following three tasks to discriminate between adductor spasmodic dysphonia, abductor spasmodic dysphonia, and vocal tremor:

1. Prolonged vowel phonation usually manifests tremor if it is present. Prolonged vowel production is affected only in the more severe forms of adductor and abductor SDs.
2. Production of sentences in which most sounds are voiced and contact glottal stop at word boundaries, for example, “We mow our lawn all year” and “We eat eels every day,” are usually most difficult and demonstrate frequent breaks or voice arrest in adductor spasmodic dysphonia.
3. Production of sentences with voiceless consonants (s, t, p, k, h), for example, “She speaks pleasingly,” “Keep Tom at the party,” “When he comes home we’ll feed him,” are usually most difficult in abductor spasmodic dysphonia. Sentences with predominantly voiced sounds are much easier to produce and smoother for these patients.

Electromyography
The laryngeal muscle activation abnormalities differ greatly across patients and can account for the wide variety of symptoms. The laryngeal muscles should be examined using laryngeal electromyography to determine which muscles contain spasms concurrent with a patient’s voice symptoms during speech. In adductor SD, the thyroarytenoid is the most often affected muscle. In abductor SD, spasms can be seen either in the cricothyroid or the posterior cricoarytenoid muscles as well as asymmetries in thyroarytenoid muscle activation during speech. In others, no spastic activity is identifiable and the thyroarytenoid muscle is inactive during vowels, that is, a “negative dystonia.”

In vocal tremor, a variety of muscles can be involved. Most often the thyroarytenoid is affected, but other muscles including the strap muscles can be affected including the thyrohyoid, the sternothyroid, and in some patients with adductor tremor, either the cricothyroid or posterior cricoarytenoid, or both. By using a concentric EMG electrode connected to an amplifier with a dual channel storage oscilloscope, one channel for the EMG and another for the speech waveform, at a slow sweep speed, quick identification can be made of the muscles having spasms during voice breaks.

For the thyroarytenoid and lateral cricoarytenoid muscles, items to be examined for spasmodic bursts concurrent with voice breaks include prolonged “ee,” repeated “ee,” and all voiced sentences such as “We mow our lawn all year.” When examining abductor SD, while recording from the cricothyroid or posterior cricoarytenoid, speech should include “see-see-see,” “pea-pea-pea,” “he-he-he,” “K athy took a potato,” and “Keep Tom at the party.” Muscles with bursts of activity before and during voice breaks can be considered for injection with botulinum toxin injection.

Treatment
In the last 20 years, the following treatments have been used for managing symptoms of patients with adductor spasmodic dysphonia.

Voice Therapy. Voice therapy can assist mildly affected patients but may not have long-lasting effects. When uncertain of the diagnosis of a patient’s voice disorder, a trial of voice therapy is recommended. Usually within three sessions, a speech pathologist experienced in voice therapy will report whether or not voice therapy might be beneficial for a patient. Voice therapy may also be helpful after botulinum toxin injection by prolonging the benefit period.

Recurrent Laryngeal Nerve Section. Dedo28 first described unilateral removal of a short segment of the RLN below the thyroid isthmus for the treatment of adductor SD in 1976. The procedure resulted in an initial dramatic reduction or elimination of voice spasms, but symptoms may recur in up to 64% of cases.29 Recurrence of symptoms has been attributed to reinnervation of the operated side based on electromyographic and histological studies. Those patients failing surgery may still respond to botulinum toxin injections. Due to the high rate of symptom recurrence, the
permanent alteration in laryngeal function, and the requirements for subsequent medialization surgery in some patients with excessive breathiness, RLN section is less preferred to botulinum toxin injections at the present time.

**Recurrent Laryngeal Nerve Avulsion.** Netterville and his colleagues proposed a more extensive removal of the recurrent nerve in an effort to reduce the risk of reinnervation into the distal stump of the sectioned recurrent laryngeal nerve. After mobilization of the ipsilateral thyroid lobe, all branches of the RLN are identified, traced, and avulsed from their muscular insertions deep to the cricoarytenoid muscles. The total length of RLN removed averages 9 cm, in contrast to an average of 2 cm reported in previous RLN section studies. Long-term follow-up, 3 to 7 years, on 18 patients following recurrent laryngeal nerve avulsion revealed that 16 patients (89%) were free of SD symptoms at 3 years. Two of these patients, however, later developed recurrent spasms following medialization laryngoplasty for treatment of a breathy voice. Thus, an overall success rate of 78% (14/18) was reported for this series which compares favorably to long-term recurrence rates for the more limited RLN section. Weed and colleagues recommend that RLN avulsion be reserved for patients who do not benefit from or do not tolerate botulinum toxin injections and for patients who have failed prior RLN section.

**Selective Laryngeal Adductor Denervation Reinnervation.** Berke and colleagues published preliminary results with selective bilateral denervation of the laryngeal adductor muscles in an attempt to achieve a permanent bilateral adductor weakness that mimics the transient effects of botulinum toxin injection. This procedure involves bilateral section of the adductor RLN branches to the thyroarytenoid and lateral cricoarytenoid muscles while preserving the natural innervation of the posterior cricoarytenoid muscle. In addition, the distal thyroarytenoid branches are reinnervated using branches of the ansa cervicalis nerve. The aim of this directed reinnervation is to prevent unwanted reinnervation by RLN efferents and to preserve adductor muscle tone. The study presented 1- to 5-year follow-up on 21 patients with adductor SD who underwent the procedure. In general, symptoms and overall severity of SD improved from moderate to severe ratings preoperatively to mild to absent ratings postoperatively. All patients experienced severe vocal fold bowing and breathiness in the early postoperative period that improved after 3 to 6 months. A aspiration of greater than 2 weeks duration was noted in 2 patients, one of whom required hospitalization for aspiration pneumonia. Additional treatments (botulinum toxin, voice therapy, collagen injection, thyroarytenoid myotomy) were also performed in several patients to enhance the postoperative voice result. These authors have subsequently published an analysis of the long-term results of these procedures. The average follow-up was 49 months. A total of 83 patients filled out pre- and postoperative Voice Handicap Index (VHI) scores with an improvement from 36 to 13. Eighty-three percent of the subjects showed improvement in the VHI. Perception evaluation of voice samples after surgery revealed voice breaks in 26% of the subjects. The authors report promising results with normal conversational voice intensity, good in phonation in most patients, and patient satisfaction of 91%.

**Botulinum Toxin.** This approach was developed in 1987 and has been evaluated using unilateral or bilateral thyroarytenoid injections in adductor spasmodic dysphonia. Significant voice improvement occurs in 70% of patients for up to 3 months, followed by gradual symptom return over a 1- to 3-month period. Patients are usually retreated three to four times per year. Difficulties associated with this treatment include the wide variability of dosing response. Whereas the average patient receiving a bilateral injection is treated with a total of 4 units, patients may receive from 0.375 units up to 12 units. In patients receiving unilateral treatments, dosing may vary from 0.25 units up to 30 units. Identifying the ideal dosing is by trial and error.

The most commonly used method of injection is the percutaneous EMG-guided approach through the cricothyroid membrane. The injection needle is Teflon coated except for the bared tip which serves as a monopolar electromyographic electrode when the bared hub is connected to an EMG amplifier. This allows monitoring of the needle tip into active muscles, avoiding areas of denervation. Placing the medication at the site of active units within the muscle is the optimal treatment location.

To approach the thyroarytenoid (TA) muscle percutaneously, the needle is angled superiorly and slightly laterally to approximate the vocalis portion of the TA muscle. However, the needle tip can easily be placed more posteriorly than intended, medial to the lateral cricoarytenoid (LCA) muscle. From this, it is apparent that posteriorly placed injections may denervate portions of the LCA and cricothyroid (CT) muscles, in addition to the TA either by direct injection of these muscles or by diffusion across fascial planes. This could account for the variability in response that is often seen (1) among patients and (2) in the same patient from consecutive EMG-guided injections several months apart, although the same technique and dosages are used.

Two approaches have been used, either large unilateral injections producing unilateral vocal fold paresis or small bilateral injections which do not alter vocal fold mobility. The long-term effects of repeated needle insertion and repeated denervation by botulinum toxin on laryngeal muscles are as yet unknown. Muscle biopsies in laryngeal spasm patients treated repeatedly with botulinum toxin injection have demonstrated significant muscle scarring and atrophy. Similar changes in both thyroarytenoid muscles could have long-term effects on airway protection.

The disadvantage of the unilateral injection approach is that a large dosage of toxin must be administered, and immobility of the injected fold often results. An advantage of the bilateral approach is that much smaller dosages of botulinum toxin can be used, reducing the cost, and effective symptom control can be obtained without any observable change in range of motion. Partial denervation seems to be effective in reducing the degree of hyperadduction, resulting in less interference with phonation. The disadvantages are that injections and needle insertions are performed on both sides of the larynx. With repeated injections over many years, damage might result to both sides of the larynx. A few patients lose symptom control over a period of many years with continued injections, although the mechanisms for the loss of benefit are not clear. Some of these patients may be managed by switching injection sides and beginning treatment in a previously noninjected muscle resulting in the return of symptom control. Other injection techniques which utilize visualization of the vocal folds rather than electromyography to guide placement of the injection needle include the indirect laryngoscopic peroral method, a transcricotinal method, as well as injection using a flexible catheter through a channelled laryngoscope. The usual dosages used by each technique are presented in Table 3.

Within 5 days of TA muscle botulinum toxin injection, the numbers of breaks in phonation on vocal folds are reduced, the presence of voice roughness or hoarseness is reduced on spectrographic analyses, and speech rate is increased. Patients' subjective reports include a reduction in speech effort and tension, reduced numbers of breaks, and greater voice control. Two major side effects are reported. Breathiness and swallowing difficulties. These side effects do not occur in all patients; however, they are dose-dependent affects.

Botulinum toxin injections have been employed in adductor spasmodic dysphonia in both the CT and the posterior cricoarytenoid muscles. Only about two-thirds of persons with adductor SD are benefited and to a lesser degree than those with adductor SD following TA muscle injections. The effects of vocal tremor on voice production can also be reduced by

botulinum toxin injection; however, the outcome is less predictable and not all persons with vocal tremor are benefited. In those patients with tremor affecting only the vocal folds and involving just the TA muscles, this treatment can be as effective as in adductor spasmodic dysphonia. However, many patients with this disorder have involvement of the strap muscles and have limited benefit even when these additional muscles are injected. Great care should be exercised with strap muscle injections due to significant concerns over aspiration symptoms.

**MUSCULAR TENSION DYSPHONIA**

Muscular tension dysphonia was first described by Morrison and his colleagues as dysphonia resulting from increased muscular tension in the paralaryngeal and suprahypoid muscles, (2) elevation of increased phonatory muscle tension in the paralaryngeal muscles, resulting from increased muscular tension in the supraglottic structures. It is unclear whether this additional muscular tension is part of the SD or tremor disorder or the result of the patient using a compensatory strategy to prevent instability during vocal fold vibration for speech. In some patients, the muscular tension dissipates following injection of botulinum toxin whereas in others, voice therapy may be a helpful adjunct in alleviating some of this tension following botulinum toxin injection.

The distinction between muscular tension dysphonia and adductor SD can be the degree to which the abnormal laryngeal posture is used consistently for voice production (Table 4). In muscular tension dysphonia and other variants of vocal misuse, the abnormal vocal fold positioning seen on fiberoptic videostroboscopy is consistent regardless of the type of speech. In the spasmodic dysphonias, the abnormalities are intermittent depending upon the voicing gesture required and contain irregular rapid adductor or abductor movements causing intermittent voice breaks on particular types of speech sounds, vowels in adductor SD, and prolonged voiceless consonants in abductor SD. In benign essential tremor, these intermittent voice breaks are regular, usually around 5 Hz. However, in some of the more extreme forms of spasmodic dysphonia and/or muscular tension dysphonia, the differentiation can be difficult because the spasmodic involuntary movement abnormalities may be difficult to identify when patients have extreme muscular tension. Wheneve a possibility of either diagnosis exists, a trial of voice therapy by a speech pathologist experienced in treatment of these disorders is recommended, before considering botulinum toxin. Muscle tension dysphonia is also discussed in Chapter 81, “Muscle Misuse Disorders of the Larynx”.

PARADOXICAL VOCAL FOLD MOVEMENT

Paradoxical vocal fold movement (PVFM) is the adduction of the vocal folds during the inspiratory phase of respiration producing impaired inspiratory airflow and stridor. These patients have normal vocal fold movement during speech yet have breathing difficulties on inspiration during connected speech. This disorder may be categorized as (1) an idiopathic focal dystonia or part of M eige syndrome; (2) associated with or masquerading as asthma; (3) exercise-induced stridor; (4) psychogenic; and, (5) associated with laryngopharyngeal reflex. Most cases of PVFM have been reported as psychogenic. In such cases, the symptoms abate following psychotherapy and speech therapy.

The first presentation of PVFM as a focal laryngeal dystonia specific to inspiration suggested that in some patients this is not psychogenic, but rather due to involuntary spastic bursts in the thyroarytenoid muscle. Patients with a focal dystonia report that the symptoms are not present during sleep, but that the symptoms are often present during the daytime and may become exacerbated by exercise and stress. Some success with bilateral thyroarytenoid injection of botulinum toxin has been reported in selected cases not responsive to speech therapy, psychotherapy, and pharmacology.

Patients with M eige syndrome, an orofacial dyskinesia, can develop pharyngeal spasms producing intermittent airway obstruction, either because of pharyngeal constriction or obstruction at the epiglottis. A gain, the symptoms are absent during sleep, almost always present during the day, but are exacerbated by stress.

Patients with chronic asthma can have laryngeal vocal fold adduction during asthmatic attacks. However, the underlying pathophysiology has been hypothesized as either psychological, a learned response, or a dystonic reaction following many years of habitual use for disease management. Exercise-induced asthma has also been reported to have a laryngeal adduction component.

Loughlin and Kofman have suggested that gastroesophageal reflux is a common cause of paroxysmal laryngospasms. Patients presented with intermittent, sudden-onset, noisy obstructed breathing, that some termed choking episodes. These attacks of stridor often occurred following a meal, after the start of exercise, or after bending over. Sometimes they occurred at night. The number of reported episodes can range from twice a day to twice a year. These attacks usually last a few minutes. All complained of symptoms of reflux such as a lump in the throat, chronic throat clearing, cough, intermittent hoarseness, and difficulty swallowing. All responded well to life style modification and omeprazole 20 mg b.i.d.

Laryngeal Paralysis
Lucian Sulica, MD

Paralysis of one or both vocal folds may compromise any of the important physiologic functions of the larynx, that is, breathing, swallowing, and voicing. Individuals with laryngeal hemiparesis typically complain of a broad range of symptoms reflecting variable degrees of glottic insufficiency. The most prominent of these are breathy dysphonia and dysphagia, particularly for liquids. Breathlessness while speaking and breathlessness during physical activity may also be present. When both vocal folds are involved, patients generally complain of symptoms of glottic obstruction like stridor and dyspnea. The distinction in symptoms between unilateral and bilateral paralysis arises from the two essentially opposed valving tasks of the larynx: glottic opening for respiration, and glottic closure for airway protection, thoracic stabilization during effortful activity, and phonation.

The first important clinical task in the evaluation of an individual with vocal fold motion impairment is to identify and treat the cause, if possible. In the majority of cases, vocal fold immobility or hypomobility is caused by disease or injury of the peripheral laryngeal nerves. Less commonly, laryngeal paralysis results from central nervous system damage. Rarely, mechanical factors may result in cricoarytenoid fixation, usually after prolonged intubation or other obvious laryngeal trauma.

Effective and rational management of symptoms follows the search for the cause of paralysis. Some cases of paralysis resolve or at least improve symptomatically, without intervention, whereas others require treatment. Distinguishing between these two groups remains a challenge, and many otolaryngologists consequently choose to delay treatment, sometimes despite considerable patient disability, until the possibility of spontaneous recovery is judged remote. In patients with unilateral paralysis, a variety of procedures are available to alleviate symptoms in almost any clinical situation, regardless of prognosis. Temporary and permanent injection medialization, medialization laryngoplasty, arytenoid cartilage repositioning surgery, and reinnervation procedures have all been used with varying degrees of success. On the other hand, treatment options in bilateral immobility are less satisfactory, occasionally requiring the sacrifice of some voice quality to establish an adequate airway.

PATHOPHYSIOLOGIC CONCEPTS

In the majority of cases, laryngeal paralysis is the result of peripheral nerve damage, typically from a variety of mechanical traumas. Although the superior laryngeal nerve may or may not be affected (and in fact, may be affected alone, a clinical situation which will not be reviewed here), the fibers of the recurrent nerve at least must be involved to cause gross vocal fold immobility.

Generally speaking, mild pressure on a peripheral nerve produces segmental demyelination and impairs axonal transport, the degree and severity of the conduction block being proportional to the severity of the injury. Remyelination over a preserved axon usually restores nerve conduction and function. Injuries which interrupt the axon, such as nerve section or severe crush, produce wallerian degeneration along the entire length of the nerve distal to the injury beginning within 24 hours of injury. Functional recovery depends on preservation of neural conduits for axonal regeneration. The basal lamina of the original nerve fibers may be preserved in a severe crush injury (axonotmesis), and proximal axonal sprouts may reach the appropriate muscle. If the nerve is transected (neurotmesis), the proportion of nerve fibers that find their way to the original target is low and inversely proportional to the size of the gap between proximal and distal segments.

Regeneration of the recurrent nerve is more problematic than that of most peripheral nerves, because it carries a mixed population of adductor and abductor fibers. Furthermore, laryngeal paralysis turns out to be a heterogeneous condition according to many clinical criteria, for example, symptoms, vocal fold position, and electromyographic evidence of the degree of nerve damage.1,2 Unless due to severe trauma like transaction, each case differs from the next in degree of neural impairment, and features a mix of injury types among its nerve fibers. This latter aspect is a principal reason why the Seddon classification of nerve injury, reviewed in the previous paragraph, is not entirely useful or satisfactory in vocal fold paralysis.

In addition, both human and animal studies have shown that the larynx has a strong propensity for reinnervation.2–4 In fact, reinnervation appears to be the rule rather than the exception, even after deliberate recurrent nerve section, as was formerly done for the treatment of spasmodic dysphonia.5,6 A paralyzed vocal fold is thus only sometimes, and perhaps quite rarely, a denervated vocal fold.

In many cases, however, vocal fold reinnervation is dysfunctional and does not yield physiologic motion. This neural dysfunction extends beyond traditional notions of synkinesis, in which co-contraction of adductor and abductor fibers produces no net vocal fold motion; after all, such perfectly balanced antagonism is an extremely improbable outcome of a largely random process. Dysfunctional reinnervation may also result when nerve regrowth is appropriate but inadequate, which may result in decreased force of contraction, loss of motor unit specificity, increased muscle fatigue, and possibly also in changes in neural organization peripherally and centrally.7 The complex, highly specialized nature of the laryngeal neuromotor system leaves many ways in which reinnervation may miscarry.

Vocal fold innervation has traditionally been conceptualized as an all-or-none phenomenon, with paralysis or, more precisely, absence of motion, resulting from a lack of neural input. This view is clearly oversimplified and inaccurate. Vocal fold paralysis is probably best considered as a continuum of neurogenic dysfunction encompassing partial denervation, complete denervation, and variable degrees and patterns of reinnervation.

This has at least two important clinical implications. First, differing degrees and patterns of innervation probably account for variability in the position of the paralyzed vocal fold. For most of the last century, vocal fold position was thought to reveal the site or type of lesion, beliefs that have no physiologic basis and, moreover, have been invalidated by careful clinical and laboratory work.8–11 Terms like “paramedian” and “cadaveric” carry no topodiagnostic significance, and are useful as mere descriptive conventions, if at all. Further, it is now clear that notions of discrete “abductor” or “adductor paralysis” also have no physiologic validity.

Second, the natural tendency for reinnervation may account for the general trend for the voice to improve over time in unilateral vocal fold paralysis. Reinnervation likely acts to restore or preserve muscle bulk and tone, increasing the vocal fold’s mass and resistance to airflow, occasionally to the point that phonatory glottic closure is
restored and conversational voice sounds normal although the vocal fold itself remains immobile (Figure 1). This explanation, well supported by electrophysiologic evidence, is probably closer to reality than the notion of gradual contralateral compensation.

**CAUSES OF LARYNGEAL PARALYSIS**

Most sources of nerve injury fall into three broad categories: damage from surgical operation or other trauma; compromise from a range of medical conditions; and dysfunction due to factors yet to be completely identified, designated “idiopathic.” The relative frequency of causes of unilateral laryngeal paralysis varies considerably, both among and within these broad categories (Table 1). Differences result from demographic and epidemiologic features of populations from which case series are drawn, as well as differences specific to the reporting institution. For example, an unusually high proportion of cases due to malignancy in a Scotch series reflects the high incidence of lung cancer in that country. Because reports tally causes in relative incidences, unusual distributions may skew the relative frequency of other causes and create inaccurate impressions. The relatively high incidence of idiopathic unilateral paralysis in two Japanese series, for example, is more likely the consequence of a low prevalence of mediastinal malignancy than any heretofore unrecognized virus tending to cause laryngeal paralysis.

Despite such variability, it is possible to draw some conclusions regarding unilateral laryngeal paralysis. In the vast majority of cases, laryngeal paralysis is caused by a peripheral neuropathy rather than a central nervous system process. In most series, laryngeal paralysis tends to affect men more often than women, probably reflecting the underlying gender distribution of thoracic malignancy. Uniformly, the left vocal fold is affected more often than the right, in approximately a 60:40 ratio or greater, due to the greater length and more profound descent into the thorax of the left recurrent laryngeal nerve and its consequent greater vulnerability to disease and surgery. Left-sided paralysis is more likely to be related to malignancy, although the possibility of malignant causation in right-sided paralysis should not be discounted.

Iatrogenic sources of injury have multiplied over time. In addition to thyroidectomy, still a main source of iatrogenic laryngeal paralysis, anterior approach to the cervical spine, carotid endarterectomy, and various cardiac and thoracic procedures have all become significant sources of laryngeal nerve injury (Table 2). Table 3 shows composite data for incidences of laryngeal paralysis, including information regarding permanent and temporary paralysis where available, from several recent series. Recurrent nerve damage from the cuffed endotracheal tube was recognized in the 1960s and early 1970s and continues to account for instances of vocal fold immobility which are demonstrably neural in origin and not the result of cricoarytenoid joint disruption.

A number of neurogenic conditions remain important albeit unusual causes of laryngeal paralysis (many are discussed in Chapter 79, “Neurologic Disorders of the Larynx”). In contrast to other causes, some of these may be through a central mechanism. Vocal fold paralysis may appear in the wake of a stroke, almost always in conjunction with other deficits. Lateral medullary infarct (Wallenberg syndrome) is a well-known complex of neural injury featuring vocal fold paralysis, dysphagia, vertigo, ataxia, Horner syndrome, and hemifacial sensory deficit and/or pain. The vocal fold paralysis tends to improve with time, although measures may be needed in the short term to prevent aspiration. The vocal fold paralysis of Arnold-Chiari malformation tends to be bilateral and is important to recognize promptly because it is reversible with timely hindbrain decompression. Charcot-Marie-Tooth disease and its variants are a heterogeneous group of hereditary motor and sensory neuropathies which may involve the laryngeal nerves. Neural compromise of the vocal fold appears to evolve slowly but relentlessly and is usually bilateral, although it may be asymmetric. Vocal fold paralysis may also evolve as a complex of bulbar deficits resulting in dysphagia, dysphonia, and

Hypophonia. These can range from subtle vocal fatigue, most pronounced when speaking loudly or over background noise to obvious, near-total aphonia. These symptoms are generally directly proportional to the degree of glottic insufficiency that varies from affected individual to individual. Patients with unilateral laryngeal paralysis may also report dysphagia, also due to glottic insufficiency, although less often than voice complaints. Frank aspiration has been reported in 18 to 38% of patients with vocal fold paralysis, although it is more likely to occur in certain clinical situations. Dysphagia-related complaints are much more frequent in patients with “high” vagal injury, affecting both superior and recurrent laryngeal nerves, which adds hemilaryngeal anesthesia, piriﬁrm sinus atony, and cricopharyngeal muscle hyperfunction to glottic insufficiency from the immobile vocal fold. Situations in which laryngeal anesthesia exists alongside other cranial nerve deﬁcits, as in jugular foramen syndromes, after stroke and after skull base surgery probably also carry increased dysphagia risk. Operations which affect pulmonary reserve, as do most thoracic procedures, appear to carry a higher risk of aspiration, and age may be an independent risk factor.

Sometimes, patients will demonstrate a characteristically “wet” vocal quality, arising from pooled secretions which interfere with phonation. By deﬁnition, such secretions have at least penetrated into the laryngeal introitus; these patients should attract the otolaryngologist’s attention as being at risk for aspiration. More subtle symptoms include laryngospasm resulting from reaction to unexpected penetration or aspiration. This may occur in patients with surprisingly small degrees of glottic insufficiency and reasonably good voice quality.

Occasionally, patients may complain of shortness of breath, particularly during phona- tion or physical activity. Careful questioning will reveal that this is not obstructive dyspnea but rather breathlessness that results from excessive air escape during voicing, or from compromise of thoracic ﬁxation (Valsalva) maneuver during effortless activity. An airﬂow loop will inevitably reveal an extrathoracic obstruction; this, plus a lack of insight into laryngeal physiology, may lead the physician directly away from measures to mediate the vocal fold, restore glottic function, and relieve these symptoms.

When the onset of symptoms immediately follows an operation that places the laryngeal nerves at risk, no further search for cause is necessary. In other patients, the inquiry should be made regarding smoking history, the most recent chest imaging, and antecedent illness. A review of systems should focus on illnesses likely to affect the larynx. Relevant factors include neurogenic symptoms like weakness, tremor, and dysarthria; pulmonary symptoms suggestive of tuberculosis or malignancy; and exposure to neurotoxic agents like solid tumor chemotherapy (vincristine, vinblastine, and cisplatin) and organophosphates found in pesticides. Unilateral vocal fold immobility is rarely mechanical in nature, but the possibility should not be dismissed in patients in whom the symptoms appear in the wake of clearly traumatic intubation, external trauma, or in the presence of arthralgias or known inﬂammatory joint disease.

Physical Examination. The examination of a patient with laryngeal paralysis should include careful palpation of the neck for lymphadenopathy or thyroid enlargement. The remaining cranial nerves should be systematically evaluated, with special attention to the spinal accessory and hypoglossal nerves, which share the jugular foramen with the vagus. Finally, other branches of the vagus should be examined. The presence of ipsilateral tongue deviation, palate droop or Horner syndrome should raise the suspicion of a base of skull lesion.

The larynx itself should be examined across a variety of laryngeal tasks. Flexible transnasal laryngoscopy probably offers a more accurate impression of laryngeal function than rigid techniques, as the tongue traction necessary for the latter introduces some artiﬁcial biomechanical factors which may be misleading. Any debate about the superiority of one or the other means of examination is somewhat academic, however; there is nothing to prevent evaluation by both techniques.

A hypomobile vocal fold may sometimes be surprisingly difﬁcult to appreciate; in such cases, asking the patient to alternate sustained vowel phonation and sniffing (the so-called “eee-sniff” maneuver) should bring any asymmetry into stark evidence. The examiner should take care not to be misled by small amounts of vocal fold motion which may be caused by the interarytenoid muscle still partially innervated from the contralateral nerve, by an intact cricothyroid muscle, or even by passive lateral displacement of the arytenoid cartilage on the paralyzed side by its pair during adduction. This last is known as the “jostle sign,” described by Chevalier Jackson in the 1930s, and when present offers unambiguous evidence against cricoarytenoid joint ﬁxation.

We have seen that the position of the paralyzed vocal fold carries no signiﬁcance with respect to the site of the injury or prognosis. Nevertheless, careful examination can reveal features which may inform clinical care. Occasionally, increasing tension and length of the paralyzed vocal fold upon raising the pitch of the voice may suggest an intact superior laryngeal nerve, although the absence of such motion should not be taken as

proof positive of superior nerve compromise. Sometimes, patients may take advantage of intact cricothyroid muscle function to improve voice projection by increasing vocal fold resistance to exhaled air during phonation (Figure 2); this phenomenon, which also inevitably raises pitch, results in a characteristic voice described as “paralytic falsetto.”

The presence of supraglottic hyperfunction during phonatory effort, which sometimes obstructs the view of the vocal folds, should raise the possibility of glottic insufficiency. The ventricular folds serve as an accessory valving mechanism which tends to be engaged without deliberate effort when the vocal folds do not close effectively.29 Maneuvers such as humming or sighing can serve to relax the ventricular folds (Belafsky and colleagues have used the term “unloading the larynx” to describe this) to permit a more thorough evaluation of glottic closure.

Vocal fold adduction and abduction do not take place in two dimensions; the folds tend to abduct in a cephalad direction (into the ventricles) and adduct caudally. Thus, a paralyzed vocal fold may not rest in the same plane as its partner. Such three-dimensional judgments are difficult to make on laryngoscopy, but height mismatch is important to identify, as simple medial displacement of the paralyzed fold may not suffice for good apposition during phonation.

A symmetry of the arytenoids, with displacement of the cartilage on the paralyzed side forward into the laryngeal introitus (a so-called “prolapsed arytenoid”) is not a rare finding in laryngeal paralysis (Figure 3). This is not a sign of cricoarytenoid dislocation. The presence of a prolapsed arytenoid does, however, suggest profound denervation with loss of muscular support for the cartilage. In addition, it strongly suggests a height and tension mismatch between the vocal folds. These are all factors which argue for an arytenoid stabilization procedure, discussed further below, should surgical rehabilitation be contemplated.

The incidence of cricoarytenoid dislocation has been the subject of much debate. Experimental study has shown the cricoarytenoid joint to be strikingly robust and resistant to disruption.30-32 Most laryngologists agree that a problem-free intubation is extraordinarily unlikely to cause a joint injury and that joint injuries usually follow obvious trauma, be it from intubation or external sources. The presence of arytenoid edema and erythema and the absence of a jostle sign are suggestive of cricoarytenoid joint injury and should prompt further investigation, in which electromyography may be of special utility.

In hemilaryngeal paralysis, the glottal gap may be of two principal configurations. It may be essentially spindle-shaped, involving principally the membranous portion of the vocal fold, or V-shaped, marked by greater distance between the vocal processes of the arytenoid cartilage. This latter configuration is called a posterior gap; the term does not refer to the absolute distance between vocal processes (Figure 4). The presence of a posterior gap argues in favor of an arytenoid stabilization procedure for rehabilitation because implant medialization alone, or injection augmentation for that matter, is notoriously poor at correcting this deficit.

Although there is no single metric of severity of symptoms of vocal fold paralysis, several simple clinical tools may help grade features of the history and examination. These are important to understand, even if for no other reason than to aid in interpretation of the copious literature in this area. The Voice Handicap Index (VHI) and the Voice Related Quality of Life (VRQOL) are standardized and validated patient-completed self-rating scales which measure various aspects of vocal disability. The Consensus Auditory Perceptual Evaluation-Voice (CAPE-V) and its antecedent Grade, Roughness, Breathiness, Asthenia, Strain (GRBAS) scale, are perceptual scales which are completed by the health-care professional based on voice quality. The maximum phonation time (MPT) is the longest duration of sustained vowel phonation (typically an /i/) which the patient can sustain. Times in excess of 20 seconds are normal in adults, and the MPT is approximately inversely proportional to the degree of glottic insufficiency. The s/z ratio compares the maximum phonation time of unvoiced (/s/) and voiced (/z/) sounds. Under normal circumstances, the duration of the unvoiced sound should be approximately equal to that of the voiced (the s/z ratio should be 1.0), but when glottic insufficiency is present, the duration that the voiced sound can be sustained decreases (the s/z ratio tends to increase).

**Supplementary Investigations.** Fundamentally, diagnostic testing in addition to the history and physical examination is intended to uncover occult causes of vocal fold paralysis. In cases temporally related to an operation that places the vocal folds at risk, no additional workup is required. In others, malignancy is the principal pathology not to be overlooked. Imaging of the entire course of the affected laryngeal nerves is obligatory. This includes the mediastinum and the pulmonary apex, even when the paralysis is right-sided; it should be recalled that the right-sided nerve loops underneath the subclavian artery.

Although some authors have suggested that routine radiography may be adequate to image the chest, Glazer and colleagues have demonstrated a sobering rate of false negatives.33 This, plus...
the need to image the neck, has made CT from base of skull through the arch of the aorta or the right subclavian, as appropriate, the minimum recommended study for laryngeal paralysis. In cases where a “high vagal” paralysis is suspected according to criteria reviewed earlier, MRI may offer a more reliable means of imaging the skull base or central nervous system.

A recent survey has suggested that otolaryngologists continue to obtain serologic tests in most cases of vocal fold paralysis. Systematic examination has demonstrated a 0% yield for serologic tests in 84 patients. Moreover, the serologic tests that are ordered are inconsistent with the frequencies of the causes of laryngeal paralysis; rheumatoid factor and Lyme titer, the most frequently ordered serologic tests are for diseases that are exceptionally rare in all published series of vocal fold paralyses. In light of this information, serologic testing is probably useless unless there is clinical suspicion of a specific underlying illness. Modifying barium swallow is useful if a question of aspiration exists. The potential of morbidity related to dysphagia is a key element in determining the need for treatment.

Laryngeal Electromyography. Laryngeal electromyography (LEMG) measures the integrity of laryngeal innervation with percutaneous needle electrodes. It can provide unambiguous evidence of denervation and reinnervation, yet its utility in cases of vocal fold paralysis has been hotly debated. Its detractors have claimed that it is “subjective” and unreliable. In fact, LEMG might be better described as “qualitative,” requiring interpretation. In this respect, it does not differ from laryngoscopy and stroboscopy, except inasmuch as training and familiarity has allowed otolaryngologists to use these latter modalities more comfortably in everyday practice. In fact, LEMG exceeds both of these in its ability definitively and objectively to contribute to the diagnosis of vocal fold paralysis, as opposed to immobility.

The practical clinical difficulty in the use of LEMG for prognosis has been that the appearance of electromyographic signs of reinnervation does not always lead to a return of vocal fold function, for pathophysiologic reasons reviewed earlier. Therefore, experience with LEMG for prognosis in patients with vocal fold paralysis has been uneven, depending heavily on criteria used for “good” prognosis. The broader these criteria are, the more false positives, and the more restrictive, the more false negatives. The available literature suggests that LEMG may be more useful as a predictor of poor outcome (Table 4), principally because these signs, namely fibrillations and fasciculations revealing an absence of reinnervation, offer no physiologic ambiguities. The subject remains open for further investigation. For now, it is clear that LEMG offers a reliable way to distinguish neurogenic from mechanical vocal fold immobility and may offer variable prognostic information when used less than 6 months from the onset of paralysis. While LEMG, when used circumspectly, may offer further refinement in making treatment decisions for patients with vocal fold paralysis, it is not essential to the standard of care, which has relied on treatment delays of 6 to 12 months to resolve uncertainty about prognosis.

Treatment

Decisions regarding therapeutic intervention for glottic insufficiency from unilateral vocal fold paralysis are guided by concerns regarding morbidity from dysphagia and aspiration, the patient’s own perception of the severity of the vocal disability, and expectations and assumptions about the eventual outcome without treatment. In turn, outcome expectations are influenced by the apparent cause of the paralysis and the time that has elapsed since onset.

Observation. Patients with hemilaryngeal paralysis, especially of short duration, may simply be observed. Factors favoring observation include

1. no evidence of aspiration,
2. certainty that the injured laryngeal nerve(s) is (are) intact,
3. minimal vocal disability and/or minimal vocal demand,
4. good functional prognosis, and
5. comorbidities or other medical factors which discourage or prevent intervention.

Voice and swallowing therapy may be used as needed during the observation period. There is no convincing clinical evidence that voice therapy is useful to relieve symptoms or affect the course of vocal fold paralysis. As with many interventions for this condition, the natural tendency of glottic insufficiency to improve over time makes it difficult to evaluate efficacy. Nevertheless, a skilled voice therapist may offer patients reassurance and insight into their condition and may help prevent or reverse harmful compensatory behaviors.

The presence of severe dysphagia, history of aspiration pneumonia, or observed aspiration during clinical evaluation (either radiologic or endoscopic) effectively trumps other factors and demands intervention.

Injection Augmentation. Patients may opt for temporary relief of their symptoms, even when eventual recovery is expected. This is accomplished by injection of an absorbable bulking substance into the paralyzed fold to improve the glottic insufficiency. Such substances include various collagen and hyaluronic acid preparations, micronized human dermis, autologous fat, and carboxymethylcellulose-glycerine gel. Factors favoring injection augmentation include

1. dysphagia,
2. high degree of vocal disability or high vocal demand,
3. functional prognosis is good or indeterminate,
4. relatively small glottic gap (<2 to 3 mm),
5. no posterior glottic gap, and
6. short life expectancy (less than the expected duration of the injectate).

Injection augmentation may be performed via direct laryngoscopy in the operating room, or perorally or transcutaneously under topical

A adapted with permission from reference 24.
Laryngeal framework surgery is generally reserved for treatment of glottic insufficiency from unilateral paralysis because of well-known adverse tissue response. Calcium hydroxyapatite particle paste has been recently introduced as a durable injectable with effect exceeding 1 year, and possibly permanent, although its relatively recent introduction leaves the latter claim unsubstantiated at present. This product may reopen the possibility of using injection as a definitive treatment for paralytic glottic insufficiency. In considering this treatment option, otolaryngologists should not forget the lessons of polytetrafluoroethylene polymer, however: the larynx tends to punish careless use (such as superficial injection or overinjection) of non-biodegradable materials.

Injection augmentation has inherent limitations. It will not effectively reposition the arytenoid cartilage to rectify a height discrepancy or close a posterior glottal gap. It is not ideal for large glottic gaps. Most injection substances require overinjection to allow for reabsorption, rendering fine adjustment of vocal fold position virtually impossible. In addition, should the injectate infiltrate into an unintended site (typically the superficial layers of the vocal fold), impairing mucosal phonatory vibration, corrective intervention is challenging. Patients may have to await natural resolution over weeks to months. It should be noted that no substance, not even low viscosity hyaluronic acid preparations, is ideally suited for use in the lamina propria; all currently available substances will stiffen this tissue. The proper location of the injection is within the thyroarytenoid muscle at the mid- and posterior portions of the membranous vocal fold (Figure 5).

Framework Surgery. Laryngeal framework surgery is generally reserved for treatment of glottic insufficiency from unilateral paralysis which is not expected to improve. Factors favoring a framework approach are following:

1. dysphagia,
2. high degree of vocal disability or high vocal demand,
3. poor functional prognosis,
4. relatively large glottic gap (>2 to 3 mm),
5. posterior glottic gap, and
6. life expectancy is not shortened.

In its simplest and most common form, framework surgery consists of the medialization thyroplasty, the insertion of an implant, made of silicone, formed polytetrafluoroethylene (Gore-Tex), formed calcium hydroxyapatite, or other biologically inert material, into the paraglottic space to displace the paralyzed vocal fold medially (Figure 6). Typically, this operation is performed under a local anesthetic, with or without additional intravenous sedation. This allows the surgeon, guided by patient phonation and endoscopic visualization, to size and position the implant for optimal correction of the patient’s glottic insufficiency without functional restriction of the airway. The critical anatomic task is to identify the level of the vocal fold in relation to the thyroid lamina so that the thyroid cartilage aperture through which the implant is inserted can be placed appropriately. Medialization via thyroplasty, in contrast to injection, is precise, predictable, and durable. Often considered the most aggressive treatment than injection, medialization thyroplasty under local anesthesia can be safer and better suited to high-risk patients than injection under general anesthesia.

Serious complications include airway obstruction and perforation into the laryngeal lumen. Necessarily, medialization narrows the airway and, in combination with postoperative edema and hematoma, can cause airway obstruction. For this reason, many surgeons prefer to observe patients in the hospital for 1 or 2 nights following the procedure. Some 0.6 to 1.1% of patients undergoing medialization thyroplasty have been reported to require intubation or tracheostomy in the immediate postoperative period. Perforation of the laryngeal mucosa increases the likelihood of infection and subsequent extrusion of implanted material. Perforation typically takes place in the delicate ventricular mucosa, which lies close to the thyroid lamina, or anteriorly where there is little soft tissue cover.

The most common “complication,” however, is suboptimal voice outcome. This is typically due to technical factors, and revision rates of 5.4 to 14%, to even as high as 33% when adjunctive procedures such as fat injection are included, have been reported. Common causes of poor voice result include persistent posterior gap, undermedialization and implant malposition, generally in too anterior or too superior a position (Figure 7).
Arytenoid cartilage repositioning procedures may be added to medialization thyroplasty when there is a flaccid, poorly supported arytenoid cartilage or a posterior gap (see Figures 2 and 3). This configuration is notoriously difficult to remedy with thyroplasty alone. Arytenoid repositioning surgery is designed to internally rotate and/or suspend the arytenoid cartilage in physiologic phonatory position. Most commonly, the muscular process of the arytenoid cartilage is approached through the inferior constrictor muscle and around the back of the thyroid lamina. A nonabsorbable suture is passed through the muscular process and secured to the thyroid lamina so as to exert anterolateral traction on the muscular process and thus rotate the vocal process medially and slightly caudally; this is known as arytenoid adduction. A reduction arytenoidopexy, a less common approach, involves opening the cricoarytenoid joint capsule and suturing the arytenoid in optimal position directly to the crest of the cricoid cartilage.

These procedures are technically challenging and more time consuming than thyroplasty alone and have a higher incidence of complications, largely because edema or bleeding into the paraglottic space can cause airway obstruction. Despite these problems, for the experienced phonosurgeon, arytenoid procedures are an essential adjunct to medialization thyroplasty in achieving an optimal voice outcome.

Reinnervation. Reinnervation using nearby nerves (both the ansa cervicalis and the hypoglossal have been studied) would seem to be an attractive and logical approach to vocal fold paralysis. It is subject to the same limitations as spontaneous recovery, however. Because of the complex innervation of the vocal fold muscles, reinnervation generally improves the bulk and tone of vocal fold muscle but will not restore physiologic motion. Reinnervation is ideally suited when the vocal fold is known to be completely denervated. In fact, in patients in whom the nerve has been sectioned and the section is recognized during surgery, immediate reanastomosis, or reinnervation if tension-free reanastomosis is not possible, is the treatment of choice. However, when considering reinnervation later in the course of paralysis, the surgeon should be reasonably confident that he or she is not depriving the vocal fold of existing reinnervation by sectioning a partially recovered recurrent nerve to use the distal stump. In addition, the patient must be counseled that symptom improvement may take weeks or months. For this reason, reinnervation has sometimes been combined with other rehabilitation techniques.

The armamentarium of procedures to remedy unilateral laryngeal paralysis is flexible and effective enough so that, given an understanding of the underlying pathophysiology, as well as the advantages, disadvantages and technical requirements of each procedure, meaningful symptomatic relief can be offered to nearly every patient.

BILATERAL VOCAL FOLD PARALYSIS

Virtually any condition that can cause unilateral laryngeal paralysis may affect both recurrent laryngeal nerves to cause bilateral paralysis. Thyroidectomy remains the leading surgical cause, both nerves are also at risk at esophagectomy, tracheal resection, thyroplasty, and other mediastinal procedures. Similarly, tracheal, esophageal, and thyroid malignancies may compromise both nerves. Neurogenic disorders tend to involve both nerves. A myotrophic lateral sclerosis, postpolio syndrome, Charcot-Marie-Tooth neuropathy, Arnold-Chiari malformation, and Guillain-Barre syndrome have been documented causes of bilateral paralysis. Some bilateral laryngeal paralyses are idiopathic, attributed to the same infectious agents as unilateral paralysis.

A clinician encountering bilateral vocal fold immobility should consider the possibility of joint fixation or posterior glottic scar, particularly when the condition follows intubation. In such cases the vocal folds are not denervated but merely appear to be paralyzed because of mechanical limitation. Careful inspection, sometimes requiring operative laryngoscopy, radiologic investigation, and/or electromyography should be used to clarify the diagnosis, as mechanical limitations may occasionally be correctible.

Patients with bilateral vocal fold paralysis typically complain of dyspnea, noisy breathing, and exercise intolerance. The severity of these respiratory symptoms is inversely proportional to the size of the glottic aperture between the two immobile vocal folds. Respiratory noise is worse on inspiration, as negative pressure pulls the denervated vocal folds into closer approximation and causes greater airway restriction. Voice, while not entirely normal, may not be greatly altered, and swallowing is usually not affected.

When bilateral vocal fold paralysis is acute, symptoms may be dramatic and even life threatening. The typical situation is unexpected respiratory distress after extubation from thyroid surgery, and, in such a patient, securing an adequate airway is the only consideration. In progressive cases, as found in certain neurogenic diseases, patients may compensate as the paralysis becomes more dense and may tolerate unexpectedly small glottic airways. Occasionally, the clinician may be surprised to discover bilateral vocal fold paralysis in relatively asymptomatic patients; close questioning about noisy inspiration or limitations in physical activity may suggest that paralysis has been present for some time.

Investigation includes radiologic imaging in the manner of unilateral vocal fold paralysis, with special emphasis on the mediastinum and infralaryngeal part of the neck, where the recurrent nerves are in close proximity, as well as the central nervous system. The degree of airway obstruction may be quantified using a flow-volume loop. Bilateral paralysis typically shows a variable (rather than fixed) extrathoracic obstruction, as the vocal folds will passively adduct during inspiration and abduct with positive expiratory air pressure.

Treatment is guided by the degree of airway limitation; except in situations of acute airway distress, the patient may be the best judge of the functional disability. Tracheostomy is frequently performed emergently and may be a reasonable treatment option for the long term as well, as it provides an adequate airway with minimal compromise of phonation and deglutition. However, patients often prefer to avoid...
the inconveniences of tracheostomy if possible. Other treatment options include lateralization of one vocal fold or removal of one arytenoid cartilage or vocal fold tissue to enlarge the glottic aperture. Effort is made to preserve the membranous vocal fold to the greatest extent possible, but voice and sometimes swallowing may be adversely affected. These procedures are destructive and irreversible, so that any reasonable possibility of spontaneous improvement should be excluded before they are considered.

**VOCAL FOLD PARESIS**

A sophisticated understanding of underlying pathophysiology clearly reveals that vocal fold paralysis is not an all-or-none phenomenon, as it has been commonly conceptualized for the last century. It should come as no surprise that paresis or incomplete paralysis in which some gross vocal fold mobility is preserved exists alongside paralysis as a clinical entity. The symptoms of paresis differ only in degree from paralysis, whether unilateral or bilateral. In place of constant breathy hypophonia, for instance, the patient with hemiparesis may complain of voice difficulty only after speaking for some time or at high intensity. In place of inspiratory stridor, the patient may complain only of changes in exercise tolerance. Diagnosing paresis may be extremely challenging because preserved vocal fold mobility may mask the examiner into overlooking subtle glottic insufficiency or limitations in abduction. Perhaps the most difficult task is distinguishing paresis from innocent asymmetries in vocal fold motion, which are probably present in many individuals. Stroboscopy may occasionally be helpful. Decrease in muscular tone affects the amplitude and frequency of the vocal fold vibration, which are probably more sensitive to paresis than to paralysis. Decrease in muscular exercise tolerance. Diagnosing paresis may be particularly challenging because preserved vocal fold mobility may mask the examiner into overlooking subtle glottic insufficiency or limitations in abduction. Perhaps the most difficult task is distinguishing paresis from innocent asymmetries in vocal fold motion, which are probably present in many individuals. Stroboscopy may occasionally be helpful. Decrease in muscular tone affects the amplitude and frequency of the vocal fold vibration, which are probably more sensitive to paresis than to paralysis.

Muscle Misuse Disorders of the Larynx

Linda Ramage, PhD
Murray Morrison, MD
Hamish Nichol, MBChir

Traditionally, voice disorders have been classified as “organic or structural” or “functional or psychogenic” based on the nature of the assumed primary etiological factor(s). Such a simplistic classification system does little to delineate the complex, multifactorial nature of disorders of the larynx and, taken literally, could lead us to believe that one of two primary treatment pathways should be followed for a given individual. The term “muscle misuse disorder” refers to the broad spectrum of dysfunctional patterns that contribute to or cause voice problems, chronic cough, paradoxical vocal fold movements, and other symptoms that can be associated with muscle hypertonicity and/or asynchrony of movement patterns affecting laryngeal function.

The term “misuse” implies that the psychomotor system involved in voluntary muscle activity is providing the wrong commands with respect to the degree of muscle tone required to perform a motor act, the specific muscles that need to be involved for a particular movement, or the coordination among muscle systems that allows for efficient and effective movement patterns. Although voluntary muscles can be controlled at a conscious level, it is largely at a subconscious level that inappropriate patterns of movement are acquired, through repetitive maladaptive gestures or postures, responses to environmental stimuli or anatomical changes, or psychological mechanisms such as defense or inhibition of the expression of emotions.

CAUSES OF MUSCLE MISUSE DISORDERS OF THE LARYNX

The larynx is susceptible to dysfunction related to muscle hypertonicity and/or asynchrony of movements through the voluntary and autonomic nervous systems. A number of physiological factors result in the larynx being a target organ for muscle misuse patterns.

First, the evolutionary and developmental patterns of the larynx reinforce its primary life-preserving function of airway protection, manifested by its multilayer folding structure which creates a complex and dynamic valve system in the respiratory tract.1

Second, the larynx, pharynx, and esophagus form an embryologically related neuromuscular tube that is controlled by both voluntary and involuntary systems. Not surprisingly, nonspeech functions such as swallowing, breath-holding, and coughing have both voluntary and involuntary system involvement. Voice production for speech is a psychomotor act that is the result of complex interactions among multiple systems in the central nervous system and in peripheral structures. Speech involves contributions from cognitive, linguistic, emotional, neuromotor, respiratory, phonatory, resonance, and articulatory systems. Some aspects of vocal communication may be associated with significant contributions from high-level cognitive control while others may be considered more primal. For example, an “involuntary” scream or cry is regulated by a psychomotor command with focal activity in the limbic system and periaqueductal gray matter in the brainstem. Although this type of vocal response can be considered primal, full vocal expression of basic emotions such as fear, anger, and grief can effectively be inhibited by higher central nervous system (CNS) commands. One of the most effective ways to inhibit free vocal expression is to maintain a higher level of tone in muscles that would need to be involved in the act of crying out, laughing, screaming, etc. Through a variety of executive functions, the psychomotor system can produce tonic levels in the peripheral muscles in multiple systems involved in speech production: those of respiration, phonation, resonance, and articulation. Examples of this type of muscle pattern misuse include jaw clenching (to inhibit “biting someone’s head off/chewing someone out”) and breath-holding at the abdominal/laryngeal levels (to inhibit screaming, shrieking, or crying). It is worth noting that these executive cognitive-emotional functions are not fully developed until after puberty and so are not operational in infants and young children to the extent that they are in adults. Certain neurological and psychiatric conditions may also disrupt and enhance the tendency to repress the vocal expression of emotions through these sophisticated cognitive-emotional programs.

Third, the nonspeech functions of the face, articulators, larynx, pharynx, and esophagus may interfere with voluntary muscle activity required for vocal communication. For example, the dynamic vertical movements of the larynx during respiration may not coincide with the desired laryngeal level required for optimal resonance during vocal productions. Or, after swallowing, if the tongue does not return to its neutral position, it may result in inappropriate resonance and/or articulation patterns for vocal communication or performance.

There are also a number of individual factors that may make certain individuals more susceptible to muscle misuse patterns in the larynx. Both intellectual and emotional elements of thought are influenced by an individual’s personality and style, and these set the postural and muscle tone patterns required to deliver an utterance with the appropriate pragmatic intent. The neuromotor activities associated with vocal communication require sophisticated coordination. Some individuals appear to execute the complex motor acts with relative ease, whereas other individuals struggle to coordinate the movements between the various systems that must work together to produce energetic, fluent, and dynamic speech phrases.

Individual anatomical and health issues may play a role in the ease with which one coordinates the various muscle systems for natural and free vocal acts. The influence of gastroesophageal reflux (GER) on laryngeal function is described in Chapter 76, “Laryngopharyngeal Reflux, Infections, and Manifestations of Systemic Diseases.” Reflex hypertonicity in the larynx due to GER can interfere with normal tonicity required to initiate and sustain appropriate phonatory patterns.2 Normal developmental and aging changes can cause compensatory muscle misuses in the vocal tract that result in poor adaptation. The pubescent boy whose larynx grows quickly may adapt to the changing acoustic and kinesthetic feedback by misusing muscles to maintain a high laryngeal posture and a glottal posture that produces falsetto register. A senescent man may react to the gradually rising natural fundamental frequency (f0) of his thinning, aging vocal folds by adopting an abnormally low laryngeal posture, and a glottal posture that compresses the vocal folds in anterior-posterior and/or lateral directions to increase adduction and superior-inferior contact of the vocal folds.

Social, domestic, and/or occupational demands for some individuals result in a heavy vocal...
EVALUATION OF INDIVIDUALS WITH MUSCLE MISUSE DISORDERS OF THE LARYNX

We find it helpful to evaluate muscle misuse disorders of the larynx within a framework that encompasses four basic realities that can influence muscle use at different levels of the vocal tract.4,5 The model represents four broad areas, or “platforms,” of human function that, at any given time, are exerting a variable influence on muscle tension and coordination for vocal communication and performance and primary laryngeal functions: lifestyle, emotion, reflux, and technique (a-LERT). A primary or secondary lesion or other disease process can be superimposed on the four core platforms (Figure 1). A distinct lesion on the vocal fold(s) or a neurological disease affecting muscle coordination will always be depicted as potentially influencing or interacting with the four core platforms. More specifically, pathologic processes that affect changes in anatomic relationships will inevitably lead to adjustments in laryngeal posture and muscle use in an effort to compensate for the anatomic or physiologic aberration.

The a-LERT model assumes that any of the four basic platforms could cause laryngeal disorders and that all play an etiologic role in every patient’s symptoms if only to a minor degree. Individual platform components may be predisposing, precipitating, or perpetuating factors. We will use the a-LERT format to present evaluation strategies and techniques for individuals with muscle misuse disorders of the larynx.

During the history taking process, significant time is spent exploring both health and lifestyle profiles. The in-person interview is expedited by information obtained on a patient intake questionnaire, provided in advance for completion by the patient or guardian (Figure 2). The intake profile also serves to provide some indication which of the interdisciplinary team members may need to be present during the initial evaluation.

Lifestyle and Environment

An individual’s occupational, domestic, and recreational activities, and the environments in which vocal demands are met may contribute to or cause muscle misuse patterns, which may be associated with primary or secondary vocal fold lesions such as nodules, hemorrhagic lesions, polyps, or Reinke edema.

The environmental conditions under which one lives and works need to be described to identify potential stimuli to muscle misuse. A common cause of occupational voice disorders characterized by muscle misuse is frequent voice use in poor acoustic conditions. High ambient noise levels, poor signal-to-noise ratios, and reverberation times that are too short or too long are the most common acoustic conditions that contribute to reduced speech intelligibility and cause individuals to raise their voices above a comfortable and efficient loudness level and to change muscle patterns in the respiratory system, larynx, and articulatory system. The Lombard reflex, which predicts an increase in speech intensity in the presence of background noise, is largely responsible for changes in speech breathing, vocal intensity, and f0.6–8 The vocal dose is a useful way of documenting vocal demand.3 Measures of voice dosimetry that include both phonation time and intensity are used in some settings in an attempt to quantify vocal dose, with portable voice accumulator devices.9 Such measures of acoustical power over time may provide a good estimation of vocal dose.

Although documentation of acoustic environment for vocal use is impractical from the laryngologist’s office, initial questioning about ambient noise, reverberation (or “echo”), room size, building construction features (eg, floor surface, ceiling surface, ceiling height, windows, “open-plan” features, indoors, or outdoors) will suggest whether further steps need to be taken to assess the acoustic environment.

Some individuals are exposed to high levels of toxins and/or odors they perceive to be noxious. In certain individuals, these types of airborne stimulants can trigger hypertonic responses in the larynx, known as irritable larynx syndrome, which will be discussed in greater detail later in the text. Question patients about multiple chemical sensitivities, “allergies,” or hypersensitivity to odors. Sometimes having a patient elaborate on reactions to a specific odor will reveal a sensory memory that is associated with a significant psychological event. It is often also the case that individuals who are concerned that a particular odor represents a noxious agent in the environment will have an exaggerated reaction in the airway, and environmental testing may need to be completed to allow for reassurance or environmental corrections.

Individuals who work in environments that are extremely dry or humid may also exhibit airway hypersensitivities resulting in a variety of muscle misuse patterns in the larynx. Finally, individuals who are frequently exposed to viral contaminants may be more susceptible to muscle misuse problems in the larynx. Public school teachers are frequent targets for this environmental hazard.

It is important to consider personality features and occupational, domestic, and social activities when exploring voice use patterns with each patient. Some individuals may not appreciate the extent of their daily voice use and may need to be assigned a task to record voice use and conditions, with the help of an external observer if necessary, to reach an appreciation of their vocal demands. It is necessary to identify that nonspeech vocal activities, such as yelling, screaming, throat clearing and coughing, or imitation of mechanical noises are associated with muscle misuse in the larynx and, additionally, that they can induce trauma that may cause voice changes or trigger other laryngeal symptoms. It may also be necessary to consider sociolinguistic influences on vocal activity and acoustic targets. Attempts to match vocal intensity, pitch or quality of parents, peers, or media personalities may result in chronic misuse of muscles to emanate a particular vocal style. Listen for breathy voice, vocal roughness from glottal fry use, or inappropriate pitch, all of which may be subconsciously mediated by a desire to make a particular vocal impression.

Other lifestyle factors that affect laryngeal health, such as smoking, excessive caffeine or alcohol intake, hydration, and fitness should all be explored to gain a full appreciation of the potential influences on laryngeal muscle use.

Emotion

Emotions are a normal human function. Everyone experiences psychological stressors due to external and internal demands, and a variety of coping

mechanisms may be observed. Some coping styles are more adaptive than others, and some contribute to laryngeal problems. Personality and psychological health characteristics may contribute to maladaptive coping styles. The motor system activity associated with vocal communication and other laryngeal functions cannot be considered in isolation from emotional influences. Under some conditions, emotional reactions can and frequently do contribute to muscle misuse patterns through mechanisms of the voluntary and involuntary muscle systems and through the sympathetic nervous system. For example, misuse of muscles in the respiratory system and larynx may result in a quiet and monotone voice, which is commonly identified as a sign of depression. Feeling a “lump in the throat” and associated dysphonia is associated with hypertonicity in the pharyngeal constrictor muscles, which may result from gastroesophageal reflux, unexpressed fear, or both. Voice disorders may be caused by dry mucosa in the vocal tract, which is sometimes caused by an anxiety response of the sympathetic nervous system.

Psychological or personality disorders and unresolved emotional conflicts can result in chronic physical conditions that contribute to dysphonia or other laryngeal muscle misuse symptoms. The voluntary muscle system is by far the most common physical mechanism through which psychological factors contribute to muscle misuse in the larynx and its suspensory system. We use the words “tense” and “uptight” to refer to the body’s reaction to psychological stressors. When these factors are the primary cause of a laryngeal problem, a variety of muscle misuse patterns and subsequent dysphonia features may be observed. Certain patterns of muscle misuse affecting laryngeal posture are associated more frequently with psychological stressors, conflict, or psychiatric disorders. The classification system for muscle misuse disorders of the larynx is presented in section “Classification of Laryngeal Muscle Misuse Patterns.”

Most of the information about a patient’s psychological status is obtained by listening attentively to his or her verbal response to opened questions, listening to changes in voice or other laryngeal symptoms, watching for changes in facial expression or body posture, and probing gently as indicated by any cues to pursue issues that may provide insight into relationships between emotions and the laryngeal disorder. More specifically, in the history, seek evidence of:

- a traumatic event around the onset of the dysphonia;
- difficulties in communicating with significant others;
- suppression of significant amounts of negative emotion, such as sadness or anger;
- abusive relationships in childhood or later;
- narcissistic preoccupation with voice;
- overt anxiety or depression;
- potential primary or secondary gain factors (primary gain is the benefit of reduced anxiety about some internal stressor, such as concern about a potentially life-threatening illness, by focusing on the laryngeal problem; secondary gain is benefit from external sources enjoyed by the person with the laryngeal problem, such as not having to go to work in an unpleasant environment).

Most people will agree that their voice difficulty gets worse at times of high stress. It is helpful to ask which stressors seem to affect the voice most noticeably and which stressors are current because this may direct the interview to the source of psychologically based muscle misuse.

The inclusion of a psychiatrist or psychologist who is knowledgeable about muscle misuse disorders on the voice clinic team expedites identification of prevailing personality or psychological factors that are contributing to laryngeal dysfunction. The American Psychiatric Association has provided a standardized protocol for differential diagnosis of recognized disorders of psychological and personality function: the Diagnostic and Statistical Manual (DSM) of Mental Disorders. The current version is DSM-IV-TR. The text includes advisories that it is intended for diagnostic use by mental health specialists, and that its use by individuals who are not trained in mental health evaluation should be as a reference tool to obtain information, not to make specific diagnoses.

Personality tests can provide helpful supplements to the interview, for example, the NEO

Five-Factor Personality Inventory, or inventories to identify depression, anxiety or other common symptoms of psychological dysfunction, such as the Million Behavioural Inventory or the Beck Depression Inventory.

Patients' self-evaluation inventories include items intended to identify the psychological impact of a laryngeal disorder. Chronic and unexplained symptoms of dysphonia, cough, globus pharyngeus, or laryngospasm may themselves become psychological stressors that perpetuate or exacerbate muscle misuse in the anatomic region associated with the symptom. The Voice Handicap Index and the Voice-Related Quality of Life inventory probe the psychosocial impact of a voice problem.

Look for signs of muscle misuse in the face, which can reveal prevailing emotions, both conscious and subconscious. Psychological mechanisms may result in the misuse of facial muscles to inhibit emotional expression, particularly in persons suppressing the urge to cry in sorrow, shout in anger, or scream in fear (Figure 3). Freedom of speech and voice movements can be jeopardized by tension in the muscles of the upper, middle, and lower facial areas.

Emotional distress aggravates most laryngeal disorders by adding muscle misuse to a system that may already be hypertonic. Even in the presence of a primary neuromuscular disorder, such as laryngeal dystonia, the voice may be normal when an individual is relaxed, and symptomatic when he or she is experiencing emotional distress. Vocal abusive behaviors may be associated with aggressive or attention-seeking personality characteristics. Certain psychopathological conditions identified in the DSM IV-TR, such as schizophrenia, obsessive-compulsive disorder, or Gilles de la Tourette syndrome may also lead an individual to misuse the voice by yelling, screaming, cursing, using inappropriate pitch or voice registers, or producing noncommunicative vocal gestures such as throat clearing, moaning, grunting, or coughing. A few researchers have investigated statistical relationships between vocal abuse-related voice disorders and personality or psychological characteristics. This research suggests strong relationships between psychobehavioral characteristics and the incidence of vocal fold lesions that are secondary to vocal abuse and muscle misuse, sometimes in combination with reflux. Common behavior patterns associated with these secondary lesions in children include aggression, tension, frustration, argumentative behavior, poor coping skills, and disobedience. It is helpful to ask significant others, parents, guardians or teachers, about an individual's behavior patterns, as a patient may not have full insight into features that are perceived by others as pathological or dysfunctional.

Gastroesophageal Reflux and Associated Medical Conditions

GER, retrograde movement of gastric contents into the esophagus, is a transient, usually postprandial event that occurs undetected and without symptoms several times a day in healthy individuals. Relaxation of the lower esophageal sphincter (LES) is thought to be a normal adaptive function that relieves pressure on the stomach after eating to enhance the digestive process. Gastroesophageal reflux disease (GERD) is characterized by a broad spectrum of clinical presentations from heartburn to ulcerative esophagitis. GERD is an important cause of both chronic laryngitis and muscle misuse in the larynx. The mechanism through which GER can cause muscle misuse in the larynx has been described both theoretically and through study of a porcine model and reflects the primary life-preserving role of the larynx in protecting the airway. GERD seems to increase laryngeal, pharyngeal, and esophageal muscle tone; accompanying symptoms include postnasal drip, globus, and the feeling of a need to clear the throat. Habitual throat clearing contributes to vocal abuse and hoarseness. An irritated esophagus reflexively affects the muscles of the pharynx and larynx, causing them to be hypertonic; the resulting muscle misuse contributes to wear-and-tear injury.

Technique and Vocal Skill

Motor learning theory tells us that both adaptive skills and maladaptive motor patterns become programmed through repetition and feedback and that the CNS codes change with time to accept the frequently reinforced patterns and associated
kinesthetic, visual, and/or acoustic manifestations as normal technique.\textsuperscript{25–28} Physical trauma or disease processes can precipitate or perpetuate muscle misuse, as can developmental and aging changes. Whiplash injuries sometimes result in long-term “splinting” of neck, shoulder, throat, and jaw muscles, which contributes to muscle misuse voice disorders. Body alignment, linguistic competence and comfort, communication strategies and pragmatics are among many factors influencing the neuromuscular commands that orchestrate complex muscle patterns for vocal communication.

Inquire about degree and type of vocal training and specific skills that were acquired through the programs. Consider linguistic competence, general cognitive level, and communication style of the patient throughout the evaluation. Is he or she comfortable using the primary language required to conduct his or her daily activities? Does the individual listen attentively; take turns; ask appropriate questions at appropriate times; treat others with respect; and hear well? Or does he or she seem distracted or impatient; interrupt frequently; and perseverate on issues? Does the individual speak at a normal rate; quickly; slowly? Is it difficult for someone who speaks quickly, holds his or her breath while waiting to speak, or whose message is unfocused and language disorganized to coordinate the component systems for speech.

Good body posture is essential to healthy vocal production. Poor posture is often related to both technique and unhealthy ergonomic support. Ask about ergonomics in various life situations, particularly with respect to furniture and electronic props, such as computer keyboards, screens, and telephones. Some typical postural misuses may be observed in the clinical setting, depending on the type of furniture provided. You should observe informally first, then ask the patient to stand or adjust sitting posture depending on what you observe.

During conversation and a variety of vocal tasks, look for signs of

- head and neck extension, a commonly observed misuse resulting in “jaw jut,” or exaggerated neck flexion, sometimes seen in individuals with globus pharyngeus;
- collapsed shoulder and rib-cage position with increased cervical lordosis;
- clenched jaw and jaw restriction during speech;
- static facial postures around the eyes, and “perma-smile” with minimal lip movement during speech; and
- strap muscle activity, especially omohyoid action with speech.

During conversation and a variety of vocal tasks, listen for signs of

- vocal tension and strain, pitch breaks, phonation breaks;
- inappropriate pitch (registration) or loudness;
- rough voice quality due to glottal fry use;
- dipliphonia, typically related to asymmetry in structure or tension of the vocal folds;
- breathy voice quality;
- inappropriate resonance focus, hypernasality, hyponasality, cul-de-sac resonance with a backed tongue posture, inappropriate juvenile resonance with a fronted tongue posture;
- audible inhalation with laryngeal friction or stridor; and
- variability in any of the perceptual acoustic features with changes in posture, conversation topic, or vocal task.

During conversation and a variety of vocal tasks, palpate for signs of

- inappropriate speech breathing movements: exaggerated thoracic cage activity during inhalation or vocalization; limited or no abdominal excursion during inhalation;
- hypertonic activity in suprapharynx, thyrohyoid, cricothyroid, and inferior pharyngeal constrictor muscles; and
- crepitus, bulging, or limited movement around the temporomandibular joint.

During conversation and a variety of stimulability tasks, observe improvement in muscle misuse symptoms and voice with appropriate diagnostic therapy techniques (Table 1).

The evaluation of vocal technique continues as the laryngoscopic examination is conducted. The glottal and supraglottal shapes or postures that are noted on indirect laryngoscopy have been used traditionally to classify patterns of muscle misuse. A typical example is hyperadduction of the false vocal folds, historically referred to as “dysphonia plica ventricularis.”

Signs of organic change secondary to misuse may complicate the clinician’s diagnostic task. Symmetrical bilateral vocal nodules are mucosal changes known to be secondary to vocal overuse and muscle misuse. Nodules often can be identified with a laryngeal mirror and, if assignment of a diagnosis is based solely on this readily identified clinical sign, it seems logical to label the disease process “vocal nodules.” Such an approach to classification focuses on organic pathology, often out of context with an individual’s habitual voice use patterns and may bias a clinician to focus on the organic change when planning treatment for patients. If instead, the primary etiology (misuse of muscles) is implied in the diagnostic classification, as in the descriptive term muscle misuse dysphonia with secondary vocal nodules, then management will more likely be directed appropriately toward reducing chronic dysfunctional muscle use.

**CLASSIFICATION OF LARYNGEAL MUSCLE MISUSE PATTERNS**

Our current classification of laryngeal muscle misuse patterns includes six postures, observable during phonation, often seen in combination.

**Laryngeal Isometric Pattern**

The laryngeal isometric pattern is most commonly seen in untrained occupational and professional voice users including singers, teachers, actors,
media personnel, and sales representatives. It represents a generalized increase in muscle tension throughout the larynx and in paralaryngeal structures. A key feature is sustained hypertonicity of the posterior cricoarytenoid muscle (PCA) which may create a posterior glottal chink (PGC) (Figure 4). The etiology usually includes a combination of poor vocal technique, extensive and extraordinary voice use demands, and interacting or secondary psychological factors. Anxiety is most commonly identified; and, in some cases, the diagnosis of generalized anxiety disorder is made based on criteria listed in the DSM-IV-TR.12

Other forms of muscle misuse may accompany the laryngeal isometric pattern. Disease of the vocal fold mucosa, most commonly bilateral symmetrical nodules (in prepubertal males and females) or chronic Reinke edema (in postpubertal males), often is identified as a component to the diagnosis and generally assumed to be secondary to the specific pattern of muscle misuses associated with the laryngeal isometric posture.

The laryngeal isometric pattern frequently is associated with palpable increases in suprahyoid muscle tension on phonation particularly in higher pitch ranges during singing and during high vowels and phoneme transitions in connected speech. Elevation of the larynx in the neck and mandible extension may be observed as the

*These techniques are used in various combinations for the purpose of diagnostic therapy, often during laryngoscopy with flexible fiberoptics to observe changes in laryngeal and supralaryngeal postures and vocal symptoms. Techniques that result in symptom reduction may be developed further during voice therapy.
patient ascends a sung scale. “Jaw jut” describes the frequently seen posture that results from simultaneous extension of the neck and mandible. During transnasal fiberoptic endoscopy, correction of the inappropriate laryngeal posture may be elicited with nasilization or humming, relaxation of supralaryngeal muscles (by palpation or head, tongue, or jaw movements), and during “coordinated voice onsets” on spontaneous utterances such as “Hm!”5,31

Lateral Compression

Lateral compression is a dysfunctional pattern and is a type of tension fatigue syndrome in which the larynx tends to be hyperadducted in a side-to-side direction. It may exist at the glottal level, the supraglottal level, or both. The glottal form usually is related to technical errors, but sometimes acute anxiety states may be identified. By contrast, supraglottal compression (or plica ventricularis) is often associated with ongoing psychogenic factors.

Subtype A: Glottal Compression. Speech associated with hyperadduction of the vocal folds typically is characterized by a harsh or strident voice quality and aggressive voice onsets, that is, glottal attacks (Figure 5). Phonation is associated with high laryngeal resistance that explains why patients complain of vocal fatigue and discomfort at the end of a working day. In some situations, an organic illness such as an upper respiratory infection triggers the problem, but persistent hoarseness remains many weeks after the viral illness has resolved. Koufman and Blalock have used the term “habituated hoarseness” to note this relationship.12

Lateral compression of the vocal folds generally is accompanied by incoordinate breathing, which requires that the larynx functions as a valve to control expiratory airflow. Laryngoscopy with stroboscopy will show a prolonged closed phase, reduced vibratory amplitude, and suppression of the mucosal wave in persons with lateral glottal compression. A associated ventricular fold adduction may be seen to a limited degree. It may be important to differentiate between primary glottal level compression and primary supraglottal compression because relegation of a patient to the supraglottal contraction category may carry a stronger inference of psychogenic etiology.5,11

During transnasal fiberoptic endoscopy, reduction of the lateral compression may be seen during more relaxed phonation, with a greater emphasis on speech-breathing and flow phonation. The status of the true vocal folds can be difficult to identify if the supraglottal adduction is extreme and occluding view of the true vocal folds.

A supraglottal compression pattern is sometimes compensatory for glottal incompetence, such as that created by sulcal vocalis, senile atrophy of the vocal folds, or vocal fold paralysis. In some cases, it may contribute to dysphonia; in other cases, adduction and phonation of the ventricular folds may contribute a desired (if not ideal) sound source. In some rare instances, supraglottal adduction may be intentional, when an individual uses the ventricular folds as a voice source. This might be trained in individuals who have congenital or acquired glottal incompetence that cannot be adequately treated with surgery.

In our experience, the lateral supraglottal compression pattern seen on laryngoscopy in patients who do not have glottal incompetence is usually associated with unresolved psychological conflict.11 Conscious or unconscious repression of anger or sadness is common in depressed patients, and primary or secondary gain may be accruable from the voice disorder. Therapy approaches must combine correction of specific misuses with a careful evaluation and management of the psychological factors. It is in this area that the advantages of a joint approach within a multidisciplinary voice clinic, encompassing laryngology, speech pathology, and psychiatry or psychology, are most obvious. During transnasal fiberoptic endoscopy, some relaxation of the supraglottal larynx may be elicited during imitation of a sigh, yawn, breathy voice, or inhalation phonation. Watch carefully for the patient’s response to improved voice. A denial or negative reaction to improved voice, and inability to reproduce the better sound, may be an indication of psychological gain factors and/or malingering.

Anteroposterior Supraglottal Compression

Koufman and Blalock have presented a voice type labeled “Bogart-Bacall syndrome,” in which patients exhibit a tension-fatigue dysphonia with phonation at the bottom of their vocal dynamic ranges, that is, anteroposterior (A–P) supraglottal compression.22 They have reduced space between the epiglottis and the arytenoid prominences in the anteroposterior direction during phonation (Figure 7). It is commonly seen in association with the laryngeal isometric pattern. Hypertonicity in the thyrohyoid muscles is typically noted in conjunction with the A–P constriction. Individuals using this posture complain of effortful voice and rapid fatigue when speaking at a low pitch, but they are able to talk more clearly and freely at a higher pitch. This kind of voice can be “put on” by those wishing to get a particular effect of authority or slurriness; as a result it is often present in the speech of vocal performers. Singers may exhibit a similar A–P contraction pattern on phonation in association with tense pharyngolaryngeal postures. This pattern may be used to achieve a particular resonance quality, an example of which is native North American throat singing, but in other singers it may be unintentional and secondary to technical error. Some singing teachers are beginning to use transnasal flexible videolaryngoscopy with their students to provide instant visual feedback that enables them to avoid or create this contraction pattern.

This laryngoscopic pattern is not readily seen with mirror examination or with the rigid telescope because the tongue pull may extend the aryepiglottic length. Transnasal fiberoptic examination during connected speech or singing is the most effective way to demonstrate this misuse. Elicitation of slow glissando pitch glides may effect some release of the A–P constriction.
Incomplete Adduction in Conversion Reaction Dysphonia

The psychological stressor or conflict that leads to a conversion reaction has produced such psychological distress that a physical symptom such as aphonia is more bearable to the person. The type of psychological stressors and resulting muscle misuse pattern differ from those associated with other muscle misuse voice problems. In conversion disorder, the misuse may be beyond the patient’s awareness, hence the typical belle indifference affect and facial expression. The vocal folds have full movement and can adduct normally for cough or other types of vegetative phonation such as laughter, but they stop short of sufficient adduction for voicing, and thus breathiness or a harsh whisper is the common perceptual feature. Generalized hypertonicity can be identified in the larynx; when sound does come out, it is usually high pitched and harsh or breathy. Forced adduction, distraction, glottal fry, or high pitches may elicit vocal fold approximation during diagnostic therapy, in which case the successful technique is used to initiate therapy in the absence of unresolved psychological gain factors that may affect motivation to achieve a normal voice.

Bowed Vocal Folds Associated with Psychogenic Dysphonia

In older patients, presbyphonia is associated with loss of muscle bulk and tone, as well as weakening and fragmentation of elastic and collagen fibers. This often results in a bowed glottal closure configuration. This so-called senile atrophy is not necessarily the principal dysphonia factor in patients who have bowed vocal folds. Occasionally, patients who appear to have a psychogenic dysphonia will phonate with a bowed glottis but may resume normal phonation and laryngoscopic appearance after voice therapy, psychotherapy, or both. This may also represent one of the forms of dysphonia in “habituated hoarseness” that follows an upper respiratory infection or other organic trigger. During the fiberoptic laryngeal examination, normal approximation of the vocal folds may be elicited with pitch change (typically elevated pitch); humming or vowel resonance; coordinated voice onset (“Hm!”); inhalation phonation; or glottal fry.

Figure 9 Bowed vocal folds due to muscle misuse.

Falsetto Register in Adolescent Transitional Voice Disorder

Normal adolescent voice change during puberty is often accompanied by pitch breaks, register breaks, and a degree of embarrassment. Psychological factors may lead to inhibition of the transitional event and establishment of perpetual falsetto phonation. Laryngoscopy reveals laryngeal hypertonicity, and the cartilaginous glottis may be hyperadducted, restricting phonation to the anterior membranous part of the vocal folds. The larynx generally is elevated by suprahypoid muscle contraction so it approximates the hyoid bone or base of tongue. Downward traction on the thyroid cartilages sometimes results in modal register phonation at a pitch that is more representative of the adult male voice. During the fiberoptic laryngeal examination, more appropriate phonation may be elicited with a cough or throat clear; glottal fry register; effort closure; loud phonation; or coordinated voice onset (“Hm!”).

Muscle Misuse Laryngeal Disorders in the Elderly

Certain voice changes are a normal part of the aging process and should not be considered disorderly, but it is important for the voice clinician to recognize and understand these, to be in a position to help out when problems develop. It seems that there are two primary altered states in the larynx that develop with aging. One, which predominates in women, is a thickened, chronically edematous larynx, resulting in a naturally lower f0 that may be below the typical “gender-ambiguous” f0 around 160 Hz, sometimes with accompanying dysphonic features. In the other altered state, atrophic changes predominate. These patients, most of them men, develop a higher f0 which may be above the gender-ambiguous f0 and thin voice timbre. Other age-related changes, such as reduced vital capacity, elasticity in structures of the chest wall, and strength in articulators, can contribute to altered speech and voice dynamics and muscle misuse patterns. Additionally, changes in the neurological system, cognitive functioning, and peripheral hearing may contribute to muscle misuse compensations. Neurogenic disorders of the larynx are discussed in Chapter 79, “Neurogenic Disorders of the Larynx.” Benign essential tremors tend to emerge in middle age or later, as do some neural events and degenerative disorders, such as cerebrovascular accidents (CVAs) and Parkinson disease. Medical and surgical procedures used to treat disorders common to the elderly, such as cardiovascular disease, may result in peripheral nerve damage, most commonly to the left recurrent laryngeal nerve during cardiac surgery or intubation injuries in the larynx during general anesthesia. Presbyacusis may play a role in voice changes as self-monitoring becomes more difficult. Finally, in older patients, loneliness or separation from family, loss of independence, and other lifestyle changes may lead to adjustment disorders with depression and anxiety, which may contribute to muscle misuse affecting the larynx.

The aging process in the male larynx involves muscle atrophy and loss of elasticity. The normal voice effect is increased pitch and “thinning” of the vocal tone. Attempts to compensate for these changes usually result in glottal fry phonation, increased laryngeal effort, and rapid vocal fatigue. Indirect laryngoscopy reveals apparent shortening and bowing of the true vocal folds. The vocal folds may adduct more efficiently if lengthening can be achieved with a higher pitched voice.

A more masculine-sounding voice in women (particularly those who have smoked for many years), caused by Reinke edema and polypoid degeneration, may be socially unacceptable. Those women who attempt to correct the pitch change by compensatory muscle misuse may develop lateral glottal and supraglottal compression and increased vocal effort. Phonation becomes easier and clearer when the patient is encouraged to allow the vocal tone to drop to a more natural range that is consistent with the age-related mucosal changes.

How far do these changes have to go before they cease to be normal? The answer usually rests with the individual patient’s physical and psychological reaction to the changes and the ease and effectiveness with which he or she is communicating. A change in vocal image is often at the core of an individual’s concern. When the older woman’s voice is so low in pitch that she is addressed as “sir” on the phone, she may consciously or subconsciously make muscular adjustments to raise the pitch. This tactic may work to a point, but soon the dysphonic voice...
Other forms of treatment, such as psychotherapy and managed care, are designated as a priority. The management program is informed by patients’ a-LERT profiles and any complicating lesion, life traumas (PTSD), chronic pathologic conditions that might be lumped together as central hypersensitivity disorder (CHD). Causes of CHD include personality predisposition, life traumas (PTSD), chronic pathologic stress, immune disorder, infections, and others. The presence of significant GER seems to play a role in development of throat (ILS) symptoms in patients with CHD.

**MANAGEMENT OF MUSCLE MISUSE DISORDERS OF THE LARYNX**

The management program is informed by patients’ a-LERT profiles and any complicating lesion, disease process or other physiologic changes. In some individuals, reflux may play a major role in predisposing, precipitating, and/or perpetuating the hypertonicity, and an appropriate level of reflux management is designated as a priority. Other forms of treatment, such as psychotherapy or voice therapy may be less effective if reflux symptoms are not minimized first. In other cases, reflux may not appear to contribute significantly to muscle misuse patterns, and focus for management may be primarily on changing specific factors that are contributing to muscle misuse. Suggestions may be made about modifying the acoustic environment, using voice amplification systems, or changing people management styles, for example, using nonvocal approaches to behavioral management in the public school classroom.

For patients in whom muscle misuse in the larynx is associated with general body posture misuses, voice rehabilitation will include a comprehensive hierarchical motor relearning program for body alignment, appropriate use of muscles around the head, neck and shoulders, and specific adjustments and exercises for tongue, jaw and facial muscles. If dysphonia is associated with the muscles misuse problem, motor relearning activities will be introduced to improve speech breathing and voice onset, resonance, vocal flexibility, vocal dynamics and meaningful speech phrasing. This type of comprehensive program is often provided in a group format, which can offer time and financial efficiencies to a number of individuals needing similar instruction and mutual support. Self-evaluation inventories are used at various stages to help clinician and patient chart progress and document areas that need more intense focus. A self-help guidebook is used in our clinic to provide specific direction for practice.

Group therapy is not recommended for individuals who may have significant psychological factors contributing to their muscle misuse disorder, who are reserved about working with others, who have difficulties attending and turn-taking, or other personality features that might reduce the benefit for themselves or others. Individual programs of voice therapy and psychotherapy should be coordinated to ensure appropriate ordering of treatment. In instances where psychological gain factors, personality disorder, or psychological illness are imposing on a patient’s motivation to participate fully in a voice therapy program, it should be deferred until the psychological issues are managed.

Symptomatic therapy may be used to deal with short-term, specific symptoms of muscle misuse. Specific techniques may be identified during the evaluation that result in improved function, and these can be shaped into more appropriate muscle function for speech, relaxation, or the laryngeal valve system. For example, a 15-year-old boy with adolescent transitional voice disorder is using the posture for falsetto during speech. By manually releasing the larynx down and/or initiating a cough or glottal fry, modal register may be produced. The patient can take on the responsibility of lowering his larynx and practicing the designated voice onset technique. Once he can consistently initiate his voice in modal register, he is encouraged to sustain the tone, using any combination of kinesthetic feedback to reinforce appropriate muscle use patterns. Once tone can be extended reliably in the modal register, articulatory movements can be introduced to allow for speech sequences. Any combination of facilitation techniques may be used in a similar way to assist a patient with conversion dysphonia, assuming psychological factors have been identified and resolved. The support of a family member or friend during therapy can be reinforcing and help the patient adjust to the dramatic difference that is typically experienced rapidly.

Manual therapy, specific manipulation of hypertonic muscles, is used both as primary and adjuvant therapy for some individuals with muscle misuse disorders of the larynx. The techniques often involve release of large muscle sets first, followed by more manipulation of specific paralaryngeal and laryngeal muscles. This type of management requires a thorough understanding of anatomy, indications and contraindications, and specific techniques for effective and safe application, and training should be sought from an experienced manual practitioner.

In addition to the various techniques used in comprehensive and symptomatic therapy, a variety of holistic approaches to body realignment, relaxation, and fitness may serve as adjuvant therapy. Patients with muscle misuse disorders of the larynx often experience benefit from participating in programs of yoga, Alexander technique, Feldenkrais, massage therapy, acupuncture, and various approaches to aerobics and fitness.

**Principles of Psychological Intervention**

In cases where it is clear that psychological factors play a definitive role in the etiology of an individual’s muscle misuse disorder, the mental health professional is advised to proceed with caution to avoid instilling skepticism in the patient who may be unaware of or unwilling to accept this aspect of the diagnostic profile. Begin by asking patients to state their understanding of the cause of their symptoms. It is astonishing how frequently intelligent patients respond to this request with something as simplistic as, “My stomach makes too much acid,” immediately after the team has explained that all four a-LERT factors are relevant. After correcting this misunderstanding, it is possible to continue the discussion with some hope of receptivity and collaboration.

Despite Descartes’ apparent separation of mind and body in his well-known comment, “Cogito ergo sum,” we are indeed unitary organisms: thought, emotion, and bodily action are all united. A thought that evokes no emotion gives
rise to no impulse to action. A thought that does evoke emotion elicits the impulse to action. It is not possible to act without the use of muscles. In those situations in which an individual has long been suppressing the impulse to express emotionally charged sounds, muscles of the vocal mechanism will be compromised, hence the need for voice therapy and psychotherapy.

**Management of Compensatory Muscle Misuse Problems Due to Aging Changes**

Management of voice problems that are compensatory to aging changes and their complications may include assisting the individual to accept the natural pitch associated with his or her senescent structure, followed by voice therapy to reduce muscle misuse and facilitate use of the natural pitch range. In patients in whom compensatory misuse is an attempt to control other anatomic and physiologic processes, such as benign essential tremor (BET) with or without dystonic spasms, additional strategies should be considered. Individuals with BET typically compensate by adopting a laryngeal posture that stabilizes the hyperkinetic laryngeal movement. In doing so, they usually increase the A-P and lateral compression of the vocal folds, decrease the pitch, and increase the vocal tremor and/or spasms. Adjusting to a higher \( f_v \) range allows for a less muscular and more aerodynamic mode of phonation, reducing the tremor and spasms.

**Management Program for Irritable Larynx Syndrome**

Based on the belief that ILS is related to a hypersensitive reaction to normal sensory stimuli, we treat patients using a three-level strategy.

**Level 1.** Minimize sensory stimuli, for example, reflux, odors. When the patients are aware that they have spasm symptoms on exposure to airborne irritants such as perfume or car exhaust, they can be more attentive to avoiding exposure, such as being able to make their workplace “scent-free.” Since it is likely that GER is a strong sensory stimulant of laryngeal muscle tension, it makes sense to minimize reflux as much as possible. Most ILS patients stay on protein pump inhibitors in the long term, in addition to lifestyle and diet measures.

**Level 2.** Reprogram the maladapted central response. Voice therapy and training in relaxed muscular and more aerodynamic mode of phonation, reducing the tremor and spasms.

**Level 3.** Use neuropsychotropic medication if indicated. Selective serotonin reuptake inhibitors (SSRIs) and combined serotonin and norepinephrine reuptake inhibitors, such as venlafaxine, are the most frequently used preparations. Tricyclic antidepressants, more frequently used in chronic pain and fibromyalgia, have a mouth- and throat-drying side effect that is sometimes a problem for those with throat symptoms. Baclofen, a centrally acting spasmyloytic drug, and gabapentin, an anti-epileptic, may also be effective.

Other treatment modalities such as botulinum toxin (Botox) injection into the vocal folds might be employed in selected patients. Considerable benefit can be achieved through regular and progressively increasing exercise. Being in better shape makes all the parts of the body work better, and the benefits of regular production of endorphins probably exceed those of exogenous medication.

**Responsibility of the Patient and Voice-Care Professionals**

Patients who are successful in rehabilitation programs are those who own their problem and assume ultimate responsibility for their rehabilitation. Barriers to acceptance of the diagnosis and responsibility to participate in a rehabilitation program include poor understanding of the nature of their dysfunction, psychological gain factors, untreated or untreatable psychological or personality disorders, mistrust of the referring health practitioner and/or therapist, and stories of success or failure of other individuals in therapy. To best prepare a patient for acceptance of the problem and solution(s), it is critical to ensure that he or she fully understands the multifactorial etiology of muscle misuse disorders, which justifies a multifaceted rehabilitation program. Once the patient understands the problem, it is helpful to offer immediately a suggestion for an initial treatment step that requires commitment by the individual. The task should be chosen carefully so that it has maximum impact on dominant symptoms without imposing an excessive burden on the patient. For some individuals, this may involve initial steps to minimize reflux. In others, it might be a simple postural adjustment suggestion, such as “Check your chin level ten times each day in a mirror, and lower it if it is tilted up or protruding.” Providing this simple initial step empowers the patient, by placing immediate responsibility for carrying out the necessary changes on the individual with the problem.

For patients in whom environmental factors are clearly contributing to muscle misuse, the professional team offers suggestions and support for environmental change. In instances where it is clear that uncontrollable ambient noise is interfering with normal voice function, it is important to provide support in the form of letters to employers explaining the problem and the need for solutions to be sought. These solutions may include having the acoustics assessed by an acoustical engineer, moving the patient to a different job or location, changing his or her vocal schedule, changing the room acoustics, and providing appropriate voice amplification devices. Provide written recommendations or prescriptions to employers or third-party insurers as required for the necessary environmental and/or job status changes. Often, institutions require that the chief signatory be a physician, but cosignatories including the speech–language pathologist, psychologist, psychiatrist, and other relevant members of the team may be helpful.

**Conclusions**

Muscle misuse disorders of the larynx are caused by a combination of factors and may be associated with other overlying lesions, diseases or anatomical changes related to development or aging. Identification of each of the etiological factors contributing to an individual’s voice disorder is imperative for the most descriptive clinical profile to be developed and for the most effective management to be planned.

Imaging of the Larynx, Trachea and Esophagus

Albert L. Merati, MD  
Lacey Washington, MD

Clinical laryngology continues to include radiological evaluation as an important adjunct to the hands-on assessment of patients. In contrast to the paranasal sinuses and recesses of the tympanic cavity, however, the mucosal surfaces of the larynx, trachea, and esophagus are readily accessible for examination in the office setting. As a result, relatively fewer anatomical imaging studies are used in laryngology compared to some disciplines within otorhinolaryngology. Most of this chapter is devoted to imaging related to the larynx; indeed, some topics span several organs (such as the MBS and the discussion of airway stenosis) and are reviewed in additional sections.

The importance of history and physical examination is emphasized; interpretation of imaging studies is often useless or misleading without this information. An example of this arose recently with positron emission tomography (PET) scans; a number of patients undergoing PET scans for detection or surveillance of malignancy were found to have suspicious uptake in their larynx contralateral to their known vocal fold paralysis. While understandably alarming for potential occult carcinoma causing this increased signal, 15 of the 17 patients were found to have "false-positive" studies; the enhanced uptake was felt to reflect the increased metabolic activity of the compensating vocal fold musculature and not from occult laryngeal cancer. Although this is a dramatic example, it suffices to say that patients are better served by the marriage of clinical and radiographic information.

LARYNX

Computed tomography (CT) continues to be the principal modality for imaging of the larynx. The first clinical work regarding CT evaluation of laryngeal disease emerged in 1977. This early paper from Mancuso and colleagues dealt with carcinoma of the larynx and the potential role of CT imaging of the larynx. Indeed, the clinical frontiers of laryngeal imaging involve the use of intraoperative CT scanning to follow tumor excision by the transoral laser approach. Generally speaking, the larynx may be imaged for intrinsic disease as well as for invasion by extralaryngeal neoplasms, such as thyroid cancer. Other common uses for laryngeal imaging include the evaluation of vocal fold paralysis without an obvious precipitating cause, acute external trauma as well as in the assessment of airway stenosis.

Normal Radiographic Anatomy of the Larynx

While the fine structure of the vibrating vocal folds cannot be detailed with standard radiographic imaging techniques, CT imaging of the larynx allows for precise assessment of the framework of the larynx and the hyolaryngeal complex (larynx and hyoid bone). The epiglottis, preepiglottic space, aryepiglottic folds, false vocal folds, true vocal folds, arytenoid cartilages, cricocricothyroid joints, thyroid cartilage, cricoid cartilage, and the paraglottic musculature can all be easily identified on CT imaging (Figure 1).

The thyroid cartilage is not perfectly symmetrical; this may be somewhat misleading when investigating trauma to the larynx. Hirano and colleagues dissected 20 larynges and found that most, if not all, had some asymmetrical features. Interestingly, there was one directional trend with a greater number of the specimens from older subjects revealing some medial rotation of the right thyroid lamina and corresponding lateral rotation of the left thyroid lamina. The clinical significance of this asymmetry is not known.

Structural Abnormalities of the Larynx: Benign Masses, Trauma, and Stenosis

Benign Masses. Some congenital laryngeal masses, such as the thyroglossal duct cyst (TGDC), are intimately associated with the hyolaryngeal complex. TGDC can present early in life as a painless midline neck mass overlying the thyroid notch. The mean age at presentation in one series was 21.5 years. If the mass is higher in the neck, that is, the submental space, the differential diagnosis favors other masses, such as a ranula or dermoid cyst.

CT may be helpful in differentiating among the benign midline masses; in reality, however, the diagnosis is easily made clinically and imaging studies are confirmatory. In addition to their characteristic location, their smooth rounded appearance on radiographic images supports the diagnosis of TGDC. If atypical features, such as irregular shape or a thick wall, are present, the possibility of carcinoma arising in TGDC should be considered. In a review from the University of Utah, carcinoma was found in 6 of 6 TGDCs with soft tissue elements within the cysts on imaging whereas 3 of 18 with benign appearing cysts contained carcinoma. These usually had a peripherally based mass within the cyst; calcifications were also present in the malignancies which provided CT imaging an advantage in evaluating these patients (Figure 2).

Laryngoceles are uncommon and interesting laryngeal abnormalities in which the air-filled laryngeal ventricle is enlarged into the false vocal fold and supraglottis, that is, internal laryngocele (Figure 3); in some cases, the sac extends beyond the confines of the larynx out through the thyrohyoid membrane, that is, external laryngocele (Figure 4). Whereas the internal laryngocele typically presents with hoarseness, sense of fullness, or throat clearing, an external laryngocele will manifest as a variable neck mass with or without the other laryngeal symptoms of an internal laryngocoel.

Glazer and colleagues advocated CT in the evaluation of a suspected laryngocele in the 1980s. CT has remained the imaging modality of choice for this clinical condition. The utility of radiography depends on its ability to confirm the diagnosis of internal versus external laryngocele; although the diagnosis is clinically straightforward in most cases, CT is useful in delineating the extent of the laryngocele and, therefore, in surgical planning. Small, internal laryngoceles may be treated endoscopically with marsupialization (removal of the false vocal fold to open the sac into the aditus of the larynx) and, Traditionally, the external laryngoceles have been treated with open resection. The laryngocele may have fluid in it; if this becomes infected, it may represent a surgical emergency as swelling and inflammation may compromise the airway (Figure 5).

Laryngeal Stenosis. The management of airway stenosis represents one of the great ongoing challenges in laryngology. Imaging, particularly in the form of CT, has been advocated for assessing the diseased airway both at the site of stenosis and...
distal to it. A typical example of this might occur when a clinician obtains a CT scan to evaluate the subglottis and trachea in a patient with glottic stenosis; whereas the subglottis and trachea can certainly be viewed in the routine clinical setting with modest risk, the presence of glottic compromise is a relative contraindication to endoscopy. In other words, it may be unwise to traverse a 5 mm airway with a 4 mm endoscope in the outpatient setting unless absolutely necessary.

The clinical history associated with airway stenosis can be helpful in characterizing the extent of the obstruction and understanding its cause, whereas most patients with airway stenosis have had some endolaryngeal or external trauma, some have no history of intubation or external injury.

Figure 1 Normal laryngeal anatomy on computed tomography (CT) scanning. (A) Laryngeal CT at the level of the hyoid and epiglottis. The midline glossoepiglottic fold can be seen in this cut. (B) At the level of the aryepiglottic folds, the thyroid cartilage comes into view. The paired pyriform sinuses are present just lateral to each aryepiglottic fold. (C) At the level of the false vocal folds, the bodies of the arytenoid cartilages are seen on each side. The relative lucency in the anterior portion of each false vocal fold represents the laryngeal ventricle. In this view, less of the pyriform sinus is seen than in superior cuts. The pyriform sinus approaches its apex at the level of the true vocal folds below. (D) At the level of the true vocal folds, the facet of the cricoarytenoid joint is seen, as is the most superior central portion of the posterior lamina of the cartilage. (E) The cricoid cartilage, though a complete ring, has a limited vertical dimension anteriorly. It may appear to be incomplete in all except a few cuts of a laryngeal CT. The cartilages seen just posterolateral to the cricoid are the inferior cornua of the thyroid cartilage. The recurrent laryngeal nerve lies in close proximity to this cricoarytenoid articulation on either side. (F) At the level of the trachea, the relationship between the anterolateral cartilaginous trachea and its membranous posterior wall is seen. The cervical esophagus is in direct apposition to this aspect of the trachea. Usually, the cervical esophagus is devoid of luminal air. Distension of the esophagus with air in this region may represent distal obstruction or a swallowing artifact.

Figure 3 Computed tomography of left internal laryngocele. This sac is modestly distended with air. The normal, undistended pyriform sinuses are seen bilaterally lateral to the aryepiglottic folds and supraglottic structures. (Published with permission, copyright © 2007 M.A. Michel, M.D.)

Figure 4 Computed tomography of an external laryngocele. The external elements of the laryngocele are emerging laterally through the left aspect of the thyrohyoid membrane. The sac is partially filled with air as well as fluid. (Published with permission, copyright © 2007 M.A. Michel, M.D.)
Imaging of laryngeal stenosis is executed, for the most part, with noncontrast CT. The variable nature of the radiographic appearance limits the diagnostic information obtained from CT imaging. In one review from the Massachusetts General Hospital, many different configurations were noted in a series of idiopathic laryngeal stenoses; these included an hourglass-shaped airway in 53% of patients and an eccentric airway in the other 47% of patients. The superior and inferior margins of the stenotic area were smooth in 60% of patients and irregular and lobulated in the remainder. Interestingly, no evidence of calcification or ossification was seen in this series of patients without a history of mechanical trauma, that is, no intubation or external trauma.

Carretta and colleagues provided an interesting comparison between endoscopic and radiographic evaluation of airway stenosis in their evaluation of postintubation laryngeal and laryngotracheal stenosis. In a prospectively evaluated series of 12 preoperative airway patients, their spiral CT imaging findings were compared to both flexible and rigid bronchoscopic assessment of the airway. While all three modalities correctly indicated the presence or absence of subglottic involvement in 92, 83, and 83%, respectively, CT did poorly in predicting the length of the stenosis at the time of open surgery. Rigid and flexible bronchoscopy were accurate 83 and 92% of the time, with only 3 of 12 cases (25%) having a correct preoperative measurement of the length of the stenosis. This is an important limitation as stenosis length is an important negative predictive factor in airway surgery. Because this study was small and limited to patients undergoing open surgery, caution must be taken before applying these findings to airway patients in general. Furthermore, the negative predictive value of CT imaging in the detection of additional areas of stenosis has not been described.

Three-dimensional (3-D) reconstruction of airway imaging is an exciting frontier in laryngology. While the elegance and attractiveness of the images cannot be denied, their actual clinical utility over and above airway endoscopy and routine CT imaging has not been proven.

Trauma. Arytenoid cartilage dislocation is an uncommon entity in which the arytenoid cartilage is dislodged from its complex perch on the facet of the cricoarytenoid joint; it is almost always associated with intubation although it may occur with external trauma. Patients complain of unilateral throat pain, hoarseness, and ipsilateral otalgia in some cases. CT has been advocated to assess the position of the arytenoid cartilage in relation to the cricoid (Figure 7). The differential diagnosis to consider in these patients is acute vagal neuropathy from intubation or injury from the operative procedure itself. Laryngeal electromyography may be helpful in assessing mechanical, that is, dislocation, versus neural impairment of cricoarytenoid joint motion. Mechanical disruption of the cricothyroid articulation, also resulting in pain and hoarseness, has also been described along with its imaging features.

External Trauma. It is estimated that 1 in 23,000 emergency room admissions includes the diagnosis of blunt or penetrating laryngeal trauma. It is far less common than endolaryngeal injury related to intubation. Once again, CT imaging is the diagnostic procedure of choice in the case of

**Figure 5** Computed tomography of infected bilateral mucopyoceles. This patient had 2 weeks of progressive odynophagia and shortness of breath. She weighed only 77 lb when she was evaluated in the emergency department.

These patients without known cause are most often women. Within the larynx, stenosis can be differentiated into supraglottic, glottic, and subglottic (Figure 6). As many as 40% of patients have more than one site of stenosis. In one review from the Massachusetts General Hospital, many different configurations were noted in a series of idiopathic laryngeal stenoses; these included an hourglass-shaped airway in 53% of patients and an eccentric airway in the other 47% of patients. The superior and inferior margins of the stenotic area were smooth in 60% of patients and irregular and lobulated in the remainder. Interestingly, no evidence of calcification or ossification was seen in this series of patients without a history of mechanical trauma, that is, no intubation or external trauma.

Carretta and colleagues provided an interesting comparison between endoscopic and radiographic evaluation of airway stenosis in their evaluation of postintubation laryngeal and laryngotracheal stenosis. In a prospectively evaluated series of 12 preoperative airway patients, their spiral CT imaging findings were compared to both flexible and rigid bronchoscopic assessment of the airway. While all three modalities correctly indicated the presence or absence of subglottic involvement in 92, 83, and 83%, respectively, CT did poorly in predicting the length of the stenosis at the time of open surgery. Rigid and flexible bronchoscopy were accurate 83 and 92% of the time, with only 3 of 12 cases (25%) having a correct preoperative measurement of the length of the stenosis. This is an important limitation as stenosis length is an important negative predictive factor in airway surgery. Because this study was small and limited to patients undergoing open surgery, caution must be taken before applying these findings to airway patients in general. Furthermore, the negative predictive value of CT imaging in the detection of additional areas of stenosis has not been described.

Three-dimensional (3-D) reconstruction of airway imaging is an exciting frontier in laryngology. While the elegance and attractiveness of the images cannot be denied, their actual clinical utility over and above airway endoscopy and routine CT imaging has not been proven.

**Figure 6** (A) Endoscopic view of supraglottic stenosis. The arrow points to cicatricial stenosis at the level of the false vocal folds. The true vocal folds are below this level and out of view. (B) Endoscopic view of subglottic stenosis: this patient’s radiograph is seen in Figure 6D. The arrow indicates the approximate “center” of the normal airway. Her subglottic stenosis is eccentric; it is entirely confined in the cricoid.

suspected laryngeal trauma.\(^{18}\) If blunt anterior cervical trauma is suspected, the airway, breathing, and circulation, that is, “A B Cs,” and the cervical spine receive the first considerations. This critical paradigm of trauma care impacts radiological investigation. If the injured patient is in distress, there may not be time for radiographic imaging. A surgical airway or, in some instances, intubation precedes imaging; once the airway is secure, the surgeons may explore the neck, including the laryngeal framework, or stop the procedure at that point and obtain the radiographic investigations. If, on the other hand, a patient is not in distress, the managing physician has the luxury of pursuing CT scanning for the suspected injury. Airway management depends on sensible, conservative clinical assessment; a modest laryngeal injury in an otherwise compromised patient, for example, systemic injury, anticipated difficult intubation, and/or mental status changes, may mandate an urgent surgical airway, in contrast to some severe isolated laryngeal injuries in a slender, cooperative patient which may allow for prompt radiographic investigation prior to surgery.

An example of external laryngeal trauma is seen in Figure 8. Characteristics of cartilaginous fractures include disruption of the continuity of the thyroid ala or the cricoid ring. Few scholarly comparisons have been made to detail the respective roles of laryngoscopy and radiographic imaging; as noted above, the clinical environment may impact this greatly. Many fractures result in extravisceral air; this represents air escaping into the soft tissues of the neck. If the injury is in the airway, particularly below the vocal folds, this may result in a great deal of gas escape into the soft tissues (Figure 9); a simple supraglottic or pharyngeal injury is less likely to result in air trapping in soft tissue. Scaglione and colleagues noted that CT imaging may be advantageous even in suspected minor mucosal injuries;\(^{19}\) in these cases, the presence of a small amount of air was indicative of perforation and not simple mucosal laceration. Goudy and colleagues reported on a series of patients with air in the neck on CT scan; the location of the injury was found to be laryngo-tracheal in 37% of the cases, with a smaller amount originating from the hypopharynx (27%), oropharynx (16%), and the esophagus (5%).\(^{20}\) The source of the injury was not located in 15% of patients. Recently, ultrasound has been studied in the laboratory as a potential tool for the assessment of laryngeal injury following trauma.\(^{21}\) This rapid, noninvasive mode of imaging could theoretically allow for airway examination without moving the patient from the trauma room to the radiology department. For the time being, however, CT remains the dominant imaging tool to complement clinical assessment of laryngeal injury.

**Malignant Neoplasms of the Larynx**

**Squamous Cell Carcinoma.** Squamous cell carcinoma of the larynx continues to be a major source of morbidity and mortality. Laryngeal cancer has, remarkably, become more deadly since the early 1990s, the only solid neoplasm in which the 5-year survival rate has fallen in the past 10 years.\(^{22}\) It is believed by many that this decline is related to the trend away from total laryngectomy as a principal component of treatment for advanced neoplasms. Radiotherapy is used in the care of laryngeal cancer patients for two main objectives: initial staging and subsequent tumor surveillance. Recently, PET combined with CT scanning has become popular in surveillance.\(^{23}\) M R I is useful in these patients as well, particularly in assessing cartilage invasion.

The vast majority of laryngeal malignancies are squamous cell carcinoma. Of these, the majority arise in the glottis, with the bulk of the remaining being supraglottic in origin.\(^{24}\) Primary subglottic carcinomas are rare, comprising less than 2% of laryngeal malignancies. Initial Staging. Many of the clinical staging parameters are related to the absolute size (in maximal dimension) of the primary tumors and their metastases. For example, a supraglottic tumor smaller than 2 cm is categorized as a T1. An otherwise similar tumor measuring 2.5 to 3 cm in size is a T2, carrying significant prognostic impact to the patient. With the advent of CT imaging, the calculated volume of the primary tumor has been found to be a potent predictor of local control in both glottic and supraglottic primaries. M arcuso and colleagues, in an important prospective series published in 1999, demonstrated that local control was 89% in tumors less than 6 cc volume; in tumors larger than 6 cc, the local control rate at 2 years was 52% when primary radiotherapy was used as the principal treatment.\(^{25}\) The initial tumor size also had an impact on maintaining laryngeal function. M endenhall and colleagues, in a major review from the University of Florida, concluded that although the initial T category was the single most potent predictor of local control in head and neck cancer in general, the CT-derived determination of tumor volume was a valuable predictor of local control for both glottic and supraglottic primaries, but not for oropharyngeal and hypopharyngeal malignancy.\(^{26}\) The inter- and intrarater reliability of this approach was reported by M ukherji and colleagues in 2005.\(^{27}\) In this study, clinicians were found to have high intraclass correlation in determining the tumor volume present in a series of supraglottic carcinomas. In contrast, Hoorweg and colleagues studied 55 patients in whom the interrater reliability of tumor volume calculation, cartilage invasion, and cartilage sclerosis were found to have significant clinical variation.\(^{28}\)

Gordin and colleagues have reported on their experience with combined PET/CT scanning in the diagnosis of laryngeal cancer.\(^{21}\) In their series of 42 patients, they recorded a 96% positive predictive value for combined PET/CT as compared with 76% for PET scan alone or 48% for CT alone. As access to PET technology becomes more widespread, these promising figures will likely continue to impact the care of laryngeal cancer patients. In the Gordin and colleagues study, in 25 (59%) of their 42 patients, PET/CT studies resulted in an important clinical management decision.

**Cartilage Invasion.** Imaging if often the only preoperative indicator of cartilaginous invasion by malignancy, either from primary laryngeal carcinoma or extralaryngeal, that is, invasion by a nonlaryngeal carcinoma, for example, thyroid carcinoma (Figure 10). As noted above, cartilage invasion is an important prognostic indicator for survival and resistance to primary radiotherapy. CT scanning depends on multiple criteria to enhance the positive predictive value for the detection of cartilage invasion. Although the presence of tumor on both sides of the cartilage (understandably) is the single best indicator for primary radiotherapy was used as the principal treatment.\(^{25}\) The initial tumor size also had an impact on maintaining laryngeal function. M endenhall and colleagues, in a major review from the University of Florida, concluded that although the initial T category was the single most potent predictor of local control in head and neck cancer in general, the CT-derived determination of tumor volume was a valuable predictor of local control for both glottic and supraglottic primaries, but not for oropharyngeal and hypopharyngeal malignancy.\(^{26}\) The inter- and intrarater reliability of this approach was reported by M ukherji and colleagues in 2005.\(^{27}\) In this study, clinicians were found to have high intraclass correlation in determining the tumor volume present in a series of supraglottic carcinomas. In contrast, Hoorweg and colleagues studied 55 patients in whom the interrater reliability of tumor volume calculation, cartilage invasion, and cartilage sclerosis were found to have significant clinical variation.\(^{28}\)

Gordin and colleagues have reported on their experience with combined PET/CT scanning in the diagnosis of laryngeal cancer.\(^{21}\) In their series of 42 patients, they recorded a 96% positive predictive value for combined PET/CT as compared with 76% for PET scan alone or 48% for CT alone. As access to PET technology becomes more widespread, these promising figures will likely continue to impact the care of laryngeal cancer patients. In the Gordin and colleagues study, in 25 (59%) of their 42 patients, PET/CT studies resulted in an important clinical management decision.

**Cartilage Invasion.** Imaging if often the only preoperative indicator of cartilaginous invasion by malignancy, either from primary laryngeal carcinoma or extralaryngeal, that is, invasion by a nonlaryngeal carcinoma, for example, thyroid carcinoma (Figure 10). As noted above, cartilage invasion is an important prognostic indicator for survival and resistance to primary radiotherapy. CT scanning depends on multiple criteria to enhance the positive predictive value for the detection of cartilage invasion. Although the presence of tumor on both sides of the cartilage (understandably) is the single best indicator
In 12 of 29 patients with local failure, “grade 3” findings were present a median of 5.5 months before the clinical examination indicated failure, a much higher rate than in the first two, more favorable grades.

PET imaging has been advocated for over 10 years as a useful examination when faced with the question of recurrent carcinoma versus chondroradionecrosis following radiation therapy. Terhaard published a remarkable prospective series of 75 patients (both laryngeal and pharyngeal primaries) evaluated before and after radiotherapy with a mean follow-up time of nearly 2 years. Of the 27 initially negative PET scans following treatment, there were no positive biopsies at that time nor over the following 1-year period. The first PET scan was truly positive in 34 of 48 patients; in 12 of 14 patients with false-positive results, that is, biopsy negative for recurrence, subsequent PET scans demonstrated decreased uptake, thus raising the specificity and sensitivity of the PET scans to 97 and 82%, respectively. They concluded that PET imaging should be the first study when recurrence is suspected following radiation for cancer of the larynx or pharynx. If the PET scan is negative, no biopsy is needed; if the PET scan is positive but the biopsy is negative, decreased fluorodeoxyglucose uptake measured in a follow-up scan is indicative that local failure is unlikely.

Even in the absence of tumor, CT may be helpful in characterizing the status of the irradiated larynx. Chondroradionecrosis (Figure 11) is a painful and frustrating byproduct of laryngeal radiation in which the cartilage framework of the larynx becomes nonviable. Laryngeal function, including voice, swallowing, and airway, can be affected. Although hyperbaric oxygen has been recommended for treatment, many patients undergo laryngectomy for the removal of a painful and dysfunctional larynx. The principal goal of imaging in cases of suspected chondroradionecrosis will be detection of viable carcinoma in the larynx; that having been said, there are some helpful but nonspecific CT characteristics of chondroradionecrosis, such as articular cartilage sloughing, collapse or fragmentation of the thyroid cartilage, or the presence of gas bubbles around the laryngeal framework.

Other Malignancies. Although uncommon overall, imaging is particularly helpful in identifying and determining the extent of nonepithelial malignant neoplasms, such as chondrosarcoma. These rare neoplasms comprise only a small percentage of laryngeal malignancies. Most arise in the cricoid cartilage; surgical removal is the treatment of choice. Imaging, particularly with CT, can distinguish between varieties of epithelial-derived neoplasms and these cartilaginous neoplasms (Figure 12). A review of CT findings in chondrosarcoma was published by Wippold and colleagues in 1993. In this paper, the authors noted that coarse or stippled calcification within the neoplasm was the most helpful radiologic finding and was universally present in their 10 patients with chondrosarcoma. Eight of 10 patients had both endolaryngeal and extralaryngeal growth patterns. Other neoplasms do occur in the larynx, including neuroendocrine carcinomas, basosquamous malignancies, and soft tissue sarcomas.

Inflammatory Disorders

A cute laryngeal inflammation ranges from the routine, such as viral laryngitis accompanying an upper respiratory infection, to the life threatening, such as epiglottitis. It is uncommon for imaging to be performed for the clinical extremes of these problems; for example, when a patient is in marked distress, management is focused on relief of airway obstruction. In less severe situations, a soft tissue plain lateral radiograph of the neck may be obtained by the emergency department physician. In the patient with suspected epiglottitis, the classic “thumb print” sign can be seen. The clinical impression made by the patient on the physician will be dominated by the history and endoscopic examination, if it is possible to perform laryngoscopy on the patient.
A typical chronic laryngeal inflammation, often infectious in nature, may be the subject of imaging. Laryngeal tuberculosis, although rare, may be endoscopically confused with carcinoma of the larynx due to the irregular appearance of the mucosa and chronic symptoms such as hoarseness and cough. In two review papers from the last decade, mycobacterial infection of the larynx was studied and noted to have several suggestive features that may help to distinguish it from malignancy.40–44 Laryngeal tuberculosis is more likely to demonstrate bilateral abnormalities, diffuse thickening of the epiglottic-freemargin, and the absence of submucosal or preepiglottic space involvement when compared to laryngeal malignancy. In addition, cartilage destruction was not seen in any patients with tuberculosis in these series. It would be hard to imagine deferring a biopsy of the laryngeal abnormality despite a high clinical suspicion of mycobacterial disease. The supportive radiographic information may be helpful in alerting the clinician to handle the sampled tissue with caution and directing appropriate cultures in addition to histopathological examination.

While the management of other challenging laryngeal conditions, including Wegener granulomatosis and sarcoidosis, often includes imaging, the specific CT findings usually do not add to the information gathered from the endoscopic examination.42

Vocal Fold Paralysis

Vocal fold paralysis continues to generate a great deal of discussion in laryngology; the radiographic evaluation of these patients does not, however, focus on the larynx itself but rather on extralaryngeal structures along the course of the vagus nerve and its branches. That is not to say that the larynx is devoid of interesting findings in vocal fold paralysis; several diagnostic features, such as medial position and thickening of the aryepiglottic fold, hypopharyngeal dilatation, and ventricular dilatation, all on the involved side, have been established as characteristic findings (Figure 13). Occasionally, unusual causes of mechanical impairment of vocal fold and arytenoid motion will be detected, as shown in Figure 14.

Nonetheless, the principal motivation for clinicians pursuing imaging related to vocal fold paralysis is to evaluate for a possible neoplastic cause. It is not clear what is the likelihood of detecting an otherwise occult neoplasm with radiography along the course of the laryngeal nerves. A recent publication from Finland has found that 9 of 34 patients in the “noniatrogenic” category harbored neoplasia, including those secondary to goiters and chest malignancies. Overall, the relative incidence of neoplasia as the cause of vocal fold paralysis has declined in the past few years, with more cases of idiopathic and iatrogenic neuropathy.44–47 Nonthyroid surgical procedures, such as anterior approaches to the cervical spine, have surpassed thyroid surgery as the dominant cause of iatrogenic vocal fold paralysis.

The debate between advocates of plain chest radiography (CXR) and CT with regard to imaging of “idiopathic” vocal paralysis has died down in the past few years. This matter has not been settled because of the advent of any thorough investigation or even a major retrospective study; it is a matter of practicality. It has been argued that CXR should be used as screening based on its relatively low cost and high yield (upward of 50% in some series).48 Proponents of CT imaging, on the other hand, cite several important studies, including the Glazer and colleagues study in which 27 of 33 patients had positive CT scans.49 This high incidence of abnormal findings in the Glazer and colleagues study is well above that seen in otolaryngology practice; the potent message of the paper is that 13 (72%) of the 18 patients with left-sided vocal fold paralysis with aortopulmonary masses on CT scan had a normal appearing mediastinum on CXR. The mean size of the chest mass in the negative CXR-positive CT group was 2.3 cm. In contrast, the smallest lesion detected in the positive CXR group was 3.8 cm.

Despite these conflicting views, in practical terms a normal CXR would likely be followed by a CT to evaluate the chest further in a patient with an otherwise unexplained vocal fold paralysis; by the same token, a positive CXR would also mandate a CT for more detailed characterization of the thoracic lesion. This commonly employed logic renders the CXR less useful, regardless of the scientific evidence supporting this approach.

With regard to MRI, there is not much evidence for or against this modality in the evaluation of vocal fold paralysis; several papers report on a small number of MRI evaluations for the evaluation of “idiopathic” vocal fold paralysis.50,51 Although the yield for MRI in these retrospective papers was high, the absolute numbers (6 of 10 patients having abnormalities detected on their MRI examinations) are quite small and preclude significant conclusions. While MRI is useful in related clinical conditions, such as in the detection of recurrent laryngeal nerve involvement by thyroid cancer,52 it has a high false-positive rate in patients with lower risk,53 limiting its role in many practices.
TRACHEA

The trachea (formerly trachea arteria, Greek for rough artery) harbors relatively few neoplasms compared to the larynx or the lungs. CT is the imaging modality of choice for the vast majority of tracheal disorders. Most imaging of the trachea is by CT, either for the evaluation of stenosis or malignant invasion.

The normal trachea is composed of 14 to 22 C-shaped rings of cartilage with a membranous posterior segment. The cross-sectional diameter of the trachea approaches 20 mm in some adults.

Global airway physiology is dependent on respiratory mechanics, in addition to the “baseline” cross-sectional area, as the trachea lies partially in the neck and partially in the chest; it is thus subject to the thoracic negative pressure necessary for normal inspiration. Conversely, the trachea is also subject to compressive force from expiration. This dynamic quality is exploited in radiographic examination of patients with suspected tracheomalacia.

Tracheal Stenosis

As noted in the section on laryngeal stenosis, imaging may be helpful in characterizing the length of the stenotic segment as well as in detecting secondary lesions. Plain radiography (Figure 15) may be revealing; however, if the clinician suspects extramural compression by a thyroid lesion or a vascular ring, CT imaging will provide superior information (Figure 16). The radiological findings are generally not exclusive to any one cause, although, as noted above, patients with no history of mechanical injury, that is, no intubation or external trauma, are less likely to have calcification or ossification on their studies. While this is a retailable clinical “pearl,” it is unlikely to supersede the patient’s history of an intensive care unit stay or an incision on their neck.

Improvements have been achieved in the past few years with the advent of helical CT scanning. In this modality, rapid image acquisition has significantly reduced respiratory and cardiac motion artifact in airway studies; prior to this, 3-D reconstructions of airway lesions were put together from multislice images taken from different breath-holds. In a significant early paper, Whyte and colleagues reported on 25 patients who underwent helical CT and multiplanar reconstruction and compared these findings to plain tomography and bronchoscopy for evaluation of central airway obstruction. The helical CT with reconstruction accurately demonstrated both the site and severity of stenoses with a sensitivity of 93% and a specificity of 100%. Interestingly, the one false-negative study was in a patient with tracheomalacia. The patients (often debilitated and dyspneic) are required to hold their breath for 15 to 45 seconds, a potential limitation to this technique.

The next phase of imaging in airway evaluation for stenosis is referred to as “virtual endoscopy” by its proponents. In this, the collected data from the 3-D airway assessment are synthesized into video format with a tour through the airway. The overall contribution of virtual endoscopy to clinical care is not known for tracheal stenosis. A still image from the 3-D reconstruction is seen in Figure 17.

Neoplasms Affecting the Trachea

Primary neoplasms of the trachea are rare; when they do occur, more are likely to be malignant than benign. Squamous cell carcinoma (SCC) accounts for about 50% of tracheal malignancies, adenoid cystic carcinoma for 30%, adenocarcinoma for 10%, and the remainder of the principal cell types for 10%. There are few imaging distinctions among these cell types, other than their local behavior and what is known about their natural history. Patients with SCC of the trachea are certainly at risk of a synchronous or metachronous SCC in the larynx or lungs.

CT images of adenoid cystic carcinomas may feature submucosal growth and a resultant “thickened” appearance to the trachea. Computed tomography is particularly useful in determining the extent of tumor extension into the mediastinum. Other tumors, such as mucoepidermoid carcinomas, are believed to feature more “endoluminal” growth patterns but no one of these findings is consistent enough to be diagnostic. Although quite rare, carcinoid tumors have dependable CT findings which may assist in the diagnostic process. Carcinoid tumors, derived from neuroendocrine cells, tend to arise in central bronchi and not in the trachea. When they are seen on CT scan, however, they feature high contrast enhancement due to the vascularity of the tumor. Other paratracheal masses, such as a tracheocele, may be detected on CT imaging. They are characterized by air in a paratracheal mass. In some cases, the tract connecting the air sac to the trachea can be seen on CT (Figure 18). If the tracheocele becomes fluid filled, it may be more difficult to distinguish it from other paratracheal masses.

Figure 15 Postero-anterior (PA) radiograph tracheal stenosis, as most commonly seen following intubation or tracheostomy. It shows smooth narrowing of the tracheal air column (arrow) a few centimeters below the level of the larynx. The narrowing of the tracheal air column is readily evident although detailed characterization is limited.

Figure 16 Computed tomography of compression and displacement of the cervical trachea by a massive goiter. The tracheal air column is displaced from the prevertebral area.

Figure 17 Three-dimensional reconstruction of computed tomography of tracheal stenosis. The presence of normal trachea above and below the stenosis is particularly helpful in these patients, as is the determination of the length of the stenosis.

Figure 18 Computed tomography image at lung window settings in a patient with a tracheocele and severe diffuse bronchiectasis, demonstrating a bubbly airspace along the right posterior tracheal wall with a small tract communicating with the tracheal lumen (arrow).
Tracheomalacia

Tracheomalacia typically presents with dyspnea on exertion or chronic cough. It may be congenital or acquired following prolonged intubation. It is believed that the endotracheal tube cuff pressure destabilizes the cartilaginous trachea. On clinical examination, the endoscopic appearance of the trachea may be normal; the ideal clinical imaging to supplement awake or even sedated endoscopy would be dynamic CT. In this modality, both end inspiratory and end expiratory CTs are taken of the trachea. The dynamic change in the tracheal configuration is noted in comparing the two images; Boiselle and Ernst described the expiratory “frown sign” which was found in over one-half of their patients (Figure 19). In their study, the images of patients with bronchoscopically proven malacia were reviewed in a blinded manner. During inspiration, 16 of 17 patients had normal configuration; on expiration, all of the patients demonstrated some degree of abnormality, the “frown sign” being the most common, seen in 9 of 17 patients. They also suggested that the presence of this finding may aid in the detection of tracheomalacia in patients who inadvertently breathe during CT scans.

ESOPHAGUS

Imaging of the upper esophageal sphincter (UES) area and esophagus is directed at both form and function; important structural abnormalities can be detected by contrast radiography (such as the barium esophagram), CT, and even by endoscopically guided ultrasound. Dysphagia is a major clinical issue, and aspiration is a common cause of morbidity and mortality. More patients died each year of aspiration pneumonia complicating stroke than the head and neck cancers combined.

Dynamic Evaluation of Swallowing

The standard examination for the investigation of pharyngeal and upper esophageal function is the modified barium swallow (MBS), also known commonly as the video swallow study. The indications for this study include the assessment of patients with dysphagia, with or without suspected aspiration. In addition to providing structural and dynamic information about the area, this study provides an opportunity for a speech-language pathologist to assess the impact of postural maneuvers, swallowing strategies, and choices of ingested material in an attempt to guide the patient toward idealized safe oral intake if at all possible. Contrast entering the aditus of the larynx but not passing inferior to the vocal folds is referred to as penetration. If the ingested material enters the subglottis or trachea, aspiration has occurred. Other key findings on the MBS include a description of hyolaryngeal movement, base of the tongue propulsion, and upper esophageal sphincter opening, including timing, degree of opening, and duration (Figure 20).

Martin-Harris and colleagues reviewed a series of 608 MBS studies and noted that only 10% were classified as “normal,” whereas aspiration occurred in 32% of patients, swallowing abnormalities without aspiration occurred in 57%.

![Figure 19](image-url)
Clinical management was influenced in over 80% following the MBS, mostly by the initiation of referrals to specialists, the institution of compensatory strategies and dietary changes, as well as the recommendation for swallowing therapy. The authors concluded that “the low percentage of normal studies coupled with the high percentage of change in measurable variables indicate high clinical utility for the modified barium swallow study.” This important study supported the belief that the MBS should be viewed as more than just a method for detecting the presence or absence of aspiration. Some concern has been raised over the possibility that the subjective nature of the test leads to variability in test results. In one study of normal volunteers, some variation was noted among experienced clinicians in their interpretation of MBS findings; the differences did not, however, reach statistical significance.64

Certain specific MBS findings deserve further comment, such as the enigmatic cricopharyngeal (CP) bar. This common and conceptually embraceable radiographic finding does indeed have clinical significance (Figure 21). It is associated with the manometric high-pressure zone of the UES.65 This function alone makes the CP bar an important area to examine during MBS studies. The functional UES is about 1 cm in length and moves rostrally with swallowing. Interestingly, the changes implied by the presence of a bar are more complex than simple mechanical impedance. Dantas and colleagues from the Medical College of Wisconsin studied a small group of dysphagic patients with CP bars and compared their pharyngeal and UES manometry to a group of controls.66 They noted that whereas this group of patients with CP bars demonstrated normal peristalsis and flow rates across the sphincter, as well as normal duration of opening, there were several important abnormalities noted. The subjects with CP bars had reduced maximal dimensions of UES opening and increased resulting intrabolus pressure in the pharynx upstream of the sphincter. They suggested that the underlying pathogenesis of the bar reflected reduced muscle compliance.

Endoscopic Evaluation of Swallowing versus Modified Barium Swallow

The advent of the flexible endoscopic evaluation of swallowing (FEES) study with7 and without sensory testing in the 1990s had some advocates predicting the demise of the MBS. In this valuable procedure, the patient is “fed” while a flexible nasopharyngoscope is in place. With the addition of laryngopharyngeal sensory testing, this purely endoscopic approach may have significant benefit in the care of stroke patients to give one important example.62 Proponents of this approach have pointed out several key advantages over standard MBS; first of all, endoscopic examination can take place at the bedside. The sensory testing that accompanies the FEES examination (in some cases) does not depend on a cooperative patient. In addition, the examination can take place at the bedside or in the clinic at the time of the initial examination and does not require transportation to the radiography site. Wu and colleagues compared MBS to FEES testing in 28 patients with dysphagia.67 They found that the effectiveness of the cough reflex and determination of velopharyngeal incompetence were under-reported on MBS in 1 of 3 subjects. Premature oral spillage into the pharynx was better detected on MBS; in general, however, even other familiar MBS findings such as aspiration, penetration, and...
pharyngeal stasis were all slightly more likely to be detected during FEES than MBS.

A major prospective paper from Aviv studied 126 subjects prospectively and followed them for 1 year. The MBS and FEES with sensory testing studies were equivalent in guiding behavioral and dietary management in a series of outpatients with dysphagia in terms of their ability to avoid pneumonia and further morbidity from aspiration. The overall familiarity with MBS and its ability to detect UES dysfunction as well as allowing for more objective assessment of response to postural maneuvers has kept MBS in the forefront of clinical dysphagia assessment. FEES continues to be a reliable tool in the clinic or at the bedside in many circumstances as well. Unfortunately, despite excellent clinical research and promising initial data, enthusiasm for the laryngopharyngeal sensory testing component of the endoscopic swallowing evaluation has not expanded into general practice.

**Structural and Inflammatory Disorders**

**Zenker Diverticulum.** Discussion of this disorder is properly included with the hypopharynx as its origin is above the UES. The presence of a “sac” containing contrast extending past the cricopharyngeal muscle, usually on the left side, is the classic finding in Zenker diverticulum (Figure 22). These may be treated with open surgery or by endoscopic techniques. Radio-lum (Figure 22). These may be treated with open or extravasation of contrast from the hypopharynx into the soft tissues of the neck or the mediastinum. It is important to note that there are several other findings which may be of note on these “leak” studies. Regardless of the mode of surgical treatment, it is not uncommon to detect a remnant of the Zenker diverticulum sac; this is an important item to communicate to the patient and the radiologist and speech-language pathologist reporting on the study. Jaramillo and colleagues reported on a series of Zenker diverticula treated with endoscopic stapling; 15 of the 32 patients were restudied 2 years postoperatively. All 15 who underwent postoperative MBS had evidence of a persistent pouch; indeed, of the 12 with both pre- and postoperative studies, only 4 of the 12 showed any decrease in the size of the pouch. Twelve of the 15 patients surveyed were satisfied with the results of their procedure. There was no correlation between symptomatic outcome and pouch persistence.

Tsikoudas and colleagues investigated the association between radiological findings and outcomes in endoscopic stapling of Zenker diverticula. Interestingly, when examined retrospectively, an association between pouch configuration and clinical outcome was noted. In short sacs with a broad angle between the sac and the native esophagus, there was a higher incidence of perioperative complications, both technical and medical. Zenker sacs with long necks and large pouches were associated with a higher rate of revision surgery.

**Reflux.** Few topics in laryngology and bronchoesophagology generate as much disagreement as gastroesophageal and laryngopharyngeal reflux. Generally, radiographic studies are not used as the first line of investigation for these disorders; nonetheless, contrast examinations of the esophagus may be helpful in some patients both in the assessment for reflux as well as for the detection of peptic complications. Ambulatory pH monitoring and impedance testing continue to be the dominant quantitative tests for reflux; esophagoscopy, either traditional transoral sedated or by transnasal awake technique continues to be the definitive test for the assessment of esophageal mucosal disease, including inflammation and injury from reflux as well as neoplastic disorders.

Esophagitis, resulting from peptic injury of the esophagus, can be readily detected in the double (barium and air) contrast esophagram; when used in combination with single-contrast views, the sensitivity approaches 90%. This sensitivity does, however, result in a notable rate of false-positives. The most common finding of reflux esophagitis on these studies is a finely nodular or granular appearance with poorly defined radio-lucencies due to edema and inflammation of the mucosa (Figure 23). These reflux-associated findings typically occur in the area immediately superior to the gastroesophageal junction.

**Strictures and the Schatzki Ring.** Contrast esophagography is useful in distinguishing between neoplasia and luminal narrowing of the esophagus, as in the case of stricture. These are often peptic in nature, although they may also be associated with other disorders, such as collagen vascular diseases and radiation injury (Figure 24). In symptomatic lower esophageal concentric narrowing, that is, Schatzki ring, if the lumen is compromised to a maximum diameter of 13 mm, dysphagia is almost always present; in contrast, a lumen of 20 mm rarely results in swallowing complaints. Esophagography may be superior to endoscopy in some cases of lower rings.

**Neoplasia.** Benign tumors, such as leiomyoma, represent the minority (20%) of esophageal neoplasia. They have some characteristic imaging features on contrast esophagography; they are smooth and submucosal and form a broad angle with the native esophagus when viewed in
study noted that the plain chest radiographs were effectively elevated filling defects with homogeneous low or isoattenuation. Interestingly, the same thickening within the distal esophagus is better demonstrated by EUS compared to 40% by CT. An example of an EUS of esophageal cancer invading the aortic wall is seen in Figure 28. Periesophageal lymph node assessment is also significantly more accurate with EUS than CT (73% vs 33%). Even obstructing lesions that prevent the probe from passing may be accurately categorized.

CONCLUSIONS

Imaging will continue to be a tremendous tool for clinicians dealing with disorders of the larynx, submucosal masses, peptic injury, and neoplasia. The ability to assess deep structures and their association with pathological changes, such as thyroid cartilage invasion by laryngeal malignancy, continues unrivaled except perhaps by surgical exploration with its inherent morbidity.

REFERENCES

Laryngoscopy, that is, viewing of the larynx, can be accomplished by two basic methods. These are grouped into either indirect or direct techniques. Indirect laryngoscopy uses mirrors, glass prisms, fiberoptic glass rods, or microchip cameras to view the larynx and hypopharynx with the patient’s head and neck in a neutral position. The image obtained from indirect laryngoscopy is viewed after it has been reflected and/or transmitted by one of the previously mentioned systems (Figure 1). Direct laryngoscopy, on the other hand, is performed with the neck flexed forward while the head is extended on the atlanto-occipital joint. The tongue is displaced either laterally or anteriorly. This position affords a direct line-of-sight for visualization through an open mouth to the larynx (Figure 2).

It is critical to understand that any manner of viewing the larynx which is not accomplished through direct line-of-sight and requires bending the image through glass fibers or reflecting the image with mirrors or prisms is considered an indirect technique. Prior to the development of fiberoptic technology, this distinction was clear. Fiberoptic techniques transfer light and the image along flexible glass fibers. Therefore, by the historical definition, fiberoptic techniques for laryngoscopy are indirect techniques. With improvements in image and light transfer, the miniaturization of charge coupled device (CCD) cameras placed at the end of the flexible scope, and the development of instrumentation which may be used through side channels on the flexible endoscope, the larynx can be indirectly viewed and manipulated. These indirect flexible techniques are gaining popularity among the current generation of laryngologists due the relative ease of performance and enhanced patient comfort. Some surgeons may elect to consider “fiberoptic” laryngoscopy an entirely different form of indirect laryngoscopy and may have valid arguments for this point.

Both the direct and indirect forms of laryngoscopy have advantages and disadvantages for viewing and intervening in laryngeal processes. The purpose of this chapter is to discuss the technical aspects of each form of laryngoscopy. The forms will be discussed as indirect rigid laryngoscopy, indirect flexible laryngoscopy, and direct rigid laryngoscopy.

HISTORY AND INSTRUMENT DEVELOPMENT

A review of the development of indirect and direct laryngoscopy is complicated due to discrepancies throughout historical records. However, the concept of viewing the larynx, mainly for the purpose of placing “tubes” for ventilatory support, was introduced by Hippocrates and reported intermittently by various physicians throughout the Middle Ages and into the eighteenth century. History is replete with descriptions from physicians of innovative instruments developed to view the various cavities of the human body. Commonly, these tubed instruments used curved mirrors and lenses to focus and reflect light from the sun, candles, or gas lamps. This light, which was largely inadequate by today’s standards, was shone into the body cavity. Instruments were adapted to distend the cavity or soft tissues so that the region could be viewed in a direct line-of-sight, that is, direct endoscopy. In other descriptions, mirrors were employed to reflect the image around an angle back to the observer, that is, indirect endoscopy.

Development of Indirect Mirror Laryngoscopy

In 1829, Guy Babington was most likely the first physician to present an instrument designed entirely for the purpose of viewing the larynx. Babington’s instrument, termed a “glottiscope,” consisted of an oblong mirror mounted on a handle which was designed to be held against the palate, while the tongue was retracted with a spatula. The mirror reflected both light and image. The technique, due to complexity and limited patient tolerance, was not adopted by other physicians. It was not until 1855, when Manuel Garcia, a music teacher, used a series of mirrors to reflect light and image to view his own larynx that attention was directed to the practice of indirect laryngoscopy. Garcia is therefore credited with inventing indirect mirror laryngoscopy. Garcia reported his observations to the Royal College of Surgeons, but initial reviews were guarded. The technique of indirect mirror laryngoscopy was adopted by Turck, a physician in Vienna, who studied its use in cadavers. Turck’s systematic evaluation of the clinical technique, developed by Garcia, provided the scientific validation required for the process to continue in patients. Turck’s findings were reported to the Vienna Imperial Society of Medicine in 1857. Czmerak, a student of Turck’s, pursued the technique and improved on applicability by developing a head mirror which reflected artificial light. This obviated the clinician’s dependence...
on sunlight and further popularized the practice of indirect mirror laryngoscopy.3

Development of Direct Laryngoscopy

A gain, from Hippocrates and throughout the Middle Ages, multiple surgeons reported designing instruments to view body cavities with direct line-of-sight visualization. Many of these instruments were long tubes designed to look into the urethra, bladder, uterus, and esophagus. Viewing of the larynx was primarily considered as the larynx needed to be passed to enter the trachea. However, in 1852 Horace Green designed a bladelike instrument specifically to view the larynx. Green reported his experiences with the excision of laryngeal lesions using this instrument in one hand and a curved forceps in the other. Due to the difficult nature of the technique and poor patient tolerance, without anesthesia, Green’s reports were also viewed skeptically by the medical community.1 Green lost credibility and, therefore, most of the credit for developing or popularizing direct laryngoscopy is given to Alfred Kirstein.2

In the 1880s, working with a tubed esophagoscope modified from a urethroscope,2 Kirstein noted that if the scope intended for the esophagus accidentally slipped into the larynx and trachea, an excellent view could be obtained. Therefore, in 1895 Kirstein began developing a reproducible method to view the larynx directly.3 Initially, Kirstein used a 25 cm tubed esophagoscope with the upper incisors serving as a fulcrum. This allowed Kirstein to displace the base of the tongue and epiglottis anteriorly with the tip of the scope. In addition, Kirstein used an electrical light source fixed to the proximal end of the scope. The light was reflected down the scope with a 90° prism. Worried about pressure placed on the upper incisors, Kirstein made adjustments to his original tubelike laryngoscope. By eliminating the posterior aspect of the esophagoscope, Kirstein created a bladelike instrument that resembled the laryngoscopes used by anesthesiologists for intubation today. In addition, Kirstein designed one type of blade that was developed to expose the larynx by lifting the tongue base from the vallecula rather than lifting the epiglottis directly. The tip on this scope was thickened to reduce the likelihood of injury to the mucosa of the vallecula and appears similar to the Macintosh blade in use today.

Kirstein’s practice of direct laryngoscopy was termed “autoscopy.” Historical accounts depict Kirstein performing “autoscopy” from in front of the patient with the patient leaning forward and from behind the patient with the neck flexed on the chest and the atlanto-occipital joint extended.2 It is probable that Kirstein performed direct laryngoscopy in either position to improve on the technique. What is important is that Kirstein recognized that extreme extension of the neck was not needed for the procedure, and he reported that “the body must be placed in such a position that an imaginary continuation of the laryngotracheal tube would fall within the opening of the mouth...”3

Gustav Killian learned about Kirstein’s technique of direct laryngoscopy at a meeting in 1895 and realized the potential. In 1912, Killian was the first to report suspension laryngoscopy. The advantage of the technique was that it permitted bimanual manipulation of laryngeal structures.4 This was a new concept as prior surgeons, such as Green and Kirstein, stabilized the bladelike laryngoscope with one hand and operated with the other. In his suspension system, Killian used the bladelike laryngoscopes designed by Kirstein to reduce pressure on the upper incisors. The system provided excellent visualization and was reported by Lynch and others in the United States for use during the resection of laryngeal lesions.6

The cumbersome nature of the Killian and Lynch suspension systems provided the stimulus for other surgeons such as Samuel Roberts and Robert Lewy to work on developing a system that was easier to use. This development occurred during the middle of the twentieth century. One fundamental difference between the Killian suspension system and the “newer” system developed by Roberts and Lewy was that the “newer” laryngoscope stabilizer system was designed for use with tubular laryngoscopes.3 This led Roberts to use the upper incisors as a partial fulcrum as was originally described by Kirstein. In an attempt to simplify the process of suspension laryngoscopy further and to reduce pressure on the upper incisors, Lewy reevaluated patient positioning. The standard practice during the time was that most rigid direct endoscopy was performed under local anesthesia. Cocaine had been introduced in the 1880s. The procedure often started with the patient sitting and the head and neck extended. As the endoscope was introduced, the patient was reclined. This required two assistants. One assistant stabilized the shoulders and upper torso, and one stabilized the head while the physician controlled the endoscope. Even if the patient was positioned supine to start the case, one assistant was still required to stabilize the shoulders in case of coughing, while still another controlled the head. By starting with the head on the operating table, Lewy was able to eliminate the need for a second assistant (Figure 3A). Lewy claimed that with his “laryngoscope stabilizer” device, direct suspension laryngoscopy could be accomplished with atlanto-occipital extension and variable degrees of flexion of the neck on the chest (Figure 3B). The results were that with tubular laryngoscopes the upper incisors were often used as a partial fulcrum. Lewy recognized this and cautioned against applying undue pressure as should all laryngologists teaching residents techniques of bimanual suspension microlaryngoscopy. In addition, at the time that Lewy was practicing, most tubular laryngoscopes were narrow and provided inadequate binocular visualization. Therefore, Lewy described modifications of the “new” suspension system for use with open or bladelike laryngoscopes for a larger field of visualization. These devices incorporated a Jennings type mouth gag to hold the upper incisors out of the field of view. Ultimately, the Lewy “suspension” system has become the most popular system in use today. When combined with appropriate head positioning and attention to pressure on both the upper incisors and the soft tissue over the mandible, the system can be used with relative ease to provide stabilization for suspension laryngoscopy in the majority of patients.

Advances with Light Delivery Systems

The practice of both indirect and direct laryngoscopy has also been influenced by the development of adequate lighting. Today, surgeons take the phenomena of adequate light for granted. It is amusing to hear ourselves asking our assistant to turn down the light intensity when we think...
that our historical counterparts worked by sun light, candlelight, or dim electric light produced by the original light bulbs of the late nineteenth and early twentieth centuries.

During the development of laryngoscopy, one area of debate revolved around the use of proximal or distal lighting. Before electricity was harnessed, light for endoscopy was only available from external sources. Therefore, by necessity light came from the proximal end of the endoscope, and it was required that the light be focused down the endoscope shaft. With rela-

tive short laryngoscopes, this was possible, but difficult. For anyone performing esophagoscop
y or bronchoscopy, one can readily appreciate the difficulty in reflecting and focusing and exter-
nal proximal light source down a long tubular endoscope. Many types of focusing lenses were introduced. The equivalent experience today is obtained when the surgeon attempts to focus the CO₂ laser and the helium-neon aiming beam down the bronchoscope for CO₂ laser bronchos-
copy. Regardless, when electrical lighting was developed, Kirstein originally proposed placing a light at the proximal end of the laryngoscope. This practice of using a source of proximal illumina-
tion was also continued by Billian and Lynch who used electric headlamps during suspension laryngoscopy.

In 1904, Chevalier Jackson proposed distal illumination through the use of miniature light bulbs placed at the end of a long carrier. The light carrier was fitted in a second tube alongside or inside the lumen of the endoscope. These light bulbs were small, and the electric current used to supply energy was often erratic. Commonly, bulbs needed to be replaced multiple times throughout one case as they would fail. However, as frail as the systems of distal illumination may have been, the principle of distal illumination for laryngoscopy and bronchoscopy was introduced and continued by other surgeons, many of whom had spent time with Jackson in his clinic.1

Improvements in distal illumination awaited the development of the principle of fiberoptic light transmission. This discovery revolutionized all forms of endoscopy and was advanced by multiple scientists. Baird, in 1927 identified the concept that glass fibers can transmit light. This led to the development of the “clad fiber.” Essentially the transmission of light down a glass fiber occurs through internal refraction. Glass fibers are produced from glass with a high refractive index. These fibers are surrounded by glass with a lower refractive index. Light is transmitted along the high refractive index core. If these glass fibers are arranged haphazardly light only is transmitted. When the fibers are aligned in a parallel manner, they can transmit an image.9

In the early 1960s, the understanding of fiberoptic light transmission and technology was developed to permit replacing light carriers in rigid endoscopes with fiberoptic technology. Clad fibers were surrounded by a hard metal carrier and formed a fiberoptic carrier of small diameter which was placed through the second channel in the endoscope. The light was supplied distally. It was not a source of heat. Originally, light sources were standard 150 W electric bulbs. This was still an improvement over the small distal bulb. Later, halogen and xenon sources were developed to improve distal light delivery further.

Indirect Rigid Laryngoscopy: The Hopkins Rod

In the 1950s Harold Hopkins, a physics professor in England, developed the rod-lens optical system which transmitted an image or light through an elongated lens. The lens was essentially a short, 1 mm long, glass fiber. In a rigid rod-lens system, a series of these glass rod lenses are placed within a tube. The ends of each lens are ground precisely to provide a highly refractive surface and a small airspace between each lens allows transmission to the next lens in the series (Figure 4). The image is transmitted from lens to lens to the proximal end of the instrument. If a prism is placed at the distal end of the rod or telescope, the image is reflected through an angle prior to transmission. The optics produced by the original rod lenses were probably inferior to the image from standard lenses at the time; however, Karl Storz recognized the potential of these types of systems. In the late 1950s or early 1960s, Storz was also introduced to the concept of fiberoptic light transmission through clad fibers and patented the idea of the rod-lens optical system combined with fiberoptic glass light transmission. With time and refinements in production techniques, the quality of rod-lens production improved. This enhanced the resolution of image which was transmitted10 (Figures 5A and B). The Hopkins rod was first introduced for indirect rigid laryngoscopy in the 1960s but took nearly 10 years to gain acceptance.11 The typical rod-lens telescope contains between 2 and 20 rod lenses each approximately 1 mm in length and thousands of glass fibers around the lens system for illumination.

Indirect Flexible Laryngoscopy

The concept and practice of indirect flexible laryngoscopy was originally developed based on fiberoptic light and image transmission but currently encompasses both flexible endoscopy performed with traditional fiberoptic technology and flexible endoscopy accomplished with miniaturized CCDs small enough to be passed through the oral and nasal cavity.

Due to technical limitations in clad fiber production, the development of traditional flexible “fiberoptic” endoscopes with resolution adequate for image transmission lagged behind the develop-

ment of the rod-lens image transmission system and the development of the fiberoptic light transmission system. For image transmission, the clad fibers needed to be arranged in parallel, flex-
ible, and small enough to bend through the endos
cope. Resolution is dependent on fiber diameter and number. Scopes with greater numbers of smaller fibers produce higher resolution images than scopes with few numbers of larger fibers. Theoretically, clad fibers of 5 µ diameter would provide the greatest resolution. Production technolo
gy has not yet reached this ideal. Therefore, resolution with flexible fiberoptic endoscopes has not reached that of current rod-lens image trans-
mission systems.

In spite of limitations in resolution, flexible fiberoptic image transmission was explored for bronchoscopy and esophagoscopy and origi-
nally introduced for laryngoscopy in 1968 by Sawashima and Hirose.12 Clinical trials were reported from England in 1975 which demonstrated that the indirect flexible laryngoscopy, even with limited resolution, permitted adequate diagnosis of laryngeal pathology.13 This trial demonstrated that indirect flexible laryngoscopy could be easily performed, easy to teach to young practitioners, and well tolerated by patients. These revelations led to an explosion in the application of flexible endoscopic techniques for visualization of the larynx.
refinements in production methods for traditional fiberoptic technology resulted in improved resolution in smaller diameter endoscopes and further popularized the technique of indirect flexible laryngoscopy.

Desire for further improvement in resolution, similar to that produced with rod-lens systems, along with advances in computer technology fueled and made possible the development of computerized videendoscopy systems. In computerized indirect flexible endoscopy, a miniature CCD, a digital computer chip camera, is placed at the end of a flexible endoscope (Figure 6A and B). This eliminates the need for fiberoptic image transmission as the image is transferred electronically from the chip at the distal end of the endoscope to a processing unit outside of the patient. This information is decoded and projected on a monitor for viewing. Fiberoptic light transmission is still utilized to provide light for illumination of the body cavity. By eliminating fiberoptic image transmission, degradation of scope resolution due to fiber breakage is not a problem.

The original systems, produced in the middle 1980s, included chips that were too large to be placed transnasally. The technology resulted in an improvement in image resolution which practitioners considered useful. Therefore, as the ability to produce computer chips small enough to pass the nasal cavity developed in the late 1990s, systems were developed specifically for laryngoscopy. These fiber systems have approached external diameter sizes comparable to adult fiberscopes and have improved resolution over traditional fiberoptic systems, but controlled clinical trials comparing accuracy in diagnosis of the systems have not been undertaken. In addition, resolution and light transfer from videendoscopy systems has still not reached that achieved from available rod-lens systems. Therefore, the gold standard for laryngeal imaging remains the rod-lens system (Figure 7A and B).

Ease of use and practitioner’s familiarity with the technique which results in improved perceived patient comfort have popularized indirect flexible endoscopy in the clinic setting. Currently, prototype videendoscopes with working side ports and at lengths facilitating laryngoscopy are being produced (Figure 8). These scopes have advantages in the clinic setting. They allow laryngeal manipulation for biopsy with forces or brush and ablation of disease with laser fibers. These instruments are all passed through the side channel on the laryngoscope. These techniques can be used without general anesthesia and may prove to have a significant role in the future for patient management. However, we need to remember that the original endoscopists performed rigid endoscopy without local or general anesthesia. The techniques can be mastered but are not easy. In a similar manner, intervening in the larynx of an awake patient is not always an easy technique to master even with flexible endoscopes.

ANESTHESIA

Laryngoscopy can be performed with or without anesthesia. Aesthesia can be local or general, and it is accepted that improvements in techniques of general anesthesia have revolutionized the performance of direct laryngoscopy. The original endoscopists did not have anesthesia available. Cocainization came about in the 1880s. Ether was used for general anesthesia in the later part of the nineteenth century. Our ability to support the respiration of sedated and paralyzed patients developed in the middle and later half of the twentieth century. Endotracheal tube technology improved through the 1970s allowing the production of smaller outer diameter tubes for intubation. Use of these newer endotracheal tubes enhances intervention in the larynx because the tubes occupy less space in the airway lumen and permit a greater work area. In addition, the newer tubes permit safer application of laser energy because they are produced of flame-resistant materials. Improvements in patient’s O2 and
CO₂ monitoring have made apneic and jet ventilation techniques for general anesthesia more acceptable to surgeons. Jet ventilation for maintenance of oxygenation can be accomplished with the jet ventilation catheter above or below the larynx. With these techniques, either no catheter or only a small catheter is placed in the larynx. This allows the surgeon to work easily in the posterior aspect of the glottis or in the subglottis for extended periods while the patient’s oxygen supply is maintained.

With regard to indirect laryngoscopy, anesthesia is not usually required for either mirror or rod-lens techniques. For patients with a hyper-sensitive gag reflex, topical anesthesia to the palate and posterior pharynx (benzocaine 20%) may be helpful to reduce sensation of instrumentation. Topical anesthesia may be used in the nasal cavity (pontocaine 2%) for comfort when passing a fiberscope or videendoscope through the nasal cavity. This is not absolutely required, but it is helpful in most patients to reduce the burning sensation that may be associated with irritation of the septal and turbinate mucosa. In spite of adequate nasal anesthesia, some patients may complain of pharyngeal irritation or exhibit a hyperactive gag reflex. In this instance, topical anesthesia to the oropharynx may be helpful. It is critical that these agents be avoided in patients with known hypersensitivity to local anesthetic agents.

If laryngeal instrumentation is planned during indirect flexible laryngoscopy, most patients will require topical anesthesia. This can usually be accomplished with lidocaine 4% dripped through the side channel of the laryngoscope directly on to the vocal folds. Alternatively, lidocaine can be aerosolized and inhaled. Finally, for some sensitive patients, blocking of the superior laryngeal nerve with injection of lidocaine may be necessary. Superior laryngeal nerve blocks can be accomplished by injecting the internal branch of the nerve as it courses through the neck just inferior to the greater horn of the hyoid bone and deep to the thyrohyoid membrane. Lidocaine 1% with 2 to 4 mL bilaterally is usually sufficient.

CURRENT PRACTICE OF OFFICE INDIRECT LARYNGOSCOPY

Indirect mirror laryngoscopy is considered part of the complete head and neck examination. The mirrors used for laryngeal examination were modified from dental mirrors. They are produced in various sizes, but the #10 size mirror is most commonly used. The mirror should be heated to prevent fogging. Heating has been accomplished in the past with various techniques including small flames from gas burners and more recently electric devices which heat ceramic beads. These electric bead warmers can be turned on at the beginning of clinic. Heat is transferred to the beads, and the mirror is submersed in the beads for a few seconds. The mirror should be tested on the back of the examiner’s hand to be certain that it will not burn the palate on insertion. Once the mirror has been inserted into the patient, it should not be inserted back into the bead warmer for rewarming as this may lead to contamination of the beads. The examination is begun with the examiner placing the patient and him- or herself in a comfortable position. This can be accomplished with the examiner seated or standing in front of the patient with the examiner’s shoulders slightly above the patient’s. Light can be reflected into the patient’s mouth with a head mirror or directly from a headlight. The patient’s tongue is retracted by grasping the tip gently with a gauze sponge (Figure 1).

Indirect laryngoscopy can also be performed with a rod-lens telescope (Figure 9). In a study comparing mirror laryngoscopy with indirect rod-lens laryngoscopy, patient tolerance of the rod-lens was significantly better than that of mirror laryngoscopy (83% vs 52%). Examination sensitivity was equal between the techniques. As with indirect mirror laryngoscopy, the indirect rod-lens laryngoscopy starts by the examiner placing the patient and him- or herself in a comfortable position either seated or standing with the patient’s shoulders slightly below the level of the examiner’s. The light comes from the end of the endoscope; therefore, head- lights are not required. The tip of the endoscope should be warmed to prevent fogging. Electric bead warmers lead to early deterioration of the optical system. Therefore, it is preferable that the rod-lens scopes be warmed with hot water. Hot water for the purpose of warming the endoscopes can be kept in the room in a thermos and poured into individual cups for use with each patient. The tongue tip is held lightly with gauze and retracted gently. The examiner balances the scope on the top of his index finger to avoid touching the tongue and stimulating the glossopharyngeal nerve. Under direct visualization, the scope is inserted into the oropharynx until the desired view is obtained. A camera head can be attached to the eyepiece of the endoscope, and the examination can be viewed and recorded from a monitor if desired.

Indirect flexible laryngoscopy is performed with both standard fiberscopes as well as videoendoscopes in a similar manner (Figure 10). Many examiners topically decongest and anesthetize the nasal cavity after visual inspection to determine the larger size. The patient should be seated comfortably leaning forward with the forearms resting on the thighs. The patient’s neck is flexed forward with the head extended at the atlanto-occipital joint. Under direct visualization, the scope is passed through the nasal cavity into the nasopharynx, into the oropharynx, and into the desired position in the hypopharynx.

Interpreting Results from Office Indirect Laryngoscopy

The purpose of laryngoscopy is to view laryngeal and pharyngeal anatomy and function. With any of the three previous techniques described, the examiner can observe vocal fold abduction and adduction as well as pharyngeal wall motion to determine the functional status of the muscles and their innervation from cranial nerve X. In addition, indirect laryngoscopy can be used to inspect the mucosal surfaces for benign or malignant lesions and the status of the airway lumen. Typically the patient is asked to phonate with the vowel sound /i/. This results in flattening of the tongue base and allows better visualization of the larynx. The valleculae and pyriform sinuses are visualized and inspected for mucosal lesions and pooling of secretions. Pooling of secretions in a vallecula is indicative of tongue weakness while pooling of secretions in the pyriform sinus is indicative of pharyngeal wall weakness. The esophageal inlet is inspected and pooling of secretions in this region may be indicative of a structural lesion in the esophagus. Next the aryepiglottic folds, false vocal folds, and arytenoids are inspected. Vocal fold abduction and adduction is observed by asking the patient to alternate between phonation of the vowel /i/ and inhalation. High-pitched phonation of the vowel /i/ allows observation of lateral pharyngeal wall function. The lateral pharyngeal...
Voice production and voice quality, however, are evaluated for characteristics indicative of malignancy. In addition, vocal fold mucosal lesions can be evaluated. Indirect laryngoscopy is an excellent tool to evaluate pharyngeal and laryngeal function in breathing, swallowing, and speech production. Vocal fold adduction and abduction as well as pharyngeal wall motion can be readily observed. In addition, vocal fold mucosal lesions can be evaluated for characteristics indicative of malignancy. Voice production and voice quality, however, are determined by vocal fold vibratory characteristics. During voice production the vocal folds vibrate between 80 and 800 times each second. The human eye can only resolve five distinct images each second. Therefore, with steady state light sources, the vocal folds appear to stand still in an abducted position while the patient is phonating. Vocal fold vibration can be observed with either high speed cinematography in which film captures individual still frames 2,000 to 4,000 times each second or through the application of stroboscopy. In stroboscopy, a bright xenon light flash is used to illuminate the larynx for a fraction of a microsecond. The image of the vocal folds at the instant in time is captured by the human retina and persists for 0.2 seconds. The light is then flashed repetitively and another image captured when the vocal folds are in a different position. The process is repeated. A microphone is used to sense vocal fold vibration rate so that the flashing of the strobe light can be synchronized with the frequency of vocal fold vibration. If the light is flashed in phase with the rate of vocal fold vibration, the vocal folds appear to stand still as the same point in the vibratory cycle is sampled repetitively. If the light is flashed slightly out of phase with the vibratory rate, a montage of images is collected which provide an apparent slow motion view of vocal fold vibration.

For complete evaluation, vocal fold vibratory characteristics should be observed at multiple phonatory frequencies. At low and modal pitch frequencies, the vocal folds have large vibratory patterns. As the phonatory frequency increases, due to increased vocal fold tension, the vibratory patterns become smaller possibly because vibration is only occurring within the most superficial portion of the mucosa. Observing stroboscopy at high frequencies of phonation allows the examiner to observe the supple nature of the vocal fold mucosa. If the mucosa is stiff on one vocal fold, then the vibratory patterns will be further reduced comparatively. At low frequencies of vibration, these mucosal differences may not be as apparent.

Originally, laryngeal stroboscopy was performed by reflecting the stroboscope light off of the laryngeal mirror. With the invention of rod-lens systems, it became possible to attach the stroboscopic light source to the endoscope. Examiners used an indirect rod with either a 90° or a 70° prism at the end. The fiberoptic delivery systems in the rod-lens improved light delivery and when combined with the rod optical system, the resolution of the scopes was enhanced over the traditional mirror systems. With the 90° endoscope, the examiner must place the scope higher on the oropharynx or toward the soft palate. This keeps the endoscope off of the base of the tongue but may stimulate gagging by touching the palate. With a 70° endoscope, the scope is placed closer to the base of the tongue. This is probably the preferred method or scope by most endoscopists.

Stroboscopy may also be viewed through flexible endoscopes. However, due to both reduced light and image transfer ability of fiberoptic systems, the resolution is reduced when compared to that obtained with rod-lens systems. Both light and image carrying are important for optical resolution. Flexible endoscopes for transnasal use are smaller in diameter than rod-lens telescope. Therefore, the number of light fibers is reduced. As mentioned previously, the ability to obtain image resolution is also dependent on fiber size. While technology is improving, fiber size is limited and the overall number of optical fibers is also limited by the size of the endoscope. With videendoscopes, resolution is limited in part by the number of illuminating fibers in the scope as well as the primary resolution capabilities of the distal chip camera. While these systems are approaching the resolution capabilities of the rod-lens endoscopes, they are not yet the same.
RECORDING SYSTEMS

With the use of indirect endoscopes, the ability to attach a camera over the eyepiece of the scope is simplified. This provides the opportunity to record the examination for playback, review, and consultation. Examinations may be compared within and among patients. This provides a significant advantage when trying to determine the relevance of a lesion or laryngeal or pharyngeal defect in creating the patient’s problem. Serial examination can be stored for direct comparison rather than needing to rely on the physician’s memory and notes. Images can be recorded as still pictures or as video files. The images or files can be stored in the patient chart or electronically in a database system. Thanks to the work of some innovative individuals, who recognized the need, true relational databases for video storage and retrieval are currently available. These systems convert the video image to an MPEG 2 format. This is the standard format used in today’s DVD technology and movie industry. It provides excellent resolution for video images while the files are small enough to be moved easily through the database system. By encoding the data to provide security for patient records according to the United States Health Insurance Portability and Accountability Act (HIPAA) guidelines, the information can be shared over the Internet from multiple sites. It is possible to record information from several data acquisition sites, store them to a server in a different site, and review the data in yet another site. The speed with which this occurs is dependent on the bandwidth of Internet access. Within one office or one university campus, it is usually possible to allow this transfer to occur in real time.

OFFICE SURGERY

Office surgery has always been possible with direct and indirect laryngoscopy. Historically, those who began with these techniques did so in their offices without the aid of general anesthesia. The procedures were not easy. With the advent and improvement of general anesthetic techniques, direct endoscopy has moved into the operating room. Surgical procedures are still performed in the office but usually under indirect techniques. Some trained surgeons may choose to use a mirror to view the larynx. The patient can retract the tongue. This will allow the surgeon to hold the mirror with one hand and a curved instrument to reach the glottis with the other. Alternatively, the mirror can be replaced with a rod-lens telescope. In addition, a video camera can be attached to the end of the rod telescope so the procedure can be viewed and recorded on a video monitor if desired. Using these techniques, injection laryngoplasty can be accomplished with a curved needle of sufficient length, and laryngeal biopsy can be accomplished.

Visualization can also be accomplished with a flexible scope placed through the nasal cavity. With this technique, an assistant can position and stabilize the endoscope. If a video monitor setup is employed, the surgeon can view the larynx on the monitor and use both hands for patient and laryngeal manipulation. In this manner, the surgeon can control the patient’s tongue during peroral techniques. If the goal of the procedure is to inject the larynx, either transoral or percutaneous techniques can be utilized. For percutaneous techniques, the surgeon can stabilize the larynx in the neck with one hand and pass the needle, either through the cricothyroid membrane, the thyrohyoid membrane, or transcartilageneously, with the other hand. Observing on the video monitor allows the surgeon to verify needle placement during the procedure as well as position of the injected substance.

TECHNIQUES OF DIRECT LARYNGOSCOPY

As mentioned earlier, direct laryngoscopy is most commonly undertaken in the operative room with the assistance of general anesthesia or heavy sedation with local anesthesia. Direct laryngoscopy for the purpose of biopsy or injection can be accomplished by either technique. Some surgeons prefer local with sedation specifically for injection laryngoscopy as this method allows the patient to phonate at times during the procedure to aid in determining the degree of medialization. For these types of procedures, a monocular tubular laryngoscope of the Holinger variety is most commonly used. These monocular scopes are designed to be placed on the side of the mouth along the floor. The tongue is displaced to the opposite side of the oral cavity and oropharynx from which the laryngoscope is introduced. Most surgeons prefer to place the endoscope in the right gutter. The surgeon uses his left hand to distract the maxilla. By pulling on the maxilla, the atlanto-occipital joint is extended. The neck can be placed in variable degrees of flexion as required or desired by the surgeon. The fingers on the surgeon’s left hand are also used to distract and protect the lips so the lips are not inadvertently pinched between the endoscope and the teeth (Figure 13). The endoscope itself is held in the surgeon’s right hand. The scope is advanced with the vector of force upward on the mandible. The patient’s head can be lifted off the bed. The head is resuspended by adding pillows or flexing the headpiece of the operating table upward. The surgeon can support his or her hand by resting the ipsilateral elbow in the operating table. Commonly, maxillary dentition is protected with a tooth guard. Tooth guards can be purchased inexpensively and used as disposable items for each patient. Alternatively, individualized custom-molded teeth protectors can be used for each patient. Some surgeons find this preferable for patients who may need repeated endoscopy for surveillance of disease. If the maxilla is edentulous, then a folded gauze sponge to protect the gum is usually sufficient. One sponge can be moistened and placed between the lip and maxillary ridge. A second sponge can then be placed over the lip and first gauze sponge to hold it in place. If biopsy or injection is required, most surgeons will switch hands so that they are holding the positioned scope with their left hand and manipulation can be accomplished with their right hand.

Suspension laryngoscopy is most often performed under general anesthesia with the patient deeply sedated or paralyzed to avoid movement. This technique affords the surgeon excellent control during delicate surgical interventions in which precision is required to achieve reliable outcomes. Patient position starting with the head on or off the operating table has been previously discussed. The key to obtaining laryngeal exposure is to utilize both the atlanto-occipital joint and the neck positioning until the desired view is obtained. Most commonly this is through atlantoooccipital extension and variable degrees of neck flexion. If the surgeon starts with the neck in a neutral position, flexion or extension can be added as needed. Tubular laryngoscopes for suspension laryngoscopy are designed to accommodate binocular vision. Therefore, they are wider than endoscopes used for direct laryngoscopy without suspension. Binocular microlaryngoscopes are made with either a straight distal tip as in the original esophagoscopes used for laryngoscopy or with a flared distal tip similar to the tip originally produced by Kirstein on his bladelike laryngoscope. If a flared distal tip scope is used, the posterior aspect of the proximal opening needs to be eliminated or flared in the opposite direction to allow adequate visualization of the anterior commissure of the larynx. In addition, the binocular scopes are designed to be placed over the patient’s tongue, rather than along the floor of the mouth. The tongue is displaced anteriorly (see Figure 2).

Once the scope is in position, a suspension apparatus is used. These suspension devices are either the Killian gallows type or the Lewy type. As long as the surgeon takes care not to use the maxillary teeth as a fulcrum for the endoscope, suspension can be accomplished with either system. During suspension, pressure is placed on the tongue or on the inside of the mandible. Patients need to be warned about pressure in these regions.
as excessive prolonged pressure on the tongue can result in temporary paresthesias or an alteration in taste.28 Reports of permanent changes can be found in the literature, but most of the changes are self-limiting and most likely result from pressure on cranial nerves IX and XII or the lingual nerve. The anterior angle of the mandible is most often the limiting site for exposure of the larynx. As the endoscope is inserted in a patient with a narrow mandibular arch, the endoscope rubs on the inner surface of the mandible. This can cause ulceration on the inner surface of the mandible. The lateral mandibular incisors as well as the premolars are at risk for injury from the endoscope. To obtain exposure in these challenging patients, multiple endoscopes are available which are produced in variable widths. The Pilling Company, Fort Washington, Pennsylvania, has produced a scope which is as narrow as possible but still allows bimanual visualization.29

Once stabilization has been applied, the surgeon is able to operate with both hands. If a narrow scope has been placed, room for bimanual manipulation will be limited. Therefore, ideally, only the lesion and reduce injury to surrounding tissues. For visual documentation, a camera can be attached to the eyepiece of the endoscope, and photographed.

CONCLUSIONS

Laryngoscopy has been performed since ancient times but was developed as a distinct clinical intervention in the middle of the nineteenth century. There are two basic forms, direct and indirect. These forms are categorized by the method of viewing the larynx. In indirect laryngoscopy, a mirror, prism, or flexible fiberoptic rod is used to transfer the image of the larynx back to the observer. The patient’s head and neck are maintained in a relatively neutral position. In direct laryngoscopy, the patient’s head and neck are positioned so that the larynx can be viewed directly through a long rigid tube.

Fiberoptic light delivery technology has improved our ability to view the larynx. The principle of fiberoptic light transmission is now used routinely to transfer light through smaller channels to the distal end of the endoscope without an internal source of heat. This has resulted in better illumination and better resolution of the laryngeal image. Resolution has also been improved through rod-lens technology, advances in fiber production technology for fiberoptic image carrying fibers, and advances in CCD production technology which have resulted in microchip cameras small enough to be placed at the distal end of a flexible endoscope.

Improvement in image resolution due to the new technologies in both image transfer and light delivery has resulted in rapid advances in our capability to perform office procedures. Rather than using indirect rigid laryngoscopy or direct laryngoscopy techniques in the office, many surgeons are using indirect flexible laryngoscopy, either with a fibroscope or a videolaryngoscope to guide their interventions. Finally, direct rigid laryngoscopy, with or without suspension, continues to allow the finest control over patient movement and enhances precision in surgical intervention. Suspension direct microlaryngoscopy remains the gold standard against which results from other techniques must be judged.

Bronchology

Marshall E. Smith, MD
Mark R. Elstad, MD

Bronchology refers to the diagnosis and treatment of diseases of the large airways—the trachea and bronchi. The tracheobronchial tree comprises critical anatomical passages in which disease may affect health at any age, infant to elderly. Although the importance of these structures has been recognized for centuries, bronchology as a discipline began only 110 years ago. Advances in treatment have depended on the development of tools to examine the tracheobronchial tree, that is, bronchoscopes. The history of bronchology is largely the history of bronchoscopy. The utility of bronchoscopy will be well demonstrated in the discussion of airway disorders and their management. There have also been advances in other areas. For example, through image processing of computerized tomography (CT) scans of the airway a "virtual bronchoscopy" can be reconstructed with images and video which simulate the visual perspective of bronchoscopy.

APPLIED AIRWAY ANATOMY/PHYSIOLOGY

A knowledge of the anatomy of the pharynx and larynx is crucial to any airway endoscopist and is discussed in detail in Chapter 72, "Development, Anatomy and Physiology of the Larynx."

The trachea extends from the cricoid cartilage to the bifurcation into the right and left bronchi. Its length averages 10 cm in women and 12 cm in men. The average anteroposterior diameter is 13 mm, and the transverse diameter is 18 mm. The anterior wall is formed by approximately 18 incomplete C-shaped rings of cartilage, and the posterior membranous wall contains the trachealis muscle. An approximately one-third of the trachea is in the neck, and two-thirds are in the mediastinum. The airway is lined by respiratory epithelium containing a prominent basement membrane and numerous goblet cells. The length and position of the trachea vary with changes in position of the head and neck. The trachea is midline in the neck and deviates slightly to the right at the level of the aortic arch which compresses its left lateral wall.

The right bronchus averages 2.5 cm in length and has six to eight cartilages. It bifurcates at an angle of 25º lateral to the trachea. The right upper lobe bronchi takeoff, the right bronchus continues as the bronchus intermedius. The anteromedial aspect of this bronchus opens into the right middle lobe bronchus which contains medial and lateral segmental bronchi. The short right lower lobe bronchus divides into five segmental bronchi. The typical configuration is the superior segmental bronchus followed by the medial, anterior, lateral, and posterior basal segmental bronchi.

The left bronchus bifurcates from the trachea at 45º, a sharper angle than the right bronchus takes. The average length of the left bronchus is 5 cm. It divides into the left upper and lower lobe bronchi. The upper lobe bronchus opens into the inferior lingular division (superior and inferior segmental bronchi) and the superior upper lobe division (typically an apical posterior and an anterior segmental bronchi). The left lower lobe bronchus divides into the superior segmental bronchi followed by the anteromedial, lateral, and posterior basal segmental bronchi. This nomenclature is summarized in Table 1. A visual comparison of external and endobronchial views of the tracheobronchial structures is seen in Figure 1.

For interventional bronchoscopists and those performing advanced diagnostic procedures, it is critically important to understand the relationship of vascular, lymph, and other structures to endobronchial anatomy. When doing interventional procedures such as laser and mechanical resection, one can be within millimeters of large and vascular structures, the injury of which is potentially lethal. The posterior aspect of the trachea and the esophagus is joined by the so-called “party wall.” The aortic arch compresses the distal third of the left anterolateral trachea wall. The superior vena cava and azygous vein lay adjacent to the right anterolateral wall of the distal trachea. On the right, the right pulmonary artery lays directly anterior to the right and right upper lobe bronchi. The left and left upper lobe bronchi are in close association with the aorta and the left pulmonary artery. Lymph nodes are closely related to the trachea, carina, right and left bronchi, and airways in the hila.

Heffner suggested that the compliant and noncylindrical structure of the trachea, comprising incomplete cartilaginous rings, allows for more than simple conduit function.1 Enlargement of the lumen during inspiration may allow sufficiently decreased airflow velocity at the periphery of the air column so as not to impede the normal egress of the mucociliary blanket. Diseases of the airway affect all ages. They can be divided into congenital, infectious, inflammatory, neoplastic, and traumatic causes.

Congenital anomalies of the larynx are discussed in Chapter 69, "Congenital Anomalies of the Larynx." Tracheal atresia or agenesis is usually fatal at birth unless the infant has a coexisting tracheoesophageal fistula through which to maintain ventilation. In the tracheobronchial tree, congenital stenosis that narrows and obstructs the airway occurs in various forms. Mild forms include thin membranes or webs. More severe forms include segmental stenosis, funnel-shaped tracheal stenosis, or long-segment stenosis. In the more severe forms, the cartilaginous rings of the trachea are fused to create complete rings like the cricoid cartilage, with absence of membranous trachea (Figure 2). Long-segment tracheal stenosis may be accompanied by aberrant left pulmonary artery, also known as pulmonary artery sling. The diagnosis is made by bronchoscopy. Endoscopic repair of these anomalies is generally not successful. Tracheostomy is often not helpful for obstructing lesions in the middle or distal trachea. The best treatment options for congenital tracheal stenosis include tracheoplasty repair via median sternotomy. The slide tracheoplasty technique is currently the procedure of choice for lesions judged favorable for repair.

Other anomalies of the vascular arch can compress and obstruct the airway. These include double aortic arch, right aortic arch with left ligamentum arteriosum, and pulmonary sling. These develop from abnormalities in formation of the major vessels during embryogenesis. The innominate artery may also cause compression of the trachea in infants due to its origin to the left of the midline (Figure 3). With growth, usually by 3 years of age, it moves away from the trachea to the right. Pulsatile anterior tracheal compression narrows the trachea lumen in the shape of a teardrop. When vascular compression of the airway is suspected on bronchoscopy, the anatomy of the great vessels should be delineated with magnetic resonance imaging (MRI) or chest CT with contrast. The lesions are repaired by cardiothoracic surgery, with the capability for cardiac bypass if necessary.

Tracheomalacia or bronchomalacia refers to narrowing of the trachea or bronchi without extrinsic compression or internal stenosis. In infants it presents as inspiratory and/or expiratory stridor, wheezing, retractions that may be associated with feeding difficulties, cyanotic spells, or pneumonia. The pathophysiology of this condition may relate to excessive compressibility of the tracheobronchial tree during respiration in concert with intrathoracic pressure changes associated with respiration. Chest radiographs may show airway collapse depending on the phase of respiration when the radiograph is taken. Bronchoscopy of this condition demonstrates collapse of the posterior and anterior walls of the airway during spontaneous respiration. Other airway lesions may be associated with tracheomalacia or bronchomalacia such as extrinsic vascular compression or tracheoesophageal fistula. In the neonatal period, continuous positive airway pressure may be used to manage this condition until the structures grow.

**Figure 1** Drawings of the pulmonary segments, and the lobar bronchi and their segmental branches. The bronchial views are seen from the perspective of supine position. (From Jackson and Jackson, 1950.)

**Figure 2** Congenital tracheal stenosis in a 2-month-old infant.
and avoid more invasive treatment. In severe cases, tracheostomy and mechanical ventilation may be required.

Other congenital diseases that affect the bronchi include webs, abesia, immotile cilia syndrome, cystic fibrosis, and syndromes of abnormal cartilage formation (see below).

**Infectious**

A variety of viral, bacterial (including mycobacterial), and fungal infections can cause tracheobronchial disease. A cute bronchiolitis is a viral disease of the respiratory tract that occurs in children under 2 years of age. The respiratory syncytial virus (RSV) causes more than 50% of cases; other viral pathogens include influenza, parainfluenza, and adenovirus. Following a viral prodrome, patients develop respiratory distress characterized by wheezing cough, dyspnea, tachypnea, and cyanosis. Treatment is generally supportive, including O₂ supplementation. In severe cases that require intubation, bronchoscopy may be helpful to suction secretions and facilitate extubation.

Bacterial tracheitis may occur as a complication of a viral respiratory tract infection. It can cause life-threatening sudden airway obstruction due to thick tenacious mucus and mucosal edema that obstruct the large airways, especially in younger children. It is usually caused by Staphylococcus aureus, although Moraxella catarrhalis and Hemophilus influenzae can also be pathogens. Management involves intubation in severe cases, bronchoscopy to clear secretions and obtain cultures, antimicrobial therapy, and supportive care.

Pneumonias are usually divided into three groups: community acquired, nosocomial, and ventilator-acquired. Initial management includes appropriate empiric antibiotic therapy directed toward common pathogens based on the type of pneumonia and the patient’s immune status. Cultures, obtained when patients have inadequate response despite standard therapy, are often obtained from expectorated material, which may be contaminated by oropharyngeal flora. Bronchoscopy allows directed aspiration of secretions directly from the tracheobronchial tree and has proven to be of benefit in immunocompromised patients. Proper disassembly and cleaning of equipment between patients and proper specimen collection techniques must be used to prevent contamination. Bronchoalveolar lavage and bronchoscopic protected specimen brushing can retrieve specimens adequate for quantitative analysis. Bronchoscopy is indicated for lung abscesses unresponsive to postural drainage and chest physiotherapy to rule out an underlying carcinoma or foreign body and to obtain secretions for culture.

Bronchiectasis, irreversible dilatation of the bronchial tree, most commonly presents with chronic purulent sputum production and hemoptysis. Bronchiectasis may be postinflammatory, obstructive, or congenital. Stasis of secretions leads to infections that damage the bronchial walls, resulting in further dilatation and distortion. Infectious causes include RSV, pertussis, rubella, and tuberculosis. Obstructive lesions include tumors, foreign bodies, extrinsic compression, and impacted mucus. Congenital causes include bronchial webs and atresia, immotile cilia syndrome, cystic fibrosis, and syndromes associated with abnormal cartilage formation such as Williams-Campbell syndrome (absence of annular bronchial cartilage distal to the first division of the bronchi) and Mounier-Kuhn syndrome (congenital tracheobronchomegaly).

High-resolution CT is a useful imaging modality in suspected bronchiectasis.

Fungal infections of the lungs may create mycetomas. These aggregates are usually due to Aspergillus species and may develop in immunosuppressed patients. Diagnosis is generally made by chest radiographs or chest CT scan. Serum precipitin levels are usually elevated. Bronchoscopy is indicated for directed culture sampling or for evaluation of hemoptysis or progressive disease. A spigelianoma can cause life-threatening hemoptysis by erosion into bronchial arteries with 26% mortality. Surgical resection provides definitive treatment but is associated with high morbidity and mortality.

Mycobacterium tuberculosis is a bacillus transmitted by inhalation of infected airborne droplets. It is highly contagious. The highest incidence in the United States occurs among immigrants. Pulmonary symptoms include cough, chest pain, and hemoptysis. Other symptoms include chills, fever, night sweats, loss of appetite, and loss of weight. Diagnosis is usually based on skin-test reactivity to purified protein derivative of tuberculin, chest radiograph, and histologic or culture identification of the acid-fast bacillus. Bronchoscopy with bronchoalveolar lavage and/or biopsy has a high yield and should be considered in high risk patients who have negative sputum cultures, or who cannot produce adequate sputum samples. The therapy for tuberculosis involves four first-line antibiotics, including isoniazid (INH), rifampin (RMP), pyrazinamide (PZA), and ethambutol (EMB) or streptomycin. Tuberculosis in children is usually contracted from adults and adolescents in the household rather than from other children in day care or school; congenital infection is rare. The presentation of primary pediatric tuberculosis may be subtle, including erythema nodosum and nonspecific constitutional symptoms. As tuberculin skin testing may be negative in 40% of these children, chest radiography demonstrating hilar and paratracheal lymphadenopathy is important in the diagnostic process. If young children cannot provide sputum specimens, three morning gastric aspirate specimens may be obtained. Children, especially those younger than 6 years of age, have a more rapid progression of disease from inoculation to dissemination; they are treated immediately from the time of exposure until the incubation period has passed and repeat diagnostic tests are negative. The principal drugs used to treat pediatric tuberculosis also include EMB, INH, PZA, and RMP; pyridoxine is given to infants to prevent nervous system complications of INH therapy. M. tuberculosis in children is rarely contagious. Nontuberculous mycobacterial diseases encompass all Mycobacterium species other than M. tuberculosis. M ycobacterium avium-intracellulare complex is the most common nontuberculous mycobacterial disease and is treated principally with clarithromycin, azithromycin, RMP, and EMB. M ycobacterium kansasi is the most virulent of the nontuberculous mycobacterial pathogens and is treated with INH, RMP, and EMB.

**Interstitial Lung Disease.** Interstitial lung disease encompasses a wide variety of pulmonary diseases characterized by diffuse parenchymal opacities. Although more than 160 causes have been reported, pneumonia, drug-induced disease, and hypersensitivity pneumonitis account for over 80% of cases. A thorough history can elucidate patient exposure to a large variety of injurious inorganic dusts such as coal, carbon black, asbestos, or talc; chemicals such as polyvinyl chloride, sulfur dioxide, or ammonium; pharmacologic agents such as cyclophosphamide, methotrexate, certain anticonvulsants, and beta-blockers, etc.; and radiation therapy. Open or thoracoscopic lung biopsy, considered the gold standard for diagnosis, is not always a viable option in the elderly or patients whose respiratory status is significantly compromised; less invasive bronchoscopy with transbronchial lung biopsy may provide useful information.

**Sarcoidosis.** Sarcoidosis is a noncaseating granulomatous disease of unknown etiology, more common in African-Americans. Patients most commonly present with nonproductive cough and dyspnea; head and neck manifestations include cervical adenopathy, uveitis or episcleritis, parotid swelling, nasal obstruction, neuropathies such as facial palsy and sudden sensorineural hearing loss, epiglottic swelling, and nasal mucosal edema. Ninety to 95% of patients with sarcoidosis have an abnormal finding on chest radiography, most commonly hilar adenopathy. Occasionally, endobronchial granulomas or stenoses occur. Elevated serum angiotensin converting enzyme levels
appear to correlate with the activity of the disease but should not be used in isolation. Laboratory studies may also reveal elevated liver enzymes, particularly aspartate aminotransferase and alkaline phosphatase, elevated erythrocyte sedimentation rate, esosinophilia, hypercalcemia, and hypergammaglobulinemia. Fiberoptic bronchoscopy with transbronchial biopsy is the invasive procedure of choice for diagnosis; bronchoalveolar lavage is investigational. Corticosteroids are the mainstay of therapy. Pediatric sarcoidosis is rare and presents with fatigue and lethargy.

**Idiopathic Pulmonary Fibrosis.** Idiopathic pulmonary fibrosis is a chronic fibrosing interstitial pneumonia of unknown etiology associated with the histologic appearance of "usual" interstitial pneumonia. This diffuse parenchymal disease occurs almost exclusively in adults, usually over 50 years of age, who present with slowly progressive dyspnea and nonproductive cough. Rales, particularly at the lung bases, are noted on auscultation in 80% of patients; fever is rare, and the disease is limited to the lungs. Characteristic abnormal findings on chest radiograph include asymmetric, bilateral, peripheral areas of reticular opacification. High-resolution CT is not diagnostic but can help determine prognosis; a fibrotic appearance portends a worse prognosis than a predominantly ground-glass appearance. Diagnosis is usually presumptive, based on clinical criteria; bronchoscopy and laboratory evaluation may be indicated to exclude other pulmonary diseases. Open or thoracoscopic lung biopsy is generally obtained to establish a histologic diagnosis; bronchoalveolar lavage is investigative. Although corticosteroids are standard therapy, no clear evidence exists proving that corticosteroids or any other available treatment is efficacious.

**Relapsing Polychondritis.** Relapsing polychondritis manifests with acute, recurrent, progressive inflammation and degeneration of cartilage and connective tissue, including that within the tracheobronchial tree, affecting men and women in equal numbers. Serious airway manifestations occur in about one-half of patients with relapsing polychondritis; bronchoscopy is useful to identify and quantify inflammation, stenosis, or dynamic collapse of the tracheobronchial tree. Bronchoscopic stent placement may be required to maintain airway patency.

**Wegener’s Granulomatosis.** Wegener’s granulomatosis is a necrotizing granulomatous vasculitis, affecting both the upper and lower part of the respiratory tract and the kidneys. The introduction of flexible fiberoptic bronchoscopes has revealed tracheobronchial involvement in more than half of patients with Wegener’s granulomatosis.

**Neoplastic**

**Benefit Neoplasms and Tumor-like Masses.** Although some neoplasms occurring within the trachea and bronchi are histologically benign, they may still cause airway obstruction. Recurrent respiratory papilloma has a predilection for the larynx, but the trachea and bronchi may be involved by disseminated disease (Figure 4).

**Malignant Neoplasms.** Malignant neoplasms are divided histologically into non-small cell cancers, including squamous cell carcinoma, adenocarcinoma, and large cell carcinoma, and small cell cancers. Surgery is the primary treatment modality for non-small cell cancer; radiation therapy and chemotherapy are reserved for advanced cases and cancers not amenable to surgical resection. Small cell cancer is noted for rapid growth and early development of widespread metastases; although it is extremely sensitive to radiation and chemotherapy, 5-year survival is only 3 to 8% and recurrence is common. Only approximately 4% of primary lung neoplasms are not bronchogenic carcinomas. Bronchial carcinoid is a neuroendocrine neoplasm comprising approximately 2% of primary lung neoplasms. This reddish polypoidal, endobronchial mass often presents with obstructive symptoms. As the neoplasms arise from Kulchitsky cells, part of the amine precursor uptake and decarboxylation (APUD) system, they may secrete hormones such as adrenocorticotropic hormone, antidiuretic hormone, gastrin, somatostatin, calcitonin, and growth hormone. Carcinoid tumors are categorized as typical, which is relatively benign and is treated with conservative resection, or atypical, also referred to as neuroendocrine carcinoma, which is more aggressive and often has metastasized widely by the time of diagnosis. A aggressive local resection with lymph node dissection is recommended for locoregional disease; chemotherapy is indicated when distant metastases are present. Five-year survival is about 60% and is dependent on the histologic subtype. Other malignant neoplasms of the trachea or bronchi include spindle cell, oat cell, and adenoid cystic carcinomas (Figure 5); adenocarcinomas; mucoepidermoid carcinomas; malignant melanomas; sarcomas; lymphoreticular neoplasms; and malignancies invading the trachea or bronchi from adjacent structures.

**Traumatic**

Aquired stenosis of the tracheobronchial tree may result from thermal inhalation, chemical burns, or from intubation (Figure 6). Pressure necrosis from an endotracheal or tracheostomy tube or their attached cuffs may result in healing by cicatrizination, resulting in a spectrum of lesions. Management of acute stenosis is controversial; some authorities advocate cautious dilatation, and the topical application of mitomycin-C shows promising early results. The use of a laser to enlarge the airway lumen may ultimately cause more scarring and stenosis formation, although it may be indicated for highly selected lesions. A tracheostomy or T tube may be used for temporary or long-term management; definitive treatment involves surgical resection, expansion, and/or reconstruction. Flow volume curves are of little practical use in the management of severe...
Rigid bronchoscopy

History
Gustav Killian is known as the father of bronchoscopy. He used a modified esophagoscope and then practiced examination of the airway in corpses, in patients with tracheostomies, and finally on a volunteer. In 1897, a Black Forest farmer had aspirated a piece of bone while eating his soup. Listening to his breathing, Killian heard a wheezing noise in the farmer's right lung. Killian used a head mirror as light source and forceps through his bronchoscope to remove the bone splinter, which was 11 mm long and 3 mm thick. He became famous for his expertise in removing foreign bodies, including beans, buttons, coins, and a tin whistle.

In May 1898, about 1 year after his initial experiments, Killian described some basic facts of modern bronchoscopy: "The bronchial tubes are elastic, mildly flexible and can be dilated. It is hence possible under local anesthesia to carefully insert the instruments from the bifurcation into the different sites and to view the small branches."

In Philadelphia, Chevalier Jackson made the next important advancement in 1904. He produced a bronchoscope with a small light bulb at its distal end and incorporated a suction device. The main emphasis of this method was the retrieval of foreign bodies. Further technical advances in rigid bronchoscopy came through the development of rod lens optical telescopes in the 1960s and video camera technology.

Indications/Contraindications
The original use of rigid bronchoscopes was therapeutic, for foreign body removal. This continues to be an important application. Rigid bronchoscopy was the sole means of airway examination until the 1960s when the flexible bronchoscope was introduced. This was embraced by pulmonologists, yet not as rapidly by surgeons trained in rigid bronchoscopy. The flexible bronchoscope was quickly considered to be superior and expected to replace rigid bronchoscopy. However, over the last quarter century the utility of rigid bronchoscopy has been appreciated more. This is related to the introduction of new treatment modalities that are best used with the rigid bronchoscope. These include laser therapy, dilation of stenosis, stent placement, and brachytherapy. Rigid bronchoscopy is the treatment of choice for airway foreign body removal, laser procedures for tumors of the airway, dilation of stenosis and strictures, stent placement, and evaluation of massive hemoptysis.

Rigid bronchoscopy is contraindicated in patients with a difficult upper airway that cannot be instrumented with a straight rigid scope. This includes patients with severe neck kyphosis who cannot tolerate neck extension, cervical spine instability, Class II malocclusion, trismus, mandibular hypoplasia, macroglossia. Rigid bronchoscopy is not possible in these cases. In patients with a tracheostomy, the rigid bronchoscope may be passed through the tracheostome.

Techniques: General, Specific, and New
When originally performed by Killian, topical anesthesia was used for rigid bronchoscopy. After Sigmund Freud's experiments with cocaine in 1883, it was found to be an excellent topical anesthetic. This paved the way for many applications in peroral endoscopy, including bronchoscopy. Now, general anesthesia methods have improved so that it is typically used to perform rigid bronchoscopy. Anesthesiologists now commonly employ techniques of total intravenous anesthesia or deep plane insufflation of inhaled agents by spontaneous ventilation, supplemented by propofol. The position of the patient is supine, rather than the upright position employed by Killian. Suspension tracheoscopy may be used with jet ventilation. This technique allows both hands to be free to use instruments and visualize the airway through an operating microscope.

Equipment and Personnel. Rigid bronchoscopy is usually performed in the operating room. An operating room that has equipment for surgical endoscopy is preferred. The increasing use of optical rod lens telescopes in surgical endoscopy has helped to familiarize operating room personnel with endoscopes, including the rod lens telescopes that have been used in rigid bronchoscopy since the 1960s. Video cameras, light sources, and monitors that are conveniently located throughout the operating room allow the nursing staff and anesthesiologists to view the examination. This allows much greater cooperation and communication in management of the airway between members of the team. The room has equipment that is dedicated to bronchoscopy with a variety of bronchoscope sizes, optical lens telescopes, suction catheters and instruments, grasping forceps, biopsy forceps, and laser if needed. Commonly used lasers in bronchoscopy include the KTP and YAG lasers with fiberoptic capability. A ron laser, and CO₂ laser.

Techniques. Before performing rigid bronchoscopy, the plan of airway management is discussed with the anesthesiologists. The endoscopist has an idea of what is to be looked for, the risk of airway obstruction relating to both the disease process and the intervention. The safety of rigid bronchoscopy lies in the simultaneous control of and examination of the airway. The patient is taken to the operating room and placed in supine position on the table. Sedation and anesthesia are induced by the anesthesiologist, usually with intravenous infusion of propofol. The patient may be intubated by the anesthesiologist and turned over to the bronchoscopist or mask ventilated until insertion of the bronchoscope. The latter method is preferred in cases of known airway
obstruction. If the patient has not received neum-
romuscular blockade, 3 to 5 mL of 4% topical 
lidocaine is sprayed into the larynx and trachea to 
reduce coughing. A anesthetists frequently 
choose to administer propofol and remifentanil 
in a total intravenous anesthesia technique for 
these cases. The operating table is turned 90º 
to facilitate examination by the bronchoscopist 
the head of the bed and positioning of the 
scrub nurse and equipment tray. At this time, 
in the tracheobronchial tree is examined by 
passing the bronchoscope to the carina, the right 
bronchus, and left bronchus. The segmental and 
subsegmental bronchial openings are visualized. 
Because the left bronchus makes a more acute 
angle from the trachea, the head is rotated to the 
right to pass the bronchoscope down the left side. 
If an examination of the distal bronchial seg-
ments is needed beyond the view through the 
rigid bronchoscope, a flexible bronchoscope may 
be passed through the rigid scope. Interventions 
taken after the diagnostic process are completed 
and are discussed below. At the completion of 
the procedure, the patient may be mask venti-
lated or intubated until emergence from general 
anesthesia.

Complications

Rigid bronchoscopy is a procedure that has both 
great therapeutic potential and risk of major com-
lications. Because the instruments are metal and 
the soft tissue of the airway is elastic and pliable, 
the possibility of injury exists. This can lead to 
perforation of the airway which can cause pneu-
omediastinum, pneumothorax, hemorrhage of 
the great vessels into the airway, and esophageal 
injury. These serious complications may cause 
respiratory compromise, mediastinitis, or death. 
In the airway that is unprotected in an anesthe-
tized patient, aspiration of secretions can cause 
pneumonia. Edema of the larynx and subglottis 
can be created or worsened by rigid bronchosco-
oscopic manipulation. This may cause airway 
obstruction requiring intubation or tracheostomy.

FLEXIBLE FIBEROPTIC 
BRONCHOSCOPY

Definition

Flexible bronchoscopy is an invasive procedure 
used to examine the tracheobronchial tree and, 
in addition, the nasal passages, pharynx, and lar-
ynx. It has both diagnostic and therapeutic appli-
cations for lung and airway disorders. Flexible 
bronchoscopy is most commonly performed in an 
endoscopy suite but may also be performed in the 
operating room, at the bedside, in the clinic, or 
in other locations. Indeed, flexible bronchoscopy 
has been safely performed on climbers with high-
altitude pulmonary edema in a tent on Denali 
(Mt. McKinley, Alaska) at 4,200 m.21

History

A prototype flexible fiberoptic bronchoscope 
was developed by Dr Shigeto Ikeda in the mid-
1960s and used for a series of clinical trials. The 
fiberscope, which became commercially avail-
able in 1967, rapidly caught on and transformed 
the practice of pulmonary medicine. In 1987 Dr 
Ikeda introduced a prototype video bronchoscope 
that transmitted an improved image to a high-
definition monitor and allowed processing of the 
digitized image.

Indications

The flexible bronchoscope is used for both diag-
nosis and therapy. Guidelines for flexible bron-
choscopy are reviewed in detail elsewhere.22 
Table 2 compares flexible and rigid bronchosco-
py with respect to advantages, disadvantages, 
and indications. Diagnostic indications include 
the evaluation of lung masses and infiltrates, 
selected cases of pneumonia, hemoptysis, endo-
bronchial lesions, airway stenosis or malacia, 
mediastinal lymphadenopathy, cough, wheezing, 
and stridor. Diagnostic procedures include airway 
inspection, bronchial wash, bronchoalveolar 
lavage, bronchial brush, endobronchial biopsy, 
transbronchial biopsy, transbronchial needle 
aspiration, endobronchial ultrasound, and auto-
fluoroscopy bronchoscopy.

Therapeutic indications may include pul-
monary toilet, foreign body aspiration, airway 
obstruction by tissue, stenosis or malacia, or dif-
ficult intubation. Therapeutic procedures include 
suctioning, laser ablation, balloon dilation, phot-
dynamic therapy, intraluminal radiation, and stent 
placement. As discussed below, many thera-
pic procedures are more efficiently performed 
using the rigid bronchoscope.

Contraindications and Risks

Many consider the inability to oxygenate the 
patient adequately to be the only true contrain-
dication to bronchoscopy. The risk of compli-
cations is increased in patients with an unstable 
cardiac status, respiratory failure, or bleeding 
diathesis (if biopsy is performed), and these con-
ditions are often considered relative contraindica-
tions. More importantly, one should treat these 
conditions prior to bronchoscopy if possible and 
pay particular attention to their management dur-
ing bronchoscopy.

Equipment and Personnel

All of the necessary equipment should either be 
out in the room or readily available. For typical 
cases in a hospital setting, this includes patient 
monitoring equipment (oxygen saturation, blood 
pressure, heart rhythm), resuscitation and airway 
management supplies, suction, bronchoscopes of 
different sizes, video processor and monitor, 
biopsy forceps, cytology brushes, needle aspira-
tion catheters, bronchoalveolar lavage supplies, 
and fluoroscopy.

Flexible bronchoscopy is most often per-
formed by an operator who is dedicated to the 
diagnostic aspect of the procedure and two other 
personnel. One person, typically a registered 
nurse in our institution, administers medications 
and monitors sedation. A second person assists 
the bronchoscopist with specimen handling and 
other technical duties.

Techniques

In a bronchoscopy suite or operating room set-
ing, the patient is positioned appropriately (the 
supine position is most commonly used),

monitors are attached, and vital signs are taken. Intravenous access is obtained, and supplemental oxygen is supplied by nasal cannula or face-mask. If sedation is used, slow titration is started immediately. Numerous approaches to moderate or “conscious” sedation are used. We most commonly use an infusion of a fixed combination of propofol and remifentanil as the rapid onset and short duration of action of these drugs are excellent for this procedure. A topical anesthetic (lidocaine and/or cocaine) is applied to the nasal passages and pharynx.

After appropriate sedation is reached, the bronchoscope is passed either through the nares (preferred) or an oral bite block. Careful examination of the nasal passages, pharynx, and larynx is considered an important component of bronchoscopy, and particular attention is paid to the appearance and function of the vocal folds. A flter traversing the larynx, a complete airway examination is performed using topical lidocaine, and titration of sedation as indicated.

Following inspection, the diagnostic and/or therapeutic procedures are performed. It is critically important that the order of various procedures is considered prior to the bronchoscopy and modified as needed. We generally perform the high yield and low-risk procedures first and progress toward those with lower yields in the event that the bronchoscopy has to be terminated.

In our outpatient airway disorder clinic, we routinely perform flexible laryngoscopy, tracheoscopy, and esophagoscopy on unsedated patients sitting upright in a chair. With a flterable fiberoptic laryngoscope, the trachea down to the carina and the proximal bronchi can be seen in most patients. This is a safe, simple, and effective way to evaluate central airway problems. For laryngoscopy and tracheoscopy, topical anesthesia is atomized in the nasal passages and transorally. A lubricated laryngoscope is passed through the nares, pharynx, larynx, and into the distal trachea. Careful examination is performed and recorded. A similar technique is used for transnasal or transoral esophagoscopy. We find that the vast majority of our patients tolerate the procedure well and that, in many cases, it obviates the need for scheduling additional visits to the endoscopy suite.

Complications

Diagnostic flexible bronchoscopy is a safe procedure. Mortality is rare with a reported death rate of 0 to 0.04%. Major complications such as significant bleeding, respiratory depression, pneumothorax, arrhythmias, and cardiac arrest occur in <1% of cases.

Therapeutic Bronchoscopy

Although bronchoscopy is most frequently used for diagnostic indications, the bronchoscope was initially invented for foreign body retrieval. Bronchoscopy by otolaryngologists is typically done with the rigid instrument. However, a recent survey of members of the American College of Chest Physicians noted that 99% of bronchoscopies in the United States by pulmonologists were performed with the flexible instrument and that only 8% of pulmonologists use the rigid bronchoscope. Pulmonologists generally lack training in rigid bronchoscopy, and surgeons generally lack training in flexible bronchoscopy. However, there is no doubt that the rigid bronchoscope is an invaluable tool for those performing therapeutic bronchoscopy. It is our opinion that many of the therapeutic procedures listed below are performed more efficiently and safely with the rigid bronchoscope. In our practice, we usually perform suspension laryngoscopes, rigid and flexible bronchosopes, and rigid and flexible esophagoscopes. Having all of these tools available allows one to choose the correct tool for the task at hand.

The interventional procedures discussed below have recently been reviewed in detail and extensively referenced in guidelines published by the American College of Chest Physicians.

Laser Therapy

Lasers (light amplification of stimulated emission of radiation) interact with endobronchial tissue to cause vaporization, coagulation, and hemostasis. The lasers most commonly used for bronchial therapy are the neodymium:yttrium-aluminum-garnet (Nd:YAG), carbon dioxide (CO₂), and potassium titanyl phosphate (KTP) lasers. The Nd:YAG and KTP laser light can be transmitted through flexible fibers. A flexible guide for CO₂ laser delivery has also become available recently. We use the CO₂ laser, which has precise cutting but minimal hemostatic properties, primarily for benign lesions in the larynx, subglottis, for example, subglottic stenosis and proximal trachea. The Nd:YAG laser, which provides deeper tissue penetration and superior photoagulation and hemostasis, is used for malignancies and lesions in the trachea and bronchi. The KTP laser is used most often for benign lesions in the more distal airways.

Although the laser therapy can be performed through either rigid or flexible instruments, we prefer use of the rigid bronchoscope for most patients because it is faster, safer, and more versatile in the performance of other techniques, for example, stenting. Nd:YAG laser therapy is a safe and effective tool for relieving endobronchial obstruction due to malignant tumors. In central lesions involving the trachea, right and left bronchi, or the bronchus intermedius, the recannulization rates are greater than 90%. Serious complications of laser therapy include death, airway perforation, hemorrhage, pneumothorax, pneumomediastinum, and myocardial infarction. Complications may be minimized by careful patient selection, careful consideration of the characteristics of the airway lesion, and meticulous technique.

Electrocoagulation

Electrocautery uses high-frequency electric current to destroy tissue. These devices require grounding the device, the patient, and the bronchoscope to complete the circuit. A snare device using electrocautery is particularly useful for removing pedunculated lesions. Argon plasma coagulation (APC) is a relatively newer form of noncontact electrocoagulation. Argon plasma formed at the tip of a probe is used to transmit electric current to the nearest grounded tissue and thereby cause coagulation. Coagulation depth of 2 mm is typically achieved. This is quite useful for providing hemostasis with little risk of perforating the airway. It is an excellent tool for controlling hemoptysis from the surface of lesions; however, laser therapy is generally more effective for debulking large masses.

Airway Dilation

Airways may be dilated using the rigid bronchoscope barrel, Pilling dilators, or “angioplasty” balloon catheters. Airway dilation (bronchoplasty) may be used as sole therapy but is most often used in combination with other procedures. For example, when there is subtotal occlusion of a right or left bronchus by tumor, we will frequently use bronchoplasty to provide a visual “path” for laser resection. In patients with central airway stenosis, bronchoplasty is frequently followed by stenting. For endoscopic therapy of subglottic stenosis, we often use radial incisions with a CO₂ laser followed by balloon bronchoplasty. The major potential complication is airway disruption.

Airway Stents

The first dedicated airway stent, the Montgometry T-tube, was introduced in 1965. Dumon introduced the first dedicated endoluminal airway stent in 1990. Currently, there are two main categories of endobronchial stents; fixed tube (silicone) and self-expanding (wire mesh). Fixed tube stents are typically placed using a rigid bronchoscope. In comparison to self-expanding stents, they are relatively easy to remove and reposition and cause minimal irritation to the airway. We prefer silicone stents for most applications. Self-expanding stents may be either covered or uncovered. Compared to fixed tube stents, self-expanding metallic stents may be placed using a flexible bronchoscope and have a larger internal/external diameter ratio. However, granulation tissue is a more common complication and these stents can be difficult or impossible to remove. The Polyflex stent is a hybrid design that uses a self-expanding polyester mesh imbedded in silicone. The Polyflex stent is placed using a rigid bronchoscope but has the property of easy removal similar to the tube stents.

Airway stents are used for obstruction by benign or malignant disorders. They are best suited for extrinsic compression or endoluminal tumor although they can be used for malacia. Stents are frequently used in combination with other therapies such as laser resection or radiation. There are now many studies that demonstrate impressive results using stents for...
malignant airway obstruction. Interventional bronchoscopists should have significant experience using all of the major stent types to ensure that the appropriate stent is selected for a given lesion. Occasionally, combined stenting of the airway and the gastrointestinal tract is required as shown in Figure 7. A necadically, we have seen numerous problems resulting from inexperienced bronchoscopists attempting to use self-expanding stents for benign disease. It is our practice only rarely to use metallic stents for benign central airway obstruction. The US Food and Drug Administration has issued a warning regarding the use of metallic stents in benign tracheobronchial disease.31

Intraluminal Radiation

Intraluminal radiation (brachytherapy) is most commonly delivered to the airway using a transnasal catheter that is placed in the airway using the bronchoscope. One is able to deliver therapeutic doses of radiation to airway tumor, with minimal dose being supplied to the normal surrounding tissues, using this technique. The after-loading catheter is advanced across the area to be treated through the working channel of the flexible bronchoscope. The bronchoscope is withdrawn over the catheter using fluoroscopy to maintain position of the catheter. Then the position of the catheter is confirmed both bronchoscopically and radiographically. The patient is then transferred to radiation oncology for dosimetry and after loading of the radioactive source. The catheter is withdrawn immediately after the treatment. Typical regimens deliver three fractions at weekly intervals. Intraluminal radiation is most commonly used for palliation of malignant airway obstruction (Figure 8). Occasionally, it may be used for carcinoma in situ or early stage lung cancer in patients who are not candidates for surgery. In addition, there are occasional uses in nonmalignant disease such as endobronchial amyloidosis.32

Photodynamic Therapy

Photodynamic therapy (PDT) involves infusion of a photosensitizer, preferential retention of the photosensitizer by malignant cells, activation of the photosensitizer by nonthermal laser light, and finally removal of necrotic tissue. Most typically, porfimer sodium (Photofrin) is injected intravenously 48 to 72 hours before light is applied through a flexible fiber. Subsequent bronchoscopy is often required 1 to 3 days later for debridement of necrotic tumor. Although PDT is effective in selective cases of endobronchial malignancies, it is our opinion that Nd:YAG and mechanical resection are more efficient in the majority of patients with obstruction of the central airways. However, PDT can be performed using a flexible bronchoscope without general anesthesia and may be more easily delivered to the peripheral airways, for example, the upper lobes. Another indication is early stage lung cancer of the airways in patients who are not surgical candidates. Skin photosensitivity for a period of time of up to 6 weeks can be a problem if patients are unable to stay out of the sun, and massive hemoptysis has been reported.

Cryotherapy

Cryotherapy uses a flexible cryoprobe to repeatedly freeze and thaw tissue causing tumor cell death. It may be used for both benign and malignant obstruction. Its major advantages include cost and relative safety. As the maximal effects are delayed, it is not as useful as other modalities for treatment of severe obstruction. In addition, it often requires follow-up bronchoscopy exposing the patient to additional procedures.

Microdebrider

Microdebriders are used by a variety of specialties including otolaryngology for laryngeal surgery. The device has a rotating blade at the tip of a hollow tube that is connected to suction for trapping and removing debris. In selected cases, it allows rapid debridement of obstructing airway lesions. As there is no coagulation of tissue, there is the potential for significant bleeding, but this has not been an issue in the reported series or in our experience. The relatively short length of the instruments commercially available limits use to the more proximal airways.

Anesthesia and Ventilation

Every detail of the approach to airway management, anesthesia, and ventilation is extremely important in the care of patients with central airway obstruction.33 One must be prepared for virtually any airway emergency. We generally use intravenous agents for induction and maintenance of anesthesia because we find induction to be smoother; we often interchange open, for example, rigid bronchoscope, circuits, and the patients have fewer postoperative symptoms. We find the combination of propofol and remifentanil to be ideal and use specific muscle relaxants based on the time required for the procedure. Ventilation can be managed using either a closed (the rigid bronchoscope is connected to
the anesthesia circuit) or an open system (jet ventilation). In most patients for whom the rigid bronchoscope is used, we start with the closed system because it is easier to monitor the adequacy of ventilation. We do not hesitate to use jet ventilation in individual patients. When working through a suspension laryngoscope, we either use intermittent ventilation with an endotracheal tube or jet ventilation. Problems related to inadequate ventilation, inadequate oxygenation, or dynamic hyperinflation must be anticipated as they may develop quickly.

Central Airway Obstruction

Central airway obstruction may result from a long list of malignant and "benign" processes.33 Bronchogenic carcinoma is the most commonly encountered malignant cause. Complications resulting from endotracheal and tracheostomy tubes are the most common nonmalignant causes. An algorithm for the management of central airway obstruction is presented in Figure 9.

Signs and symptoms of central airway obstruction may include dyspnea, wheezing, cough, and hoarseness. Dyspnea occurs when there is a significant increase in the work of breathing. Physical examination, pulmonary functions testing, and imaging techniques such as conventional radiographs may provide useful information. CT scans using new imaging protocols often provide more information; however, bronchoscopy remains the diagnostic “gold standard.”

The diagnostic and therapeutic approach, using bronchoscopy and other means, depends on the clinical urgency, the cause, and the anatomical details including the location and nature (extrinsic compression, intraluminal exophytic tumor, etc.). In certain cases, we proceed directly to rigid bronchoscopy with plans for immediate therapy. In others, we will perform flexible bronchoscopy for more detailed analysis prior to planning the therapeutic approach.

Exophytic endobronchial lesions are often managed with a combination of dilation, laser and mechanical resection, and/or APC. Extrinsic compressing lesions are typically managed using a combination of dilation and stenting. In non-emergent cases, a variety of additional therapies may be useful as outlined in Figure 9.

Foreign Body Removal

Foreign bodies in the airway are common and occasionally life threatening. They may present acutely and be obvious or chronically and be occult. The diagnosis requires a high index of suspicion and a low threshold for performing bronchoscopy. Radiographs may at times be useful but are not a sensitive test. If the history is suggestive of foreign body aspiration, one must not be dissuaded from performing bronchoscopy because of unremarkable imaging.

Bronchoscopy is the “gold standard” for the diagnosis of an airway foreign body and the most useful therapeutic tool. Either the flexible or the rigid bronchoscope may be used depending on the clinical situation. At our institution, we prefer using the rigid bronchoscope for many of these procedures. When we use the flexible bronchoscope as the initial tool, we do not hesitate to progress to general anesthesia and the rigid bronchoscope. A variety of removal devices should be available including forceps, baskets, and balloons. Complications of bronchoscopy for foreign body removal are infrequent, although great care to protect the airway is warranted. On rare occasions thoracotomy may be required.

Life-Threatening Hemoptysis

Bronchoscopy plays a role in the diagnostic and therapeutic approach to the management of patients with life-threatening hemoptysis. Although less than 5% of patients with hemoptysis are classified as “massive,” acutely fatal bleeds have been reported in up to one-third of these patients. We favor an aggressive approach to airway management, diagnosis, and
intervention because of the unpredictable course in such patients.

Localization is accomplished by combining history, physical examination, and imaging studies with bronchoscopy. Either the flexible bronchoscope, in the intubated patient, or the rigid bronchoscope may be used. Although there are no studies directly comparing the safety and yield of these two procedures, we favor the rigid bronchoscope because the larger lumen allows improved suctioning capacity and, therefore, better airway clearance.

After localization a decision is made regarding therapeutic intervention. Bronchoscopic therapies include airway blockade, topical therapies, and laser coagulation. Other therapies include arteriography and embolization and surgical resection.

Endobronchial Lung Volume Reduction

Lung volume reduction surgery has been shown to be effective for symptom palliation in selected patients with emphysema. Unfortunately, the surgery has a high morbidity and mortality rate. Intrabronchial valve treatment for emphysema uses one-way valves implanted in appropriate airways to cause lung volume reduction and other physiologic changes achieved by lung volume reduction surgery. Valves are placed into the upper lobe airways using a flexible bronchoscope. A recent multicenter trial demonstrated acceptable safety and improvements in health-related quality of life. Further studies of this promising technique are ongoing.

Airway Complications of Lung Transplantation

Lung transplantation has become relatively common in patients with end-stage lung disease in disorders such as chronic obstructive pulmonary disease, pulmonary fibrosis, and cystic fibrosis. Airway complications are significant clinical problems that occur on average in 15% of these patients. Infection and mucosal sloughing occur early, and exuberant granulation tissue formation, stenosis, or malacia may occur later on. Combinations of granulation tissue, stenosis, and malacia are handled in a manner similar to elsewhere in the airway. Typical cases require one or more of the following techniques (balloon dilation, mechanical and Nd:YAG laser debriement, and airway stenting). It is not uncommon that stenting can be temporary, for example, 6 to 12 months, and following removal of the stent, the airway remains patent.

NEWER PROCEDURES

Endobronchial Ultrasound

Endobronchial ultrasound (EBUS) uses a miniature probe that can be inserted through the working channel of a flexible bronchoscope. A fluid-filled balloon surrounds a rotating piezoelectric crystal allowing an ultrasound view of the airway. The penetration depth allows visualization of the airway wall layers as well as mediastinal and paratracheal lymph nodes and peripheral lung lesions. This technique can be used for visualization of the airway, guiding transbronchial needle aspiration, and assessing airway anatomy to guide other therapeutic procedures. EBUS with transbronchial needle aspiration is emerging as a safe and accurate means for staging lung cancer.

Navigational Systems

A variety of navigational systems have been used to supplement direct vision of the airways through the bronchoscope. Traditionally, fluoroscopy has been used for guiding transbronchial biopsies. CT scanning, which allows more precise localization, may be used although it is cumbersome. EBUS is discussed above. Most recently, a navigational system has been developed that uses previously acquired CT images coupled with an electromagnetic field around the patient’s chest to localize an endoscopic tool with a microsensor. Preliminary studies have suggested that, although time intensive, this technology may improve accuracy in biopsy of peripheral lung lesions.

A autofluorescence Bronchoscopy

A autofluorescence bronchoscopy was developed to differentiate normal from malignant tissue. This technique uses a blue light for illumination. Images are captured and manipulated in a way that normal tissue appears green and abnormal tissue appears reddish brown. A normal tissue that is discovered can be biopsied during autofluorescence inspection or under white light. It is proposed that this technique can increase the yield of fiberoptic bronchoscopy for the detection of dysplasia, carcinoma in situ, and early invasive cancers.

Bronchial Thermoplasty

Bronchial thermoplasty uses a catheter that can be delivered through a flexible bronchoscope to coagulate bronchial tissue using controlled therapeutic radiofrequency. It is suggested that this can reduce the amount of airways smooth muscle and may benefit selected patients with asthma.

ADDITIONAL TOPICS

Pediatric Bronchoscopy

Bronchoscopy is a critical skill for evaluation and treatment of airway disorders in children. It has saved the lives of many children who aspirated foreign bodies (Figure 10). Pediatric rigid bronchoscopes with rod-lens telescopes have been available since the early 1970s and have made a large improvement in ability to examine the small airways in children. The smallest rigid bronchoscope available (Karl Storz, size 2.5 mm about 3.3 mm outer diameter) will fit nearly all premature newborns, and the smallest flexible fiberoptic laryngoscope or bronchoscope is 2 mm diameter. This is useful for examination of the airway of an intubated infant with a 3.0 or 3.5 mm inner diameter endotracheal tube. Common indications for bronchoscopy in children include congenital stridor, postextubation stridor, cough, hemoptysis, suspected foreign body aspiration, difficult pneumonia, and aspiration of retained...
surgical head and neck oncology, laryngology, and pediatric otolaryngology. For pulmonologists who desire skills beyond diagnostic flexible bronchoscopy, additional training in interventional pulmonary medicine is available at a few centers in the United States.

SUGGESTED READING

Esophagology

Gregory N. Postma, MD, Melanie W. Seybt, MD, Catherine J. Rees, MD

Esophagology is the study of the normal anatomy and physiology of the esophagus as well as the diseases and disorders that arise or involve the esophagus. In particular, congenital anomalies, infectious and inflammatory processes, disorders of motility, systemic diseases affecting the esophagus, trauma and neoplasms of the esophagus and treatment of patients with these processes are the central focus of esophagology. The field has been revolutionized by the development of rigid and flexible esophagoscopes and highly informative imaging permitting a wide array of diagnostic and therapeutic options.

ANATOMY

The esophagus is a conduit between the pharynx and the stomach. Measuring approximately 25 centimeters long, it is continuous with the pharynx at the level of the sixth cervical vertebra and passes through the diaphragm at the level of the tenth thoracic vertebra. It has been subdivided into three portions: the cervical, thoracic and abdominal. The cervical portion extends from the cricopharyngeus to the suprasternal notch. The thoracic portion extends from the suprasternal notch to the diaphragm, and the abdominal portion continues to the gastric cardia.

Histologically, the esophagus has four concentric layers. The innermost layer is the mucosa, and the mucosa changes from squamous cell epithelium to columnar cell epithelium at the gastroesophageal junction (GEJ). This junction has been termed the 'Z line' or squamocolumnar junction (SCJ). The second layer, the submucosa, surrounds the mucosa. The third layer is muscular and is divided into two portions, with the inner muscular fibers arranged in a circular fashion and the outer fibers oriented longitudinally. The proximal one-third of the esophagus consists primarily of striated muscle. Smooth muscle predominates in the distal portion, and there is a transition zone of both striated and smooth muscle at approximately the level of the aortic arch. The adventitial layer is the fourth and outermost layer. Unlike the remainder of the gastrointestinal tract, no serosa layer is present in the esophagus.

The upper esophageal sphincter (UES) is more aptly described as the pharyngoesophageal segment (PES). This 2 to 4 cm high pressure zone consists of the cricopharyngeus muscle, the inferior pharyngeal constrictor muscle, and the proximal striated muscle of the upper cervical esophagus. The cricopharyngeus is tonically contracted at rest and is innervated by branches of the vagus nerve. The sling-shaped muscle attaches bilaterally to the cricoid lamina. During swallowing, the cricopharyngeus muscle relaxes and is pulled open by the anterior and superior motion of the larynx and hyoid bone. A side from allowing passage of food and liquid into the esophagus during deglutition, the cricopharyngeus also plays a role in eructation and preventing refluxate from entering the pharynx.

The lower esophageal sphincter (LES) is an anatomic and physiologic high pressure zone between the esophageal body and the stomach. It is made of up of circular and oblique muscle fibers that are contiguous with the circular muscle of the esophagus. The diaphragm also contributes to this high pressure zone. The LES relaxes during swallowing to allow passage of the bolus from the esophagus into the stomach. The SCJ is normally located at the same level as the gastroesophageal junction (GEJ), which is best identified by the termination of the gastric rugae in the esophagus and the point where the linear blood vessels of the esophagus end. When more than two centimeters of gastric rugae is present proximal to the level of the diaphragm (observed by a constriction of the lumen during a sniff maneuver on endoscopy), a sliding hiatal hernia is present. Sliding hiatal hernias are commonly observed in adults undergoing barium esophagram and increase the risk of gastroesophageal reflux. The much less common, and more serious, paraesophageal hernia occurs when part of the stomach herniates into the thorax along side the esophagus, but the gastric cardia remains in the native position.

There are three areas of constriction in the normal esophagus that can be visualized on fluoroscopy and endoscopy. The level of the cricopharyngeus is the narrowest portion of the esophagus, located at approximately the sixth cervical vertebra. The second narrowing is approximately 25 cm from the incisors where the aortic arch and left bronchus cross the esophagus. This area along the UES and the LES are three natural esophageal constrictions and are the most common sites of foreign body impaction.

Lymphatic drainage of the esophagus contains little barrier to spread. The lymphatic drainage of the upper third is to the deep cervical lymph nodes, the middle third is to the superior and posterior mediastinal lymph nodes, and the lower third to lymph nodes along the left gastric vessels and celiac artery. However, the esophageal lymphatics are all densely interconnected. Esophageal carcinoma can spread throughout the length of the esophagus via the lymphatics and may have lymph nodal involvement several centimeters away from the primary lesion.

ESOPHAGOSCOPY

The ability to visualize the esophagus was pioneered by laryngologists such as Chevalier Jackson who described the use of rigid esophagoscopy for examination, dilation, removal of foreign bodies, and biopsy. Fiberoptic lighting systems were later added to improve visualization. The next major advance was the development of flexible endoscopy by Hirschowitz et al in 1958. Today, flexible esophagoscopy is usually performed by gastroenterologists and requires patient sedation. First reported by Herrmann and Recio in 1997, transnasal esophagoscopy (TNE) has emerged as a new technology available for unsedated esophagoscopy. In 1994, Reza Shaker, a gastroenterologist, published the first report of an unsedated transnasal esophagogastroduodenoscopy (EGD). Although initially met with little enthusiasm by the gastroenterology community, interest continued to grow among otolaryngologists. The use of TNE in North America became popular after the publication of Aviv et al's work in 2001.

Rigid Esophagoscopy

Rigid esophagoscopy is often used by otolaryngologists for foreign body removal and dilation as well as part of head and neck cancer staging. Rigid esophagoscopy is superior in the evaluation of the postcricoid region and cervical esophagus, where insufflation is difficult to achieve for flexible esophagoscopy, whereas flexible esophagoscopy is best for visualizing the distal esophagus and GEJ. Although rigid esophagoscopy can be performed with topical anesthesia and conscious
sedation, most surgeons use general anesthesia in the modern era.

In the supine position, the neck should be kept in the neutral position, and the maxillary teeth and gums should be protected. The rigid esophagoscope is typically held in the left hand between the thumb and index finger. The remaining fingers of the left hand are used to control the mouth and prevent resting of the endoscope on the teeth. Following the palate, uvula, and posterior pharyngeal wall, the endoscope is passed through the mouth to the postcricoid region. The endoscope is held at approximately a 90-degree angle to the long axis of the patient, and the angulation is changed so that the endoscope is roughly parallel to the esophagus by the time the tip reaches the postcricoid region. The larynx is lifted anteriorly to expose the inlet of the esophagus and the posterior bulge formed by the cricopharyngeus muscle. The right (dominant) hand is used only for changing the angle of the endoscope and should not be used to advance the endoscope. The endoscope should be advanced only with the left thumb and index finger to prevent excessive pressure. The esophagoscope is advanced only when the lumen is clearly visualized to decrease the risk of perforation. The endoscope is passed gently to the GEJ, and the esophagus is completely examined as the endoscope is withdrawn, taking care to examine the entire circumference of the esophagus along its whole length. This examination is best performed with the aid of a rigid telescope through the esophagoscope. Biopsies, if necessary, should be performed after the entire esophagus has been examined.

**Transnasal Esophagoscopy**

The introduction of distal chip and high-quality fiberoptic esophagoscopes now allows the esophagus to be easily examined in the office using only topical anesthesia, and this has produced a major change in otolaryngologic practice. Advances in optics as well as the placement of a working channel in a thin esophagoscope have given endoscopists the ability to examine the entire esophagus, larynx and trachea in unsedated patients using the technique of TNE. A working channel in the esoscope allows for biopsies, either cup or brush, as well as laser use.5,6

Esophageal indications for TNE include dysphagia, recalcitrant reflux symptoms, odynophagia, screening for Barrett esophagus (BE), and long-standing reflux disease. Extrasophageal indications are somewhat controversial but in our practice include globus pharyngeus, chronic cough, cervical dysphagia, head and neck cancer, asthma and moderate to severe laryngopharyngeal reflux (LPR).

TNE is a safe, well-tolerated, and easily learned procedure. In the largest consecutive series published, Postma et al reported that the unsedated examination was well tolerated and that abnormal findings were present in over 50% of the patients.7 The patient population for this series consisted of patients with extraesophageal reflux symptoms, not gastroesophageal reflux disease (GERD) or “heartburn.” Complications in these 700 patients included six cases of self-limited epistaxis and two vagovagal episodes. A double-blind study by Andrus et al, confirmed that TNE is a safe and effective tool for patient evaluation.1 Wilkins and Gillies reported that 95% of patients tolerated examination with an ultra-thin endoscope introduced transorally through an appliance.9 No case of esophageal perforation has been reported with TNE.10

A complete TNE involves examination of the entire length of the esophagus. This includes a retroflexed view of the GEJ and gastric cardia. The question of whether a full EGD should be performed has been addressed by a study conducted by Wildi et al.11 In their report, when patients were classified by symptoms, patients without daily abdominal pain, nausea, or history of gastric or duodenal ulcer were unlikely to have major pathology of the stomach or duodenum. They concluded that esophagoscope was sufficient for use in the patient without those complaints.

To visualize the entire esophagus, the transnasal esophagoscope should be of sufficient length to allow for a retroflexed view of the GEJ and the gastric cardia (at least 60 cm). The diameter should be small enough to allow for easy placement through the nasal cavity. Channels for air insufflation, suction and working, i.e., for the passage of biopsy instruments, are also standard parts of the transnasal esophagoscope or sheath.

When possible, the patient should not eat or drink for three hours before the procedure; however, a recent meal is not a contraindication to TNE. Adequate nasal anesthesia and decongestion are vital to performing the procedure successfully. The patient is sitting upright across from the endoscopist. The patient’s more patent nasal cavity is first sprayed with 1:1 oxymetazoline (0.05%) and lidocaine (4%) and is gently packed with a cotton pledge soaked in the same mixture.7 Two sprays of 20% benzocaine (Hurricane) are occasionally administered to the oropharynx. The transnasal esophagoscope (VE-1530, Pentax Precision Instrument Corporation, Orangeburg, New York) is lubricated and introduced into the naris. The transnasal esophagoscope is passed along the floor of the nose or between the middle and inferior turbinates. Next, the head is slightly flexed toward the chest as the endoscope is passed toward the cricopharyngeus muscle. The patient is asked to swallow, and the endoscope is gently advanced into the esophagus. Gentle suctioning and air insufflation are used as needed, and the instrument is advanced only when the lumen is visualized.

The instrument is advanced into the distal esophagus for a view of the GEJ and SCJ, or Z-line (Figure 1). Close examination of this area may detect esophageal lesions such as BE or adenocarcinoma. The endoscope is advanced and retroflexed to view the gastric cardia. Using air insufflation and irrigation, the mucosa of the entire esophagus is examined while the transnasal esophagoscope is withdrawn. When mucosal lesions or irregularities are appreciated, biopsy forceps are passed through the working channel, and multiple biopsies under direct vision are obtained.

TNE has been demonstrated to be equal to “conventional” sedated esophagoscopy with regard to diagnostic sensitivity and specificity and equal or superior in patient tolerance and preference. In a randomized cross-over study by Jobe et al, 121 patients underwent office-based TNE and traditional sedated esophagoscopy, comparing the histological detection of BE, dysplasia, and biopsy size.12 Both procedures accurately detected Barrett metaplasia and dysplasia; however, over 70% of patients in the study reported a preference for the unsedated TNE over conventional endoscopy for future surveillance. While there was significantly more minor anxiety and discomfort associated with unsedated TNE, there was no difference in overall self-rated patient tolerability between the two modalities. In a prospective trial by Thota et al comparing sedated versus unsedated esophagoscopy, patients were randomized to either unsedated transnasal or transoral esophagoscopy prior to a second sedated transoral esophagoscopy.13 Results of this study indicate that the transnasal approach was better tolerated (initial discomfort and choking sensation) except with respect to pain. Additionally, 93% of the transnasal and 91% of the transoral patients were willing to have the unsedated procedure again. The diagnostic accuracy of the unsedated approach with a smaller endoscope was equivalent to the standard larger endoscope, which required sedation. In addition, new brush biopsy methodology may represent an improved technique to increase diagnostic accuracy,14 but further trials are needed.

**Transnasal Esophagoscopy Procedures**

In addition to diagnostic visualization, procedures that can be performed with the transnasal esophagoscope include biopsy, laser use,
esophageal dilation, and secondary tracheoesophageal puncture (TEP). The placement of a wireless pH telemetry capsule with unsedated TNE has also been reported by Belafsky et al.\textsuperscript{13}

Patients with malignancies of the head and neck often have comorbidities that make panendoscopy under general anesthesia a high risk activity. An unsedated TNE and biopsy alleviates these concerns. In a prospective study, patients underwent a TNE with biopsy followed by a standard panendoscopy under general anesthesia. Findings were congruent between the two modalities.\textsuperscript{14} This suggests that in selected patients panendoscopy can be performed in the clinic, thereby avoiding the time, risks and costs of the procedure under general anesthesia.

Traditional methods of evaluating dysphagia have included barium esophagram and modified barium swallow. While these diagnostic modalities may allow for the detection of strictures, they do not provide a description of the epithelium of the esophagus and can be a source of aspiration in patients with impaired swallowing function. Esophagoscopy can detect areas of narrowing as well as provide direct mucosal evaluation. With unsedated TNE, the peristaltic wave of a swallow can be followed by having the patient ingest an item such as a Tylenol capsule and follow its path through the esophagus. This can provide a rough estimate of esophageal motility.

When strictures are detected, it is possible to treat selected patients with use of unsedated TNE. After standard TNE anesthesia, the patient swallows 4% viscous lidocaine. A guidewire can then be positioned just in front of the esophagus and advanced to the stricture. After the transnasal esophagoscopy is advanced to or past the stricture under direct visualization, the guidewire is placed through the stricture. Alternatively, the guidewire can be passed through the working channel of the esophagoscopy. The endoscope is removed over the guidewire and reintroduced alongside it through the nose. A concentric radial expansion balloon is placed over the guidewire, and the stricture is dilated, using the transnasal esophagoscopy for visualization throughout the entire procedure.\textsuperscript{17}

For postlaryngectomy patients, it is usually appropriate to place a TEP in an unsedated patient. A catheter or the prosthesis itself can be inserted at this time. In addition, air insufflation may be useful to insert a dislodged or difficult-to-replace TEP device.\textsuperscript{18}

Tissue excision or ablation can be accomplished with use of the transnasal esophagoscopy scope by placing a laser through the working channel. Lasers such as the pulsed dye laser, KTP, thulium, or gold laser have been used to remove lesions such as recurrent respiratory papillomas, granulomas and recurrent leukoplaikia in the office without sedation. Patient tolerance of this unsedated procedure has been reported to be high.\textsuperscript{19}

Complications of Esophagoscopy

The most serious complication of both rigid and flexible esophagoscopy is esophageal perforation. Perforation is higher with rigid esophagoscopy and most often occurs in the setting of esophageal carcinoma or during procedures such as dilation. The importance of gentle technique and refraining from forcing the endoscope past a stricture or lesion cannot be over-emphasized. Bleeding in the esophageal lumen should alert the surgeon to the possibility of perforation. In the event of a possible perforation, the procedure should be aborted and broad-spectrum antibiotics should be initiated. If possible, a nasogastric tube or small feeding tube can be placed under direct visualization. The patient is awakened from general anesthesia and monitored for signs of perforation, including subcutaneous emphysema, fever, tachycardia, and chest pain. Chest x-ray should be performed. When the patient is able, a gastrogroaffin esophagram is obtained to evaluate for perforation. Small proximal esophageal injuries can be treated with nasogastric tube, antibiotics, and nothing to eat or drink by mouth. Large injuries in the cervical esophagus should be repaired surgically.\textsuperscript{20} Thoracic esophageal injuries require assessment and intervention by a thoracic surgeon. Some authors have recommended more conservative treatment of esophageal perforation with computed tomography-guided drainage of leaks and control of sepsis.\textsuperscript{21}

More common complications of esophagoscopy include aspiration and injuries to teeth or the mucosa of the oral cavity and pharynx. Aspiration may occur during rigid esophagoscopy, especially with severe esophageal phase dysphagia or an obstructing foreign body. Standard anesthesia practices to limit aspiration risk, such as rapid sequence induction, should be considered in these cases. During rigid esophagoscopy, injuries to teeth and lacerations of the tongue or pharynx can result from improper technique.

During TNE, epistaxis is a rare and usually self-limited complication. Treatment of epistaxis with nasal packing or cautery is almost never necessary, and the bleeding usually resolves with topical oxymetazoline and nasal pressure. As with unsedated flexible laryngoscopy, vagovagal episodes can also occur during TNE.

CINEFLUOROSCOPIC EVALUATION OF THE ESOPHAGUS

The most useful radiologic examination of the esophagus is the contrast esophagram using cinefluoroscopy. This differs from the standard “modified barium swallow” in that the oropharyngeal phase of deglutition is not completely evaluated. The esophagram provides a more detailed evaluation of the esophagus than the full upper gastrointestinal series. Barium is usually used for videofluoroscopic examination, although in the setting of suspected esophageal perforation or pharyngocutaneous fistula, gastrograffin is preferred because it is water-soluble. When aspiration is strongly suspected, barium is preferred over gastrograffin.

The first phase of the esophagram is performed with the patient standing in the anterior-posterior view. A single large bolus of barium is ingested, and it is followed from the mouth to the stomach. The single swallow is useful to assess esophageal motility, since rapid repetitive swallowing inhibits peristalsis. Primary peristalsis is triggered by the swallow, and normal secondary peristalsis occurs in response to distal esophageal reflux or residual bolus. Tertiary contractions are non-peristaltic abnormal contractions commonly seen in the elderly population and in the presence of dysmotility. After the initial swallow, the patient is asked to ingest barium rapidly through a drinking straw. This maneuver is performed to dilate the esophagus and aids in evaluation of strictures, webs, rings, or hiatal hernia. Mucosal relief films, with the esophagus slightly collapsed, may help to identify mucosal lesions, such as esophagitis or carcinoma. A 13 mm barium tablet or marshmallow can be used to identify levels of obstruction, since this is the amount of esophageal lumen narrowing usually required to produce dysphagia. The esophagram is repeated in a right-anterior-oblique position (simulating a prone position) to negate the effects of gravity on bolus transit. Finally, many clinicians place the patient in the supine position and proceed with rapid water drinking and maneuvers to increase intrabdominal pressure, such as a leg lift. This “water siphon” test increases the esophagram’s sensitivity for detecting reflux. However, even with this maneuver, the esophagram is neither sensitive nor specific for diagnosing GERD.

CONGENITAL ANOMALIES OF THE ESOPHAGUS

The most common congenital anomalies of the esophagus are esophageal atresia and tracheoesophageal fistula (TEF). Esophageal atresia occurs in 1 in 3000 to 5000 births. Other less common congenital lesions include stenosis, duplications and cysts.\textsuperscript{22}

Esophageal atresia and TEF often occur together. The most common situation (over 80%) is distal TEF and proximal esophageal atresia. Atresia with no TEF is the next most common variant. TEF without atresia (H-type) is the most common of the remaining types and may have subtle symptoms, presenting later in childhood. Symptoms include respiratory distress, regurgitation, aspiration and drooling and frequently present early in life. More than half of infants with esophageal atresia have serious comorbid defects such as cardiac anomalies. Prompt surgical repair is indicated for esophageal atresia and TEF.

Congenital esophageal mucosal webs or muscular hypertrophy can cause symptomatic narrowing of the esophagus. Esophageal duplications can take many forms and may present as a neck mass or dysphagia. Dysphagia lusoria is induced by vascular anomalies involving the aortic root. Complete vascular rings encircling the esophagus include double aortic arch and variants caused by a right aortic arch and left ligamentum arteriosum and/or left subclavian artery. Incomplete rings include a retroesophageal aberrant
right subclavian artery (i.e., *arteria lusoria*) and abnormal left pulmonary artery. These vascular anomalies may be seen on fluoroscopy and endoscopy, and arteriography or computed tomography confirm the diagnosis.

**ESOPHAGITIS**

Esophagitis may cause heartburn, dysphagia and/or odynophagia, or it may be incidentally noted on esophagoscopy. The many causes of esophagitis include gastroesophageal reflux, foreign bodies (e.g., pills), infection, allergy, caustic injury, and radiation therapy.

**Infectious Esophagitis**

Infectious esophagitis is most commonly caused by Candida albicans. While frequently seen in immunocompromised patients (e.g., human immunodeficiency virus infection, diabetes mellitus, and corticosteroid use), candidal esophagitis may also occur in immunocompetent individuals. The appearance is characterized by yellowish punctate mucosal plaques, which may coalesce as the infection progresses (Figure 2). The diagnosis is confirmed by endoscopic biopsy, and treatment includes topical and systemic antifungal agents.

**Pill-Induced Esophagitis**

Pill-induced esophagitis is caused by prolonged contact of the esophageal mucosa with medication resulting in inflammation and ulceration of the epithelium. This may occur in patients with normal esophageal motility. 

**Reflux Esophagitis**

Reflux esophagitis is caused by abnormal exposure of the esophageal mucosa to gastric and/or duodenal contents. The exact mechanism of gastroesophageal reflux has not been thoroughly elucidated, but it is likely related to transient relaxations of the LES allowing passage of gastric contents into the esophagus. Symptoms of reflux esophagitis include pyrosis and dysphagia, although it may be asymptomatic. It is characterized by areas of mucosal slough or erythema which are well demarcated from adjacent normal mucosa and termed mucosal breaks. Chronic esophageal reflux may result in development of mucosal bridges secondary to repeated episodes of inflammation and healing, leading to scar formation and possible strictures. Signs of reflux esophagitis may be noted on cinefluoroscopy. Other tests, such as ambulatory pH monitoring, are useful for diagnosing GERD, but the presence of esophagitis can only be confirmed with endoscopy. Numerous classification systems based on the severity of endoscopic findings have been developed. The Los Angeles classification based on the number and size of mucosal breaks is currently the most generally accepted system.

Nonerosive GERD may be treated with behavioral modifications, antacids, and H2-receptor blockers such as ranitidine. Erosive esophagitis is usually treated with a once-daily proton pump inhibitors in addition to behavioral modifications. Endoscopy is rarely indicated in routine esophagitis promptly responding to therapy. However, it is the practice of many clinicians to confirm the resolution of esophagitis with endoscopy after appropriate treatment if symptom resolution is slow, incomplete or if symptoms have been present for more than three to five years. Endoscopy after treatment of esophagitis is also useful to evaluate for BE, which may not be apparent in untreated esophageal inflammation.

**Barrett Esophagus**

BE is the metaplastic replacement of squamous cell epithelium of the esophagus with specialized columnar cell intestinal epithelium that extends proximal to the GEJ. This condition predisposes to esophageal adenocarcinoma, which has one of the fastest growing malignancy rates in the United States and England. Endoscopic findings of BE include finger like projections or islands of salmon-pink mucosa that extend beyond the squamocolumnar transition of the GEJ (Figure 3). The diagnosis can only be made with biopsy, which will show intestinal metaplasia with goblet cells. Biopsies are also important to evaluate for dysplasia. Low-grade dysplasia should be followed closely and does not greatly increase the risk of malignancy over nondysplastic BE. However, high-grade dysplasia is typically treated as esophageal adenocarcinoma. Currently, experts in BE disagree about how frequently the esophagus should be screened for high-grade dysplasia and adenocarcinoma in patients with biopsy-proven BE or low-grade dysplasia.

**STRUCTURES, WEBS AND RINGS**

Narrowing of the esophageal lumen becomes symptomatic when the normal 20 mm lumen is reduced to about 13 mm. Narrowing of the lumen is evaluated with cinefluoroscopy (including a 13 mm barium tablet or marshmallow) and endoscopy. Strictures may result from peptic injury in the distal esophagus, postradiation injury, or caustic ingestion. Less common causes include prior esophageal trauma. Treatment is serial dilation with bougie, balloon, or Savary dilators. The most
dreaded complication of dilation is esophageal perforation, and the safety of the procedure may be improved by using a soft flexible guidewire.

Esophageal webs are thin bands consisting of squamous cell mucosa. Webs may be congenital, idiopathic, or associated with diverticula. These can often be treated successfully with a single dilation. A common type of cervical esophageal web is associated with iron deficiency anemia in Scandinavian women and is termed Plummer-Vinson or Paterson-Kelly syndrome.

There are two major types of esophageal rings: A and B. The A-ring is a muscular hypertrophy occurring at the most proximal aspect of the LES. A-rings are frequently incidental findings. Dilation is not likely to improve symptomatic A-rings, and treatment often entails endoscopic botulinum toxin injection. B-rings, or Schatzki rings, occur at the SCJ and are typically associated with a hiatal hernia and gastroesophageal reflux. The proximal aspect is lined with squamous cell epithelium, and the distal aspect is composed of columnar cell epithelium. Schatzki ring can be treated with endoscopic dilation and frequently recur.

**ESOPHAGEAL DIVERTICULA**

Esophageal diverticula, or outpouchings of the lumen, include pharyngoesophageal (Zenker) diverticulum, midesophageal diverticulum, and epiphenic diverticulum. Many esophageal diverticula are asymptomatic; the most common presenting symptoms are dysphagia and regurgitation. The diagnosis of esophageal diverticulum is most readily made with cineradioscopy.

Midesophageal diverticula are found in the middle third of the esophagus and are likely caused by traction from mediastinal disease or scarring, such as tuberculosis. These are usually asymptomatic and do not receive treatment. Epiphrenic, or distal esophageal, diverticula cause large volume regurgitation and dysphagia, when symptomatic. They are pulsion diverticula strongly associated with esophageal motility disorders. If symptomatic, they are treated with surgery directed at both the diverticulum and the underlying motility disorder.

Zenker diverticulum is the most commonly encountered esophageal diverticulum and is the most likely to be symptomatic. The outpouching occurs between the inferior pharyngeal constrictor muscle and the cricopharyngeus, in an area called Killian dehiscence. This pulsion diverticulum likely results from cricopharyngeal dysfunction and is frequently associated with gastroesophageal reflux and esophageal motility disorders.31 Spontaneous regurgitation of undigested food is the most common symptom, although a Zenker diverticulum may also present with dysphagia, aspiration, cough, halitosis, or weight loss. Zenker diverticula are much more common in the elderly population. Rarely, they are associated with carcinoma of the esophagus or fistula formation.

Zenker diverticula frequently require treatment. Small diverticula may be treated with open or endoscopic cricopharyngeal myotomy alone. Classic surgical therapy is open diverticulectomy with cricopharyngeal myotomy. A left lateral cervical approach is used to expose the diverticulum, which can be excised with the aid of a stapling device or using excision and meticulous closure of the resulting pharyngoesophageal defect. Open cricopharyngeal myotomy is usually performed over an esophageal dilator with a scalpel. Great care must be taken to incise the entire length of the cricopharyngeal muscle and proximal esophageal musculature without entering the lumen. Many surgeons recommend excising a strip of the cricopharyngeal muscle to prevent recurrence. Diverticulotomy, with repositioning of the diverticulum to a more superior position so that it drains by gravity, is an option for large diverticula in poor surgical candidates.

Over the past decade, the endoscopic approach has become the standard of care. Endoscopic Zenker diverticulostomy, also called the Dohlman procedure, has been refined since its original description in the 1960s. A bivalved diverticuloscope, such as the Weerda, is used to expose the common wall between the diverticulum and the esophagus, which contains the cricopharyngeal muscle. Either a gastrointestinal stapling device (preferably) or the carbon dioxide laser is used to divide this wall.26-29 This technique does not result in the removal of the diverticulum but instead eliminates the retention of food in the diverticulum by opening it to the esophagus lumen and divides the muscle which produces the outpouching. Therefore, fluoroscopy will still appear abnormal after the procedure. In a series of 159 endoscopic staple diverticulostomies, the procedure was successfully completed in 94%, with 98% of subjects reporting symptom improvement.29 The most common complications in this series were chipped teeth and postoperative fever. The recurrence rate was 11.8% after an average of 33 months. The endoscopic approach has a lower complication rate than the open approach with an equivalent success rate. Other advantages of the endoscopic procedure include shorter operating times, shorter hospital stays and more rapid return to normal diet. The endoscopic approach is standard in most institutions, with the open approach reserved for patients in whom the endoscopic approach failed, most commonly because of low-laying diverticula or an inadequate hypopharyngeal opening. Flexible endoscopic-assisted diverticulostomy has recently been suggested as an alternative for diverticula that cannot be exposed with rigid endoscopes.30

**ESOPHAGEAL MOTILITY DISORDERS**

Motility disorders of the esophagus, which may present as dysphagia, reflux symptoms not responding to treatment, regurgitation, or chest pain, are best evaluated with esophageal manometry. Cinefluoroscopy and esophagoscopy may be normal in many individuals with motility disorders. Primary esophageal motility disorders include ineffective esophageal motility (IEM), hypertensive LES, diffuse esophageal spasm (DES), nutcracker esophagus, and achalasia.

**Manometry and Impedance**

Esophageal body and LES manometry can be performed with solid state or perfusion catheters, usually passed into the esophagus and stomach through the nose. Manometry assesses contraction pressures and peristaltic coordination at multiple sites in the esophagus (more than 30 sites using high resolution manometry). The resting pressure of the LES and the degree of LES relaxation are also assessed. Manometry systems incorporate impedance testing as well. Impedance measures bolus transit throughout the esophagus by detecting changes in electrical current across electrodes. Impedance testing permits differentiation of retrograde and anterograde bolus flow and detection of all types of reflux, including weakly acid or alkaline reflux.31 Manometry may also be used in the evaluation of the PES and pharyngeal muscle dysfunction. Individuals with a hypertonic cricopharyngeus muscle or one that fails to relax may benefit from the injection of botulinum toxin or division of the muscle in an analogous manner to a hypertensive LES.

**Ineffective Esophageal Motility and Hypertensive Lower Esophageal Sphincter**

IEM is common in people with GERD, although it is not clear that IEM is directly caused by GERD. The diagnosis is made by the observation of >30% of swallows with low amplitude (<30 mm Hg) peristaltic contractions. Patients with IEM may have a normal esophagram. The primary therapies for patients with IEM are behavioral modifications and pharmacologic treatment for GERD. Patients with severe IEM may respond to botanichoel.32

A hypertensive LES is diagnosed if manometry reveals LES resting pressure greater than 45 mm Hg. Typically, the hypertensive LES relaxes completely and is associated with either normal or ineffective esophageal body peristalsis. Treatment includes endoscopic injection of botulinum toxin into the LES, surgical myotomy, or smooth muscle relaxants.

**Diffuse Esophageal Spasm and Nutcracker Esophagus**

DES is diagnosed by the presence of high amplitude simultaneous nonperistaltic contractions.33 Dysphagia and atypical, i.e., noncardiac, chest pain are common symptoms of DES. Cinefluoroscopy may show the classic “corkscrew” appearance of the simultaneous esophageal contractions. Treatment may be medical or surgical, including myotomy, botulinum toxin injections, calcium channel blockers, nitrates, and smooth muscle relaxants. If present, GERD should also be treated in patients with DES.
In contrast to DES, the high amplitude contractions seen in nutcracker esophagus are peristaltic. Cinefluoroscopy is usually normal in the setting of nutcracker esophagus. The symptoms are similar to DES, and smooth muscle relaxants and antireflux therapy may be useful treatments.

**Achalasia**

Achalasia is characterized by absent esophageal peristalsis and absent relaxation of the LES. Slowly progressive dysphagia may be accompanied by weight loss as the disease progresses. The etiology of this disorder is unknown. Classic signs of achalasia on fluoroscopy include a dilated esophagus with minimal or no contractions and a tapered “bird’s beak” appearance where the distal esophagus meets the contracted LES. Manometry reveals nonperistaltic low amplitude contractions and incomplete LES relaxation. Endoscopy must be performed to exclude an obstructing carcinoma at the GEJ (pseudoachalasia). Patients with achalasia are treated with LES botulinum toxin injections, pneumatic dilation of the LES, or surgical myotomy.

**Systemic Diseases Affecting the Esophagus**

Many connective tissue disorders and systemic diseases may affect the esophagus. Scleroderma is surprisingly common and involves the smooth muscle of the esophagus, while the proximal striated muscle remains unaffected. The LES may be incompetent in scleroderma, leading to profound gastroesophageal reflux. Inflammatory myopathies, such as dermatomyositis, involve the proximal striated muscle of the esophagus and the UES, leaving the distal esophagus and LES unaffected. Systemic lupus erythematosus can also cause esophageal dysmotility. Diabetes mellitus can lead to autonomic dysfunction affecting both esophageal motility and gastric emptying. Hypothyroidism may cause reversible esophageal dysmotility.

**ESOPHAGEAL TRAUMA**

**Esophageal Perforation**

Esophageal perforation is usually iatrogenic from esophagoscopy with or without dilation. Perforation is most common in narrow strictures or esophageal cancer. In eosinophilic esophagitis, the esophageal mucosa is extremely friable and susceptible to laceration. While these injuries are usually superficial, great care should be taken during esophagoscopy and dilation in patients with eosinophilic esophagitis. Blind placement of nasogastric or feeding tubes has also been associated with hypopharyngeal and esophageal perforation.

Other causes of perforation include blunt and penetrating chest and cervical trauma, esophageal foreign bodies, or acute esophageal necrosis. Progression or treatment of mediastinal neoplasms, such as lymphoma, may result in esophageal perforation with or without tracheoesophageal fistula. A rare transmural perforation of the distal esophagus, known as Boerhaave syndrome, is frequently associated with forceful emesis. Unlike Mallory-Weiss tear, hematemesis is not common with Boerhaave syndrome.

**Foreign Body Ingestion**

Ingestion of foreign bodies may account for up to 1,500 deaths a year in the United States, and the pediatric age group is most commonly affected. Foreign bodies typically become lodged in the normal anatomic constrictions of the esophagus, especially at the level of the cricopharyngeus. Since the party wall between the trachea and esophagus is thin and deformable, esophageal foreign bodies often present with respiratory distress, in addition to drooling and dysphagia. By far, coins are the most common foreign bodies to become lodged in the esophagus; other commonly ingested items are large food boluses and toys. Hot dog pieces are especially dangerous and may completely obstruct the adjacent trachea leading to death. Button batteries may appear as coin-shaped objects on radiographs but should be treated as surgical emergencies. Batteries cause rapid necrosis of the esophageal mucosa by strong alkali injury and should be removed immediately before severe esophageal injury and perforation ensue. Impaction of a food bolus in a child, especially when recurrent, should alert the surgeon to the possibility of eosinophilic esophagitis.

Foreign body ingestion should be evaluated promptly with thorough history and chest radiographs. The addition of lateral films can help clarify the location of the foreign body (trachea versus esophagus) and provide clues to the presence of multiple foreign bodies (Figure 4). Coins and batteries are well visualized on plain films, but toys and food boluses may not be seen. Some clinicians use contrast esophagography to demonstrate esophageal foreign bodies. Evaluation for an esophageal foreign body requires endoscopy.

![Figure 4](image)

*Figure 4* Double esophageal foreign body. Lateral chest radiograph showing two overlapping coins lodged in the proximal port of the esophagus.

Esophageal foreign bodies are best managed with rigid endoscopy under general anesthesia although reports have suggested that flexible endoscopic removal or pushing the foreign body into the stomach with a bougie may be acceptable for coins.

Rigid endoscopy provides the benefit of a protected airway, and limits the risk of converting an esophageal foreign body to a laryngotracheal foreign body during extraction. Optical forceps provide excellent visualization of the foreign body and firm control of the object. A impacted distal food bolus can sometimes be managed by carefully pushing it into the stomach. A full evaluation of the esophagus is recommended after retrieval of the foreign body to evaluate for multiple foreign bodies, esophageal injury, and underlying esophageal disorders, e.g., stricture or eosinophilic esophagitis. Since up to 25% of esophageal coins will pass spontaneously, chest x-ray should be repeated prior to general anesthesia if more than two hours have passed since the original film. Some clinicians also utilize gastrointestinal motility agents, such as glucagon, in an attempt to promote passage of the object into the stomach before surgery.

Complications of esophageal foreign bodies are rare but may be serious. Chronic foreign bodies may cause esophageal perforation, severe inflammation with resultant stricture, or tracheoesophageal fistula. Button batteries and sharp foreign bodies (such as safety pins) may rapidly lead to these complications. The potential complications of esophagoscopy, such as perforation or aspiration, also apply to esophageal foreign body extraction.

**Caustic Ingestion**

Ingestion of caustic substances is a common problem although federally regulated labeling of hazardous materials has decreased the incidence of accidental ingestion. Caustic ingestion occurs most commonly in small children or suicidal adults. In the case of children, the volume ingested is usually small, as children are deterred by the foul taste of most toxic substances. The exposure volume may be significantly higher in adults with intentional ingestion.

The history and identification of the ingested substance are most important when evaluating a patient with caustic ingestion. Alkali substances (pH > 7) include lye and laundry detergents. Alkali ingestion leads to liquefaction necrosis with deep esophageal injuries. Acidic substances with pH < 7 (e.g., battery fluid) cause corrosive injury which is frequently limited to the mucosa. Household bleaches usually have a pH around 7. While bleaches may irritate esophageal mucosa, permanent sequelae are uncommon. Hair relaxers are another commonly ingested substance in the pediatric population, with a pH of 11.2 to 11.9. Hair relaxer does not appear to cause serious or permanent esophageal sequelae. Liquid caustic ingestions have the potential to affect a greater area of the aerodigestive tract, and solid caustics (such as solid lye) tend to cause more localized
injury. Thermal injuries are also possible from hot ingestions.

Evaluation of patients with caustic ingestion should include a careful examination of the entire upper aerodigestive tract. Oral and pharyngeal injuries are common, especially with acid ingestion (acidic substances are especially foul-tasting and stimulate gagging and retching). Attempts to neutralize the substance are usually misguided and may result in further injury to the esophageal mucosa. There may be some benefit from water or milk ingestion to dilute the substance. Gastric lavage and emetics are strictly contraindicated in caustic ingestion.

If the ingested substance is believed to be injurious, or if it is unknown, endoscopy is indicated.41 The amount of damage may be underestimated if endoscopy is performed too early (less than 12 hours). Therefore, endoscopy is best performed 24 to 48 hours after injury. Any further delay significantly increases the risk of perforation during esophagoscopy, and esophagography should be considered. Due to its small caliber of the endoscope and the ability to perform it without sedation, TNE is a good option for evaluation of injuries due to caustic ingestion. In cases of suspected perforation, flexible esophagoscopy of any type is contraindicated.

Injuries are graded on esophagoscopy according to the extent of mucosal injury. Grade 1 injuries are superficial and do not usually lead to permanent sequelae. These injuries do not usually require treatment. Grade 2 injuries are transmucosal and have a high risk of stricture formation. Grade 3 injuries are transmural and are at high risk for perforation and strictures, almost always requiring surgical intervention. Circumferential injuries are more likely to lead to late complications. If possible, nasogastric tubes should be placed during esophagoscopy in the setting of transmucosal or transmural injuries to allow esophageal rest and prevent acute complete stricture. The administration of corticosteroids to prevent strictures is highly controversial and should be avoided for grade 1 or 3 injuries. In grade 2 injuries, some authors have suggested that corticosteroids decrease stricture formation, but other studies have refuted this.42,43 Antibiotics should be reserved for cases with clear evidence of perforation or secondary infection. Antireflux therapy may be of some benefit in preventing strictures.

A side from the acute risk of perforation, caustic ingestion (grade 2 and 3 injury) can lead to serious long-term complications. The most common is stricture formation, which often requires serial endoscopic dilation or surgical resection. A history of caustic ingestion predisposes the patient to a much higher risk of esophageal squamous cell carcinoma throughout life as well.

**Esophageal Bleeding**

Hematemesis of bright red blood is a gastrointestinal emergency. The most common cause of upper gastrointestinal bleeding is ulcerative disease of the stomach or duodenum. Esophageal causes of hemorrhage include varices, Mallory-Weiss tear, esophagitis, and neoplasms. Rare causes of bleeding are aortoesophageal fistula or acute esophageal necrosis.44 TNE is contraindicated in acute hematemesis.

Esophageal varices are most commonly associated with portal hypertension as a result of cirrhosis of the liver. On endoscopy, these varices typically appear as tortuous blue or white submucosal lesions. Endoscopic sclerotherapy or clipping or systemic drugs, such as vasopressin or somatostatin, are frequently used for acute variceal bleeding although uncontrolled life-threatening bleeds may require balloon tamponade. Asymptomatic varices seen upon endoscopy are a serious finding since such patients often present with life threatening hematemesis that can be avoided with beta-blockers or surgical shunts.

Mallory-Weiss tear occurs at the gastric cardia or GEJ and is the result of prolonged retching, often associated with alcoholism and binge drinking. This tear usually involves only the mucosa. The bleeding stops spontaneously in 90%. Treatment options for life-threatening active bleeding include endoscopic clipping, electrocautery, or injection of saline with epinephrine.

**Benign Esophageal Neoplasms**

Benign neoplasms of the esophagus are rare and usually slow-growing and asymptomatic. Dysphagia is the most common symptom that ensues and is dependent on the size and location of the mass.

Leiomyomas are intramural and represent 60 to 70% of benign esophageal neoplasms. These are generally found in the distal esophagus, where smooth muscle predominates. These neoplasms typically occur as a single mass and can be difficult to visualize on endoscopy. An intact layer of mucosa is usually present over the neoplasm. Most are discovered incidentally. Enucleation at thoracotomy is an effective treatment for large symptomatic leiomyomas.

Esophageal cysts are the second most common benign mass. These intramural masses are often congenital. As with leiomyomas, most esophageal cysts are asymptomatic. A cute inflammation may result in growth and the subsequent development of symptoms. On esophagoscopy, the cyst may appear as a blue, smooth, round mass beneath an intact layer of mucosa. Enucleation and excision at thoracotomy are effective treatment options.

Fibrovascular polyps are intraluminal lesions that are found in the upper esophagus or the postcricoid region. Generally pedunculated, they can grow to “giant” proportions. Laryngeal obstruction with subsequent asphyxiation by a regurgitated fibrovascular polyp is a well-described cause of death.45 Therefore, surgical excision by cervical esophagotomy is the typical treatment although some of these lesions may be removed successfully endoscopically. There is typically a large vessel in the stalk of the polyp that must be addressed during resection.

Inflammatory pseudotumors appear as polypoid masses. Although they may appear malignant, they are not comprised of neoplastic cells but contain fibrous and granulation tissue. Often located in the middle or distal parts of the esophagus, they are frequently associated with mucosal ulcers (Figure 5).

Single or multiple papillomas may be present in the esophagus. Both human papilloma virus and mucosal irritation have been implicated. Malignant change may occur in large papillomas. Snare cautery may be used for endoscopic excision.

**Malignant Esophageal Neoplasms**

The vast majority of esophageal neoplasms are malignant. While fluoroscopy may suggest the presence of malignant neoplasms, the most sensitive method of detecting esophageal cancer is esophoscopy with biopsy. Barium esophagram should not be used to “rule out” malignancy. Most symptoms of esophageal carcinoma are nonspecific and include weight loss, vomiting, and mild hematemesis. With rare exception, all patients with solid food dysphagia should be evaluated for esophageal carcinoma by esophagoscopy. Unfortunately, dysphagia does not usually occur until the esophageal lumen is narrowed to 13 mm, so patients with esophageal carcinoma often present at a late stage. More than half of patients with esophageal malignancies have distant metastases at the time of diagnosis.

Squamous cell carcinoma of the esophagus has been traditionally considered the most common malignancy of the esophagus, but this is changing. Among cancers, the incidence of adenocarcinoma of the esophagus is the fastest growing in America and is now greater than its squamous cell counterpart.46 Squamous cell carcinomas appear most commonly in the middle
third of the esophagus, with the lesion often friable and notable for an area of central ulceration with raised edges. A denocarcinoma is almost always found in the distal third of the esophagus, and an area of BE is commonly seen adjacent to the neoplasm. On esophagoscopy, adenocarcinoma may appear as a mucosa-covered nodule or as an ulcerative mass with esophageal obstruction in more advanced cases (Figure 6).

As mentioned earlier, esophageal malignancies may spread throughout the length of the esophagus from any primary site because of the lymphatic network. Therefore, the entire esophagus is usually treated regardless of the primary location in the esophagus. Primary surgical therapy, usually with total esophagectomy and gastric pull-up or colonic interposition, is the traditional mainstay of esophageal carcinoma treatment, with chemotherapy and radiotherapy used for lesions that invade the muscularis or deeper.

Sleep Medicine and Surgery

B. Tucker Woodson, MD

Pharyngeal resistance is normally a minor component of upper-airway resistance during wakefulness. During sleep, however, pharyngeal resistance increases. The sequence of increasing resistance, persistent respiratory effort, hyperventilation, and obstruction ultimately lead to snoring and sleep apnea. The starting point of sleep disordered breathing is a structurally small or vulnerable upper airway. At its center is inspiratory flow limitation which is a biologic marker of airway obstruction. This disorder’s intricate pathology remains inadequately understood and is a complex interaction of structural and physiologic factors. Understanding this complexity is critical to successful treatment and advanced care of the patient with a medical and surgical sleep disorders.

PREVALENCE

Snoring and sleep apnea are common disorders. Accurate determinations of the prevalence of sleep apnea and snoring are confounded by varied definitions of disease and by age, ethnicity, and gender effects. Occasional snoring is common. A community-based study demonstrated 80% of subjects snored at least 10% of the night and 20% snored for greater than 50% of the night. Habitual frequent or “always” snoring affects more than 21% of men and 8% of women. Sleep apnea is estimated to affect 34 to 60% of habitual snorers when defined by having symptoms of fatigue and observed apneas. Estimates of snoring in children range from 3 to 12%.

Sleep apnea, defined using polysomnography plus symptoms of sleepiness, has a prevalence in a United States population of middle-aged employed adults of 4% in men and 2% in women. Based on polysomnography only (apnea-hypopnea index [AHI] greater than 15 events/h), the prevalence of was 9% in men and 4% of women. The risk of developing sleep-disordered breathing is affected by obesity but does not require it. Obesity, aging, smoking, and postmenopausal status alter the incidence of snoring and presumably sleep apnea. Few data exist about prevalence of other less common forms of sleep-disordered breathing including central sleep apnea syndromes and obesity hypoventilation, that is, Pickwickian syndrome. Data suggest that milder forms of sleep apnea may progress to more severe sleep apnea.

Obstructive sleep apnea (OSA) is common in children, and the polysomnographically documented incidence of the disorder is often stated to be 1 to 2% of the US general population. The range varies from 1 to 10%; however, in some populations, such as obese Asian children, 33% have OSA. Habitual snoring occurs in 3 to 12% of Asian children. Relative risk is increased with obesity, lymphoid hyperplasia, cough, inflammatory airway disease, and abnormal patterns of craniofacial development. Sleep apnea in children is discussed further in Chapter 66, “Sleep Apnea in Children.”

SYMPTOMS

The two primary symptoms of sleep-disordered breathing are snoring and manifestations of sleepiness. Other major symptoms of sleep apnea are listed in Table 1. Since the primary symptoms are common in the population, symptoms poorly predict disease. Clinical impression has only 60% sensitivity and specificity in identifying patients with sleep apnea in a sleep clinic population. Incorrectly considered by some as the primary motivating complaint of sleep apnea, sleepiness is a common complaint in the population and has many differing descriptions. These include fatigue, daytime impairment, depression, change in mood, poor long- or short-term memory, decreased executive function, and increased risk of accidents. Unfortunately, none of these symptoms alone predict apnea, although all may have major impact on the patient and disease severity. Snoring is also common and is a frequent complaint. As with sleepiness, alone it is poorly predictive of disease. A more significant marker of disease is observed apneas by others. Since apnea has significant health concerns, patients with higher risk such as serious cardiovascular disease, atrial fibrillation, poorly controlled hypertension, and others warrant further evaluation. In lower-risk populations, screening has a less certain role. Currently, symptom-based algorithms with high sensitivity have unacceptably low specificity, and algorithms with high specificity, that is, few false-negatives, have low sensitivity. Women may present with different symptoms than men for the same level of disease with fatigue being more common and snoring, snorting, and gasping being less common. Premenopausal women with OSA are, as a group, more obese than control males with similar levels of disease.

Children present symptomatically distinct from adults. Snoring and restless sleep are

common. Sleepiness is infrequently presented as hypersonmolence and usually with symptoms of inattention, behavior disorders, impulsivity, and poor school performance. Ancillary symptoms and signs such as growth retardation and enuresis are not specific. Although snoring, mouth breathing, and tonsil hypertrophy have high sensitivity, specificity may be low. Hypersonmolence and witnessed apneas are highly specific in the snoring child in predicting an abnormal sleep study but have low sensitivity. Diagnosis is further confounded by uncertainty about the accuracy of routine polysomnography in identifying sleep apnea.

**MORBIDITY AND MORTALITY**

OSA is associated with hypertension and increased risks of cardiovascular disease including cardiac dysrhythmias, recurrence of atrial fibrillation, stroke, and myocardial infarction. M mortality is increased in OSA, likely from increased vascular disease. The absolute risk of cardiovascular disease in OSA populations is still significantly influenced by obesity, smoking, alcohol use, and genetic factors. The thresholds of clinically significant risks are unclear and likely differ among disorders. Mortality has been associated with an apnea index (AI) of greater than 20 apneas/h and is reduced in patients treated successfully with nasal continuous positive airway pressure (CPAP), uvulopalatopharyngoplasty (UPPP) or tracheostomy. It is estimated that an AI of 15 events/h is associated with sleep impairment and that an AI of 20 to 30 events/h may be associated with hypertension. Motor vehicle accident rates may increase seven times with sleep apnea. A baseline risk of impairment may be increased with OSA but is not independent of insufficient sleep, shift work, drug and alcohol use, exposure risk, and other medical disorders. Identifying and treating OSA in the sleepy individual may not eliminate risk. Care should be used with using any single measure as a disease threshold. Mean AHI of populations evaluated for disease risk are often two to three times the lower threshold. Thresholds also do not account for comorbidities, which combined with apnea may pose significant health risks. Although an AI of 15 events/h without symptoms of excessive sleepiness or significant oxygen desaturation is a common polysomnographic definition of sleep apnea in adults, it should be viewed as only a useful benchmark.

**PATHOPHYSIOLOGY**

Upper airway collapse results from abnormal structure, ventilatory control, and sleep physiology. A structurally small upper airway increases pharyngeal resistance. Loss of airway muscle tone is both due to changes in sleep and ventilatory control. Airway obstruction leads to progressive increases in ventilatory effort, causing arousal through stimulation of airway and chest wall mechanoreceptors. Arousals and sleep disruption produce neurocognitive disorders and create breathing instability but also augment cyclic (periodic) obstruction. As such, arousal is both an effect and cause of apnea.

The pharynx and supraglottis are the sites of obstruction. Obstruction may occasionally occur due to over pathologic but obstruction is most often due to structure that is normal but structurally disproportionate. Due to this structure, the pharynx is vulnerable to obstruction under certain conditions particularly during the sleep state. There are a multitude of causes of this instability. A fundamental cause relates to the unique property of the human airway having the larynx in the neck (Figure 1). This is in contrast to other mammals where the larynx is close to the skull base. Human cranial development results in skull-base angulation and associated changes in facial and airway form. These include a longer soft tissue supralaryngeal airway (pharynx), a shorter and more vertically oriented maxilla, posterior maxillary constriction, and a vulnerable soft tissue upper airway with the loss of muscle tone. In humans, the combination of a soft tissue supralaryngeal airway, decreased airway size, and changes in physiology associated with sleep ultimately cause sleep apnea events. The “syndrome” of OSA is the pathophysiologic cascade resulting from these events.

Many variables affect the sleep-apnea airway. Anatomy, tissue mass, body position, negative inspiratory pressure, airflow velocity, muscle tone, ventilatory drive, tissue adhesive forces, and sleep physiology may contribute. Integrating such a complex process can be difficult. One method to understand and quantify the process is to use a balance of forces model (Figure 2). This model first defines the upper-airway transmural pressure (Ptm = Ptissue – Pluminal) and then divides the forces that act on the airway as those promoting stability or collapse. A decreased transmural pressure (Ptm) enlarges the airway, and decreased Ptm collapses the airway. Anatomy, muscle tone, tissue elastic forces, surface adhesive forces, and vascular volume are tissue forces (Ptissue). Intra-luminal airway pressure and flow are luminal forces (Pluminal). The balance between the two determines airway patency. No single factor determines obstruction.

Initial theories describing sleep apnea conceived that the upper airway at rest was patent. Collapse occurred from negative airway pressure during inspiration. Later it was realized that subatmospheric intraluminal pressures was not needed to obstruct the airway during sleep and that just a decrease or loss of muscle tone could lead to obstruction. Muscle tone does not differ significantly in individuals with sleep apnea compared to normal individuals. The larger magnitude loss of muscle tone in sleep-disordered breathing is a consequence of a loss of augmented waking muscle tone needed to compensate for a structurally small airway. Physiologic changes are critical in causing sleep apnea but are secondary for most, not primary.

**Obesity**

Obesity increases the risk and severity of OSA and the severity of hypoxemia during sleep. Obesity effects metabolism, ventilation, and lung volume to worsen apnea. Leptin and various inflammatory obesity-related cytokines may increase CO2 response, and central ventilatory sensitivity augment the tendency toward periodic breathing and increases airway instability. Fat distribution around the neck has long been postulated without evidence to compromise the airway.

The relationship of obesity and sleep apnea is bidirectional. A shared etiology is also supported. The metabolic syndrome of obesity, hyperinsulinemia, and hypertension is often associated with sleep apnea. Treatment reduces this association. Population data demonstrate both shared and unshared genetic linkage of obesity and apnea each to one another and support an

---

**Figure 1** Human nasomaxillary development effects on upper airway risk factors for sleep apnea are shown. (A) Skull-base angulation is associated with a decreased maxillary and mandibular projection and laryngeal descent. (B) Posterior maxillary constriction. (C) Increased vertical height of the tongue with the tongue compressing the anterior pharyngeal wall. (D) A vulnerable soft tissue pharyngeal airway requiring muscular compensation for stability.

**Figure 2** A method to model multiple forces acting on the airway is shown. The resultant force, that is, transmural pressure (Ptm), on the upper airway is the difference between collapsing and dilating pressures (Ptm = Pout – Pin). As Ptm increases, the airway enlarges, and as Ptm decreases, the airway collapses. Ptm may also be described as the difference in tissue forces (Ptissue) and luminal forces (Pluminal) (Ptm = Pmtissue – Pluminal).
interrelated origin. Sleep apnea may also contribute to obesity due to behavior factors related to sleepiness.

**Craniofacial Characteristics**

The upper airway’s bony and cartilaginous framework ultimately determine its size, shape, and compliance. The framework of the airway is highly variable. Differences exist between individuals, ethnic groups, and gender. Nonetheless, a generalized constellation of abnormalities are observed in sleep apnea. Craniofacial variables associated with OSA include: increased distance of the hyoid bone from the mandibular plane, decreased mandibular and maxillary projection, increased vertical length of the lower anterior part of the face, increased vertical length of the posterior airway, and increased cervical angulation. A fundamental abnormality in OSA is related to posterior maxillary positioning and relates to patterns of maxillary growth and development.

Facial structure interacts with obesity to create apnea risk. In the Wisconsin Cohort, a population-based study, two-thirds of the AHI was explained by a combination of facial structure and obesity. In nonobese subjects, facial structure explains AHI alone. Individuals with normal craniofacial structures generally require morbid obesity to display OSA. Those with severe facial structural abnormalities may demonstrate severe OSA without any obesity. Increased tongue size has been associated with both OSA and obesity.

**Nose**

Nasal obstruction contributes to the presence and severity of OSA. Population and experimental studies associate nasal obstruction and nasal allergies with both sleep apnea and snoring. Obstructive nasal abnormalities demonstrate greater positional dependence and increased obstruction in OSA patients compared to normals. The cause of this is unresolved but may result from both structural and physiologic medical disorders including vasomotor instability and increased inflammation. Nasal blockage may (1) reduce nasal afferent reflexes which help to maintain muscular tone of the upper airway, (2) augment the tendency for mouth opening which destabilizes the lower pharyngeal airway (by posterior rotation, vertical opening, and inferior displacement of the hyoid), (3) reduce humidification, increase mucus viscosity, and increase surface tension forces, and (4) increase upstream airway resistance predisposing to downstream airway collapse. Improving nasal airflow is critical in treating snoring and sleep apnea. Treating nasal obstruction may have significant impact on other sleep disorders including central sleep apnea and insomnia.

**Pharyngeal Soft Tissues**

The soft tissue conduit is not only the site of collapse and obstruction but in many is also a site of pathology. Contributions to apnea differ among individuals and ethnic groups. Nonetheless, there is strong familial aggregation of apnea, and, in some populations, this has been linked to soft-tissue abnormalities. Genetic studies have demonstrated inheritability of abnormal lateral wall shape and size, and tongue size in apnea populations. Such abnormalities are more common in African Americans versus Caucasians and Asian populations in whom skeletal abnormalities are more common. Soft tissue abnormalities include a longer and wider soft palate, larger tongue, smaller oropharyngeal airspace, a posteriorly placed epiglottis, and smaller posterior airspace. Abnormalities may not only relate to tissue volume but cross-sectional shape as well. The airway in apneics may be more elliptical than circular, a property which increases airway surface area and frictional resistance.

**Physiology**

Lung volume affects pharyngeal upper airway size during both wake and sleep. Increased lung volume increases pharyngeal size. Decreased lung volume reduces airway size and increases pharyngeal collapse. Effects are asymmetric with decreases in normal functional residual capacity (FRC) having larger effects on airway size than increases in FRC. Effect of lung volume on the pharynx is likely thoracic traction, commonly referred to as “tracheal tug.” Lung volume interacts with the mediastinum, intrathoracic pressures, and the trachea to change pharyngeal size and stiffness independent of neuromuscular activity. Passive tracheal traction increases longitudinal tension on the pharyngeal wall which stabilizes the pharyngeal airway. Starting at a normal resting lung volume, increases have small changes on pharyngeal volume; however, decreases in lung volume (such as during sleep) have much greater effects on the pharynx. Factors, such as obesity, which reduce lung volume below a normal FRC may have significant effects on airway collapse, and conversely, interventions which prevent this (such as positional therapy) may significantly improve airway function.

**Vascular Volume**

Soft tissues surrounding the airway and neck are composed of muscle, connective tissue, fat, lymphoid tissue, salivary and thyroid tissue, extracellular space, and arterial and venous blood volume. Of all these, only the venous blood volume is compressible under pressures of effective nasal CPAP. The vascular lateral pharyngeal walls are the structures mostly affected by nasal CPAP. Vascular blood volume causes a decrease in pharyngeal airway size of the patient with OSA by elevating the legs and by venous compression stockings. Effects are mediated through changes in central venous blood volume. Blood volume is altered in hypertension and other disorders, but its link to OSA is unknown.

**Airway Resistance**

Changes in inspiratory and expiratory resistance increase during sleep and are hallmarks defining patients who are normal, nonsnorers and nonsnoring, and have OSA. Whereas, flow limitation is not observed in normal nonsnorers, snorers demonstrate inspiratory flow limitation, and sleep apneics demonstrate both inspiratory and expiratory flow limitation. The end result is either normal ventilation (normals), airway flutter (snorers), and airway obstruction (apneics).

In normal ventilation, inspiration is associated with activation of airway dilator muscles. Normal levels of negative intrathoracic pressures will not affect airway stability. With increased airway resistance, decreased muscle tone, or increased airway compliance, negative inspiratory pressure collapses the airway. When collapse leads to the situation where increasing negative pressure does not increase airflow, the state of airflow limitation is defined. Principles of a Starling resistor (if negative inspiratory pressure exceeds the closing pressure of the airway wall, the airway collapses) apply, and snoring and airway flutter may occur. When flow limitation progresses to occur in both inspiration and expiration, collapse likely leads to obstructive apnea. At end expiration, the airway is at its smallest and most vulnerable to collapse due to loss of both muscle tone and airway positive pressure and when the upper airway is at its most risk of abnormal resistance effects.

Normally in wake, phasic augmentation of airway muscles occurs and is dependent on negative pressure sensitive mechanoreceptors located in the nasal, pharyngeal, and laryngeal airway. The reflex controlling this activation may have increased latency in patients who snore or have sleep apnea which makes their airway at risk of collapse with application of negative pressure. This reflex is also decreased with the acute onset of sleep (at the alpha theta transition) during stage I and stage II nonrapid eye movement (non-REM) sleep (but not stage 3 or stage 4 non-REM sleep). This critically important event destabilizes the airway in patients with snoring or sleep apnea. It also explains relative airway stability despite high negative airway pressure in non-REM stage III or stage IV sleep.

The “apneic” event is a process that begins several breaths prior to the scored event during sleep. In OSA, a phasic pattern of airway collapse is observed with each ventilatory cycle (Figure 3). Preceding an apneic event, progressive collapse occurs. This collapse is during expiration, presumably due to loss of muscle tone. When critical size and airway pressure are reached, increased resistance, flow limitation, and inspiratory collapse are observed. This results in increasingly negative airway pressures and arousal. The process then repeats.

**Sites of Obstruction**

No single site of obstruction exists in sleep apnea. Hypotonic and manometric methods demonstrate the most frequent site of primary obstructions in the retropalatal segment. Sites and areas of obstruction both differ among individuals and in the same individual during sleep and varying
Significant economic costs. Sleep is composed to be maintained. Disorders of sleep are related to efficient quantity and quality, life and health cannot experiences, and sleep, food, and drink are unified.

Sleep

70% or more. 10%. Combined levels of obstruction occur in ryngeal obstruction occurring alone in another vulnerability to obstruction.

Effects of the ventilatory cycle on cross-sectional area is shown. During inspiration, activation of phasic airway dilator muscles increases airway size but is countered by increasing negative pressure. Early expiration is associated with loss of negative luminal pressure, addition of positive pressure, and loss of phasic muscle dilation resulting in additional increases in airway size. In later expiration, the airway collapses and is associated with loss of muscle tone, decreased “tracheal tug” and lung volume, and decreased positive pressure. At end expiration (EE), the airway is at its smallest and most vulnerable to obstruction.

body position and sleep state. Studies suggest that an isolated palatal level of obstruction occurs in approximately 20% of adults with hypopharyngeal obstruction occurring alone in another 10%. Combined levels of obstruction occur in 70% or more.

Sleep

Fatigue, hunger, and thirst are universal human experiences, and sleep, food, and drink are universal human requirements. Without them in sufficient quantity and quality, life and health cannot be maintained. Disorders of sleep are related to significant economic costs. Sleep is composed of two distinct states: rapid eye movement (REM) and non-REM sleep. Sleep is actively generated within the brain and is regulated by both homeostatic and circadian processes. Inadequate sleep results in the primary symptom of hypersomnolence, excessive daytime sleepiness (EDS).

Sleep Stages. In clinical practice, these states are arbitrarily defined using electroencephalography (EEG), electrooculography, and electromyography. REM and non-REM sleep have multiple physiological differences and differ from each other as much as from wakefulness. The restorative nature of sleep is determined by the duration of sleep, the pattern of the sleep cycle, and sleep continuity. Abnormalities in these, by intrinsic or extrinsic factors, disrupt homeostatic sleep and lead to EDS.

Sleepiness is the result of the homeostatic sleep drive (process S) and the “biological clock” (process C) interacting with extrinsic and intrinsic sleep factors to create a level of wake and sleepiness. Intrinsic medical disorders include sleep apnea, limb movement disorders, narcolepsy, and other sleep-related disease. The homeostatic sleep drive is the biologic drive to sleep resulting from prolonged wakefulness. In the late afternoon, the homeostatic drive to sleep is countered by the circadian drive that increases and promotes wakefulness. Disorders such as jet lag, sleep phase advancement, and sleep phase delay result from mismatch of circadian rhythm and sleep homeostasis. Lack of adequate sleep increases “sleep debt.” Sleep decreases homeostatic sleep drive. If sleep is adequate in duration (approximately 8 hours in adults) and quality, process S sleepiness is normalized. Following normal sleep, upon awakening, an individual should feel refreshed and sleepiness should be absent. During periods of wakefulness, sleepiness indicates that sleep drive is increased.

Unless countered, this sleep drive (process S) would rapidly result in an overwhelming drive to sleep. Activation of the circadian rhythm counters the sleep drive. The circadian rhythm is an oscillating biologic rhythm of approximately one day’s length. The circadian drive is a wakefulness promoter and counters sleepiness. The circadian rhythm originates from a small group of neurons in the suprachiasmatic nucleus and is reprogrammed (entrained) every day by external time stimuli (zeitbigers). The most important of these is exposure to bright light.

Sleep Stages: Rapid Eye Movement and Non-rapid Eye Movement. Sleep is divided into REM and non-REM sleep states. Non-REM is further divided into multiple sleep stages. The progression of non-REM through REM sleep is referred to as the sleep cycle, and progression through different sleep stages repeats several times during a sleep period. REM periods cycle approximately every 90 minutes after sleep onset. Each REM period usually becomes longer during sleep resulting in greater amounts of REM in the second half of the night. Often sleep is terminated following the last REM of the sleep cycle. Electroencephalographically, the brain is active during REM sleep. It is more similar to wake than non-REM sleep. Eye movements have a characteristic rapid oscillating pattern (REM). There is virtual paralysis of skeletal (but not diaphragm or eye) muscles, decreased arousal threshold, loss of temperature regulation, more vivid dreaming, nocturnal penile tumescence, and autonomic instability with both hyperventilation and hyperventilation, and fluctuating heart rate and blood pressure. Loss of skeletal muscle tone contributes to increased airway collapse in REM compared to non-REM sleep. The combination of decreased muscle tone which also reduces the lungs FRC, and longer apneas from a change in arousal may result in markedly worse oxygen desaturations during REM sleep. For this reason, it is important to assess sleep apnea severity and treatment success accurately and to observe REM sleep during sleep diagnostic testing.

REM latency is the time to the onset of the first REM and is usually 90 minutes in middle-aged adults. REM latency is shortened following withdrawal of REM suppressant drugs (such as alcohol). In depression and intrinsic sleep disorders, in certain cases of circadian sleep disorders (jet lag, shift work), and following acute resolution of severe sleep fragmentation (such as occurs with severe sleep apnea). Sudden and transient increase in REM sleep duration may occur (REM rebound). If significant underlying lung or cardiac disease is present, REM mediated hyperventilation may occur. REM-related sleep apnea is worse in the second half of sleep.

Non-REM sleep predominates adult sleep (75 to 80%) and is divided into four stages (I, II, III, and IV). Brain activity, respiratory rate, heart rate, and arousal thresholds are decreased in non-REM sleep. Muscle tone to the upper-airway muscles is present but is decreased. Sensitivity to CO₂ is decreased, resulting in decreased ventilation and slight hypercarbia during non-REM sleep.

Stage I sleep (5 to 10% normal sleep) is a transitional sleep. Patients awaken in stage I may actually describe a drowsy wakefulness and deny sleep. Stage I is increased by disorders that fragment sleep or when sleeping in an unfamiliar environment (first night effect in the sleep laboratory). Stage II, is a consolidated sleep and comprises 40 to 50% of total sleep time. Spontaneous arousals are less frequent than in stage I. The EEG is a synchronized low frequency low voltage signal marked by sleep spindles and K complexes. Stage III and IV sleep, referred to as slow-wave sleep due to the presence of low frequency high voltage waves on the EEG, contributes less than 10% of adult sleep time. Slow-wave sleep represents the most consolidated non-REM sleep. It may be this association rather than the absolute level of slow-wave sleep that links it to the refreshing quality of sleep. Stage III and IV sleep is necessary for the secretion of growth hormones during sleep and decreases with aging. In addition, stage III and IV sleep is reduced with sleep apnea and most disorders that disrupt sleep.

Sleep efficiency (total sleep/total time in bed ×100, expressed as a percent) decreases with age, insomnia, or any condition that impairs initiating or maintaining sleep. Sleep latency is shortened in sleepy individuals. Arousal is transient awakening (3 to 15 seconds) during sleep. Arousals may be spontaneous but are often the result of an external environmental stimulus such as noise, apneic event, periodic leg movement, or stimulus to swallow. Arousals fragment normal sleep and increase the amount of lighter stages of sleep. Sleep fragmentation may also occur with aging, alcohol, and drugs.

POLYSOMNOGRAPHY

The goals of sleep testing are to (1) establish the correct diagnosis, (2) establish disease severity, and (3) initiate or direct appropriate treatment. Evaluation of sleep with overnight polysomnography is the consensus standard of comparison. It may measure sleep, respiration, leg movements, esophageal pH, video, and other physiologic parameters in a technician attended environment. The complexity of testing varies with some studies done nonattended, and others only measuring limited cardiorespiratory signals. Polysomnography is primarily indicated for the diagnosis of sleep-disordered breathing. Many
sleep disorders are diagnosed by careful history and physical examination.

Respiratory Events

Ventilatory events are classified into three basic physiologic types: obstructive, central, or mixed apneas based on respiratory effort and airflow (Figure 4). Apneas (complete loss of airflow) and hypopneas (partial decrease in airflow) must last at least 10 seconds in adults. Events in which airflow is reduced and effort continues imply upper-airway obstruction. Central events are characterized by no measured respiratory effort. Mixed events demonstrate an initial central component followed by an obstructive component. These are a variant of obstructive apnea. Although the definition of physiologic apnea is conceptually straightforward, the pathologic process is more complex.

The initial manifestations of obstructive apnea include snoring, hypoxemia, asphyxia, and arousal. Increasing ventilatory effort triggers arousals and not the associated hypoxemia. Since central apneas have no ventilatory effort, arousals do not occur unless asphyxia is extreme. Hypopneas may be central or obstructive and are variably defined. Common criteria include a 30% decrease in airflow and a 4% oxygen desaturation. Definitions incorporating 3%, 2%, 1%, or no desaturation with or without an associated EEG arousal are also used. Multiple methods of measuring effort are used including strain gauges, electrical impedance, or even esophageal pressures which measure intrathoracic pleural pressures. Some hypopneas have been classified into a separate category. Respiratory-related arousals demonstrate some indication of obstructed breathing but are not apneas, hypopneas, and may not demonstrate oxygen desaturations.

The AHI is the number of apnea events/h of sleep and when combined with the hypopnea index results in the AHI which is the most common metric used to describe disease severity. The respiratory disturbance index includes the AHI and respiratory-related arousals.

The prevalence of sleep-disordered breathing varies age, gender, and population studied. Consensus has defined a normal AHI for the adult population as less than five events/h and in children as an index of less than one event/h. Although widely applied, these thresholds are arbitrary; and, given the changing methods and definitions of polysomnography and improving understanding of sleep apnea, may not accurately define abnormality. An AHI of less than 15 events/h is likely mild apnea. 15 to 30 events/h defines moderate apnea, and greater than 30 events/h currently defines severe OSA. However, the AHI is an imprecise metric of severity. These thresholds are likely better descriptors of epidemiologic prevalence and may not describe actual sleep apnea morbidity. In children, an AHI of one is considered abnormal. Defined events are only a marker of blockage to breathing in this population, and various more sensitive techniques may identify aberrations including abnormal capnography, flow limitation with arousals, and abnormal esophageal pressure measurements.

Oxygen desaturation with events is primarily affected by obesity (altering FRC and total body oxygen stores) and the duration of events. Desaturation is independent of AHI. Other contributing factors to desaturation include underlying pulmonary disease, pulmonary hypertension, pulmonary or arterial venous vascular shunts, patent foramen ovale, or ductus arteriosus. Desaturation unexplained by length of events or obesity may warrant further evaluation for these diseases. Desaturations below 60% have been associated with severe cardiac dysrhythmias.

A accurate interpretation of sleep study results requires knowledge of: (1) the methods of measurement and the parameters monitored, (2) the duration and time of day of the study, (3) sleep quality including presence or absence of sleep, sleep stages, REM latency, and sleep efficiency, (4) baseline and minimal oxygen saturation levels, (5) apneic events, and relationship of ventilatory events to REM/non-REM sleep and body position, (6) cardiac rate and rhythm, (7) limb and motor movements, and (8) patients clinical presentation. No single number such as the AHI is adequate. Sleep-disordered breathing and apnea are widespread in the population, and they often coexist with other disease.

The diagnosis of OSA does not require traditional measures of sleep. Testing of sleep for breathing disorders may be done by measuring different physiologic metrics without sleep. The use of polysomnography should be to obtain the best available information to care for patients. Limited sleep testing is not a standardized method and may measure different physiologic variables and measure them with different tools. Comparison of devices is often biased and is influenced by multiple factors including risk of disease in the population studied, arbitrary AHI thresholds, and the testing environment. How well these exclude apnea in lower-risk patient groups or determine accurate disease severity is uncertain. For example, pulse oximetry may demonstrate a high false-negative rate of up to 30%. Many devices may function to identify a threshold of five or 15 events/h in normal or severe apnea populations but may be an inaccurate guide to severity (a measure that may be more critical to surgically treated patients than to medically treated patients). Using these tools to make clinical decisions requires an understanding of the device in use.

Split-Night Polysomnography

Some diagnostic sleep studies are performed and followed by a therapeutic study for nasal CPAP titration. A split-night diagnostic and therapeutic sleep study permits the diagnosis of OSA and a trial of nasal CPAP in a single night of testing. This approach is successful in titrating nasal CPAP in up to 78% of patients. Split-night studies save resources, expense, and patient time but may underestimate necessary CPAP pressures in mild sleep apnea without observed REM sleep (when apnea may be more severe and require higher pressures). Split-night studies have become a standard of care but may be inadequate for some patients.

Hypersomnolence/Sleepiness

Sleepiness is a cardinal symptom of many sleep disorders. It is variably defined with subjective sleepiness described as a state of fatigue, tiredness, personality changes, increased automatic behavior, impairment in executive functioning, decreased motor skills, and lack of alertness. A cute and chronic sleepiness may present differently due to chronic adaptation. Impaired perception, environment, age, gender, and behavioral modification all affect symptoms, and directed questioning about symptoms in passive activities requiring sustained attention may be needed.

Sleepiness may also be described by the propensity to fall asleep, propensity to stay awake, or vigilance. Sleepiness may be subjectively or objectively measured. The Epworth sleepiness scale was developed as a population measure (Table 2). The propensity or tendency to fall asleep is objectively measured by the multiple sleep latency test (MSLT). This test is a series of five scheduled daytime naps with latency to
Insomnia is the complaint of inadequate or poor-quality sleep and has variable presentation including EDS, difficulty falling asleep or poor-quality sleep and has variable presentation similar to multiple sclerosis) presenting with symptoms of extreme daytime somnolence and with a possible quadruplet of classic symptoms. These include sleep attacks, cataplexy (a sudden, brief loss of muscle tone with extreme emotion or laughter that is virtually pathognomonic for narcolepsy), sleep paralysis, and hypnagogic/hypnopompic hallucinations (vivid dreams intruding into wakefulness). These symptoms conceptually represent intrusion of REM-related phenomena into wakefulness. Sleep paralysis and hypnagogic hallucinations may occur independently or with other disorders with severe sleepiness, namely obstructive sleep apnea syndrome (OSAS) or sleep deprivation. Narcolepsy, a short nap often refreshes in contrast to severe OSAS in which a nap is minimally refreshing. Symptoms onset for narcolepsy is common in late adolescence or early adulthood. Narcolepsy may be familial. The HLA-DQB12 antigen is more common in some but not all populations of narcoleptics. Decreased cerebrospinal fluid levels of the neuropeptide hypocretin has been observed. Classic symptoms including cataplexy are diagnostic for narcolepsy.

In cataplexy-negative cases, MSLT may be used. Treatment includes stimulant medications, behavioral modification, prophylactic naps (for EDS), and tricyclic antidepressants, serotonin reuptake inhibitors, or gabapenthenurbutate for cataplexy. Narcoleptics commonly also manifest other disorders including sleep apnea, limb movements, insomnia, and depression.

Restless leg syndrome (RLS) is a common disorder that may affect 10 to 20% of the population. It is associated with: (1) extremity paresthesias, (2) an "uncontrollable" urge to move the extremities (usually lower legs), (3) relief with movement, (4) worsened symptoms at nighttime (circadian linked). RLS may often be associated with period leg movements measured on a sleep study. RLS may be associated with insomnia or hypersomnia. The cause of the disorder is a central nervous system loss of descending inhibition of a spinal motor neuron activity; the inhibition is mediated through dopaminergic neurons. It has been associated with decreased transport of iron across the blood-brain barrier. Iron is a necessary cofactor in dopamine metabolism (dopamine decarboxylase). RLS is more common in the elderly as it is associated with symptoms of insomnia. A familial form also occurs often in younger individuals and is more often associated with hyperinsomnia. Periodic limb movement disorder (PLMD) presents with repetitive stereotypical flexion extension movements during sleep that are 5 to 90 seconds apart with or without arousals and sleep fragmentation. PLMD often occurs independently of RLS and is often asymptomatic and does not require treatment. Due to the association with iron transport, RLS and PLMD warrant screening for anemia and iron replacement may be beneficial, especially if ferritin levels are low or low normal (45 μg/mL).

Drug therapy may include dopaminergic agonists, drugs, opioids, benzodiazepines, or gabapentin. These either act directly on dopamine centers or help consolidate sleep and reduce insomnia. Both disorders are worsened with caffeine and alcohol.

Multiple drugs (beta blockers), alcohol, and sedatives contribute to sleepiness. Some disrupt sleep architecture and decrease respiratory muscle tone (worsening upper-airway patency and sleep apnea). Regular snorers may convert to apnea, and apnea may become more severe. Sedatives may dangerously decrease arousal thresholds and increase event duration, elevating CO² levels and worsening of oxygen desaturation during apneic events.

### Central Sleep Apnea

Central sleep apnea syndromes are uncommon. Central sleep apnea may be idiopathic or secondary to congestive heart failure, brainstem lesions, or high altitude. Central sleep apnea often has two presentations based on daytime blood gases. Patients who hypoventilate during wakefulness may present with symptoms of morning headaches and sleepiness. Respiratory failure and cor pulmonale occur. Obesity hypoventilation, neurogenic weakness, abnormal chest wall compliance, or primary alveolar hypoventilation may be present. Ondine curse is a severe central sleep apnea syndrome that features normal ventilation during wakefulness but apnea and hypoventilation with sleep onset. Central sleep apnea patients with normal waking blood gas findings have less severe disease and complications. Symptoms often include insomnia. Therapy for either group of central apnea patients may include bilevel ventilation, nasal CPAP, oxygen, ventilatory stimulants (theophylline, acetazolamide), treatment of underlying lung and cardiac disease, and assisted ventilation.

### Upper Airway Resistance Syndrome

Upper airway resistance syndrome (UARS) is associated with increased ventilatory effort, arousal, sleep fragmentation, and symptoms of EDS. A pneas and hypopneas are not present with increased upper-airway resistance during sleep causing the clinical symptoms. UARS is

*This evaluation has eight domains and are self-reported by the patient. An Epworth sleepiness score (ESS) score of greater than 10 is often considered abnormal; however, there is a wide range of variability and overlap among individuals. Scores of greater than 15 are definitely abnormal and scores of 5 or less are likely normal.

**DISORDERS OF SLEEP**

Snoring and sleep apnea are common reasons to seek medical care due to concerns about snoring, sleepiness, risks of hypertension, and cardiovascular disease, but patients presenting with these complaints are at risk of other sleep disorders as well. Thirty-one to fifty-five percent of individuals undergoing polysomnography are diagnosed with other sleep disorders. The actual prevalence is likely higher.

Hypersomnia is not unique to OSA. Sleep deprivation and insomnia are common. Insomnia is the complaint of inadequate or poor-quality sleep and has variable presentation including EDS, difficulty falling asleep or maintaining sleep. Insomnia may be classified as primary, acute situational, secondary to medical, chronic psychiatric, or other causes. Insomnia or anxiety complicates medical treatment of sleep-disordered breathing and may coexist with snoring and OSA.

Narcolepsy is uncommon but not rare (prevalence similar to multiple sclerosis) presenting with symptoms of excessive daytime somnolence and...
associated with smaller upper airways and elevated upper-airway resistance compared to normals. Resistance is equal to those who snore suggesting the primary pathology is closely linked with a lower arousal threshold which makes the individual more prone to sleep disruption.

Snoring

Snoring is a form of a Starling resistor. When negative inspiratory pressure exceeds the closing pressure of the airway wall, the airway collapses. The closed upper airway is then exposed to the pressure of the nasopharynx or oral cavity that is greater than the closing pressure, opening the airway. When the process oscillates, flutter results and creates snoring. Vibratory tissues may include the palate, uvula, and lateral pharyngeal walls or less commonly from the lower oropharynx or epiglottis. The noise is low frequency (50 to 1,000 Hz); and the acoustic characteristics are determined primarily by the stiffness of pharyngeal tissues. Snoring has been shown to be an independent contributor to sleepiness and in epidemiologic studies has been associated with increased risks of strokes and other morbidity.

When circadian drive begins to decrease in the evening, sleepiness increases, and the likelihood of falling asleep (propensity to sleep) increases. Sleep onset usually occurs while this drive decreases. The circadian drive is linked to core body temperature, and both are lowest in the early morning (acrophase is about 1 hour prior to awakening). It is at this time of day that the impact of a residual sleep debt (Process S) is greatest. The incidence of sleep-related motor vehicle accidents increases at this time.

UPPER AIRWAY EVALUATION

Upper airway evaluation identifies structural abnormalities contributing to snoring and sleep apnea. It identifies patients at risk and those who might benefit from surgery and provides information needed for selecting appropriate surgical procedures. Little data compares methods of evaluation. Fujita defined three types of upper-airway obstruction (Figure 5). These included: Type I, upper pharyngeal obstruction at the palate; Type II, combined upper pharyngeal and base of the tongue at the palate and the base of the tongue; and Type III, hypopharyngeal or base of the tongue. Moore developed a base of the tongue classification initially based on cephalometry but also useful with endoscopy that defines three general patterns of hypopharyngeal narrowing (Figure 6). Although conceptually useful, neither has been validated. Cephalometry has not been utilized clinically to screen for patients and has limited use in selecting individuals for palatopharyngoplasty. An inferiorly positioned hyoid bone (M-P-H [cephalometric measurement from the plane of the mandible to the most anterior and superior point on the body of the hyoid bone] greater than 21 mm) had been associated with poor palatopharyngoplasty results. The Mallampati classification is most widely used (Figure 7). As the patient opens the mouth as widely as possible without protruding the tongue, in Type I the palatine tonsils, uvula, and free margin of the palate can be seen; in Type II, the free margin of the soft palate and the base of the uvula are visible, in Type III, the soft palate but not its free margin is seen; and in Type IV, only the hard palate is in view.

Müller Maneuver

The Müller maneuver is used widely to predict UPPP success. It is a reverse Valsalva maneuver performed with a fiberoptic scope visualizing the pharynx. At end expiration, the patient inspires against a closed mouth and nares and airway collapse is subjectively or objectively assessed. Although retrospective studies suggested that collapse in the hypopharyngeal region of less than 25% was associated with improved UPPP outcomes, prospective studies have not confirmed this.26 The Müller maneuver has little positive predictive value. Collapse of the airway on the Müller maneuver of greater than 50% at the base of the tongue is a negative predictor for UPPP success (5 to 10%). Physiologically, the Müller maneuver fails to correlate with manometry or endoscopy during sleep. The Müller maneuver does not relate anatomy or structure, and no data suggest it is useful in predicting outcomes of any procedure except UPPP failure.

Friedman Staging

The Friedman staging system defines three stages based on: (1) tonsil size (1 to 4+), (2) a modification of the Mallampati classification (1 to 4+, see Figure 7), (3) presence or absence of severe obesity (> or < BMI [body mass index] of 40 kg/M²), and (4) major craniofacial abnormalities.27 The Friedman staging system identifies patients at risk for apnea who present with symptoms of snoring. It also demonstrates both positive and negative predictive value with UPPP outcomes. Friedman staging groups tonsil size as “favorable” (tonsil grades 3 and 4, large tonsils) or “unfavorable” (tonsil grades 1 and 2, small tonsils). The modified Mallampati classification is “favorable” (Types I and II, visualizing the free margin of the soft palate) and “unfavorable” (Types III and IV, free margin of palate not visible) on examination (Figure 7).

MEDICAL TREATMENT OF OBSTRUCTIVE SLEEP APNEA SYNDROME

Treatment objectives of OSAS include (1) elimination of obstruction and snoring, (2) decreasing morbidity (cardiovascular and sleep), and (3) decreasing mortality. Treatment is dependent on OSAS severity, the desired outcome, and confounding medical conditions. No single treatment is appropriate for all patients. Treatment interventions include: elimination or amelioration predisposing factors, attention to medical causes, and use of drugs, nasal CPAP, oral appliances, and reconstructive surgery.

Positional therapy, weight loss, sleep hygiene, nasal interventions, avoiding sedatives and alcohol, increasing exercise, and smoking cessation
Depressants may independently reduce daytime symptoms has no role. Treatment of them may not only become worse with OSA but may or improve OSA.

Medical Causes and Treatment

Hypothyroidism, Marfan syndrome, acromegaly, and congestive heart failure may contribute to OSA in a small subset of patients. Routine laboratory screening for these conditions without symptoms has no role. Treatment of them may reduce OSA, and these disorders should be considered in appropriate patients. Heart failure may not only become worse with OSA, but may also contribute to it by making periodic breathing worse. Treatment of heart failure may eliminate or improve OSA.

Drug Therapy

Protryptiline hydrochloride (nonsedating tricyclic antidepressant), mirtazapine, and fluoxetine may reduce the AHI. Alternatively, oxygen therapy may diminish severity of oxygen desaturation and reduce periodic breathing in some individuals but does not correct anatomical obstruction.

Nasal Continuous Positive Airway Pressure

Nasal CPAP applies positive pressure to open the upper airway acting like a pneumatic splint to maintain airway patency. CPAP also increases lung volume (potentially improving oxygen saturation) and reduces tone to upper-airway muscles at therapeutic pressures. Variants of nasal CPAP are available to address specific patient needs or preferences (Table 3). CPAP levels may vary depending on sleep state, body weight, head and body position, nasal patency, and sedative use. The effective pressure to prevent collapse is pressure applied during expiration when the airway is most vulnerable to collapse. CPAP pressure is most often individually titrated in the sleep laboratory by a technician with occasional empiric adjustments as symptoms and signs warrant (persistent snoring, sleepiness, movement, worsened central apnea, etc).

Nasal CPAP objectively reduces the respiratory disturbance, EDS, hypertension, and other morbidity associated with OSA. However, even a single night without the use of nasal CPAP may result in worsening of many of the symptoms and daytime sleepiness of OSA. Rarely is it associated with severe complications. CPAP use requires a correct pressure setting, a comfortable mask, tolerance, and patient compliance. It is common to refit masks; change heated and cool settings, claustrophobia, eustachian tube dysfunction, and noise.

Clinical effectiveness requires nightly use. Many factors influence patient tolerance and compliance. Verbal reports of compliance range from 50 to 70%. Objective studies demonstrate lower compliance rates. A trough 70% of patients utilize CPAP for 20 minutes on five of seven nights (70%), only 50% of patients use CPAP for 4 hours a night. Patient compliance may be higher in patients with more severe disability. Compliance patterns with CPAP are established early in the course of treatment and may be improved by regular encouragement from the physician. The pattern of use as early as 3 weeks has been correlated to subsequent compliance. Multiple evidence-based studies have demonstrated CPAP effectiveness. Effectiveness is not universal and has not been established in patients with milder disease and in those without abnormal daytime sleepiness. Despite these limitations, nasal CPAP is widely considered first line therapy for OSAS in many adult patients.

</tr>
</tbody>
</table>

CPAP = continuous positive airway pressure.
Oral Appliances

Oral appliances are classed as mandibular repositioning devices or tongue-retaining devices. They act effectively primarily by advancing the mandible forward and enlarging both the retropalatal and retroglossal airway. Clinical observations have revealed a significant reduction in respiratory disturbance, snoring, and morbidity of OSA have been observed. Sixty to eighty percent of patients will note a decrease in snoring. Patient compliance is required for successful therapy. Adequate dentition is required for use. Some patients may report discomfort or changes in teeth, gums, and temporomandibular joints with their use.

Surgery

Surgery to treat the patient with sleep apnea and snoring effectively reduces obstruction and collapse by (1) bypassing the upper airway, (2) reconstructing soft tissues, (3) reconstructing skeletal structure, or (4) augmenting the effects of other procedures. Multiple procedures have been described for sleep-disordered breathing (Table 4). Surgery indirectly treats sleep by improving ventilation via changing airway size, shape, or collapsibility. Successful responders are defined as having a 50% improvement in apnea or AHI. Unfortunately, scant data exist to define thresholds of OSA.33

Anesthetic Considerations

Sleep apnea patients may have unique preoperative, intraoperative, and postoperative care problems. Difficulty with intubation and extubation occurs related to facial structural or ventilatory control. High-risk patients include, but are not limited to, patients with severe obesity, poor pulmonary reserve, pharyngeal tissue redundancy, hypoxemia, excessive narcotic use, multiple airway surgical procedures, and excessive sleepiness. Controversy exists as to the appropriateness of outpatient surgery and the need for intensive postoperative monitoring. Postoperative management can be assisted in many cases with the use of nasal CPAP. Rarely, tracheostomy is required. Objective monitoring to include pulse oximetry has been advocated; however, it is critical to realize that oximetry does not measure hyperventilation especially when assessed on an intermittent basis or when low-flow oxygen is in use. Close nursing observation is necessary in the perioperative period. Symptoms of respiratory insufficiency and hypercarbia may include increased pulse and respiratory rate, elevated blood pressure, and agitation or restlessness. Studies suggest that stimulating environments of the hospital provide a degree of activity and that risk may increase in quiet and unobserved areas. Risk is elevated with sedation, dehydration (increasing tenacious secretions), and higher doses of narcotics. Postoperative interventions for apnea patients who have airway and nonairway surgery may include nasal airways, nasal CPAP, patient positioning (head of bed), adequate hydration, corticosteroids, and other nonnarcotic pain medication. Patients with sleep apnea are also at elevated risk due to significant comorbidities of hypertension, cardiac and pulmonary disease, and obesity.

Tonsillectomy and Adenoidectomy

A denonsillectomy is the treatment of choice for OSA in children. Traditionally, it has been considered highly effective but with actual efficacy uncertain. In uncomplicated pediatric patients, meta-analysis of level 4 evidence (case series) demonstrated that tonsillectomy and adenoidectomy reduced AHI by an average of 13.9 events/h and normalized AHI in 80% of patients. Outcomes vary by population and are affected by airway and facial structure, obesity, nasal abnormalities, allergies, and underlying medical conditions.30 Factors predictive of postoperative elevated AHI, in uncomplicated pediatric patients include enlarged inferior turbinates, deviated nasal septum, Mallampati Types of III and IV, and retropositioned mandibles. Persistent airway inflammatory disease has been identified in other groups and responds successfully to anti-inflammatory therapies including topical nasal corticosteroids and leukotriene inhibitors.31 A denonsillectomy has demonstrated significant improvements in behavior and school performance independent of final AHI levels.38

Pediatric patients with sleep apnea may represent an at risk population for sleep apnea independent of hypertrophic tonsils and adenoids. Associated anatomic problems include disproportionate facial growth and development. Identifying and correcting these abnormalities while facial growth and development are still malleable may be critical. A family history of sleep apnea...
associated with findings of a high-arched palate, long faces, or retrognathic mandible may warrant orthodontic assessment and treatment to correct the airway independent of any dental problems. A ciliary treatment of facial growth, nasal structure, and nasal inflammatory disease is commonly needed in addition to tonsillectomy and adenoidectomy. These problems are discussed in Chapter 66, “Sleep Apea in Children.”

Removal of nonhypertrophic tonsils is generally ineffective in adults. Removal of tonsils in adults is commonly a part of other pharyngoplasty procedures.

**Palatopharyngoplasty (Uvulopalatopharyngoplasty)**

UPPPP was first described by Fujita. The procedure removes distal soft palate, the faucial tonsils, uvula, and redundant mucosa from the anterior and posterior tonsillar pillars. The posterior pillar is then sutured anteriorly, and the mucosa is approximated. Multiple variations of the technique have been described. Effectiveness for sleep apnea is not related to symptomatic reduction in snoring, instead is associated with increases in pharyngeal airway size in the retropalatal airway segment. UPPP is generally combined with other surgical procedures to treat other airway sites. The procedure may be contraindicated in patients with velopharyngeal insufficiency (VPI), submucous cleft palate, or a nonpalatal level of obstruction and in patients whose speech or swallowing may be at special risk. A aggressive resection of the palate with UPPP techniques has demonstrated no improvement in success but does increase the risk of VPI. Side effects of UPPP include mucosal dryness, sensation of oropharyngeal tightness or phlegm, pharyngeal dysphagia, and severe postoperative pain. Velopharyngeal stenosis and insufficiency are rare but serious complications. Both controlled and randomized studies demonstrate UPPP is effective in treating physiologic measures of sleep and respiration, quality of life, risk of motor vehicle accidents, cardiovascular risks, and mortality.

Failure of UPPP includes persistent obstruction at the retropalatal airway segment or obstruction in other pharyngeal airway sites. More effective treatment of the palate with reconstructive procedures and with treatment of the hypopharynx improves outcomes. Historical success rates of UPPP have included reduction in snoring in 90%, sleepiness in 84%, and reduction in AHI to less than 20 events/h in 30 to 40%. Using the Friedman staging system outcomes can be better stratified. (Stage 1 = 70% success, stage 2 = 40% success, and stage 3 = 10% success). Traditional UPPP is most useful in individuals with massive tissue redundancy of the pharynx that requires excision and enlarged tonsils. A avoidance of excessive removal of distal soft palate is important to prevent incompetence between the soft palate and tongue, worsening possible nasal CPAP tolerance by increasing possible mouth leak.

Complications and side effects of palatopharyngoplasty are common. Major complications are rare and include acute respiratory distress, VPI, rhinolalia, nasopharyngeal stenosis, and hemorrhage. Respiratory distress and fatality with UPPP are rare. Minor degrees of transient nasopharyngeal reflux are common but usually self-limiting (less than 6 months). Nasopharyngeal stenosis may be minimized by mucosal sparing surgery, avoiding simultaneous adenoidectomy and meticulous wound and surgical technique. Other more minor complications are more common and include impaired mucus clearing, sneezing, and abnormal pharyngeal sensations.

**Reconstructive Palatopharyngoplasty**

Several methods of UPPP and palatopharyngoplasty (PPP) have now been described and compared to more traditional methods using evidence-based medicine. These surgical techniques differ from traditional UPPP in reconstructing the soft and hard tissue framework of the palate and not modifying mucosa and tonsils. Described techniques include lateral pharyngoplasty, expansion sphincteroplasty, and palatal advancement. Lateral pharyngoplasty exposes and plicates the lateral pharyngeal wall muscles and superior constrictor proximal to the free margin of the soft palate. The advancement is then covered with a laterally based palatal mucosal flap (Figure 8). Expansion sphincteroplasty exposes, isolates, and divides the palatopharyngeus muscle on the pharyngeal wall and uses this muscle as a sling to advance and open the soft palate and pharynx (Figure 9). Palatal advancement removes distal hard palate to advance the soft palate anteriorly and superiorly (Figure 10).

**Other Palatal Procedures**

Multiple palatal procedures have been advocated to treat primary snoring. Most have shown short-term effectiveness. Since primary snoring is not an isolated disorder and may represent a benign point in time of a progressive upper-airway disease, conservative treatments with the least side effects and complications should be considered first, if possible.

Laser assisted uvulopalatoplasty (LAUP) using the carbon dioxide laser is hemostatic surgery of the palate and can be performed under local anesthesia. The palate, velum, and uvula could be resected with healing by secondary intent. Two vertical trenches in the soft palate lateral to the uvula of variable width and length at free margin of the distal part of the soft palate are created and the uvula reduced. The operation may be single stage or “titrated” to improvement in snoring or appearance of velopharyngeal dysfunction. LAUP is associated with severe pain and common complaints of pharyngeal dryness. Serious complications are infrequent. Palatal scarring initially increases tension and reduces snoring but long-term data (5 years) suggest recurrence of snoring is common. Airway narrowing may occur and worsen sleep apnea. Effectiveness for sleep apnea has not been demonstrated in clinical trials. Alternatives to the use of lasers have also been described. Various

---

**Figure 8** A method of a lateral pharyngeal wall flap is shown. This flap allows closure of lateral wall defect after advancement using mucosa from the dorsal palate. (A) and (B) A ventral triangle of mucosa, submucosal, and periuvular fat is removed. (C) Dorsal palatal mucosa is left intact. (D) Dorsal mucosa is incised parallel to the uvula, that is, “uvula lengthening,” to create a laterally based flap. (E) Final closure is shown.
less expensive tools for cutting and ablation have been used to shorten the palate, remove mucosa, reduce the uvula and direct healing by secondary intention, and all likely create scar and reduce snoring with variable effectiveness. Failure may be from persistent flow limitation, softening of scar, or flutter at nonpalatal airway sites. All patients seeking snoring operations should be cautioned both about the risk of recurrence of snoring and the possible later development of overt sleep apnea.

To avoid the extensive thermal damage created by the laser to all three layers of the soft palate and chronic inflammation, ulceration, and loss of seromucinous glands, alternative approaches to create palatal stiffening have been developed. Techniques using ablational radiofrequency demonstrate less pain for treatment of snoring compared to the laser. Sclerotherapy agents create scar in the mucosa of the soft palate and have been used to treat patients with primary snoring. A gent is injected into the submucosa of the soft palate creating scar and tissue slough. The procedure has less pain than laser, and long-term results for snoring are better than 70% with few major complications. Alternatively, palatal implants have been developed and are effective for the treatment of primary snoring, in selected populations.

**Base of Tongue Soft Tissue Techniques**

Obstruction at the base of the tongue level is surgically challenging. Multiple techniques have been used. These include partial glossectomy, ablational glossectomy, mandibular advancement, maxillary advancement, limited mandibular osteotomies, tongue suspension, hyoid suspension, lingual tonsillectomy, and supraglottoplasty.

Radiofrequency ablation of the base of the tongue can be performed in the office-based setting. The procedure is performed under local or general anesthesia either alone or in combination with other pharyngeal procedures. Complications including tongue abscess, infection (cellulitis), tongue weakness, changes in speech and swallowing, and acute airway edema and obstruction are rare. Randomized, blinded, controlled, and uncontrolled studies of radiofrequency ablation have demonstrated effectiveness in reducing the severity and improving the disease specific quality of life. Effectiveness has also been demonstrated in longer-term studies. Alone these procedures rarely definitively relieve the patient of OSA and must be combined with other procedures that reconstruct other segments of the upper airway.
Closure is shown.

Midline Glossectomy/ Lingualplasty

Midline glossectomy and lingualplasty are partial glossectomies to enlarge the lower pharyngeal airway and treat OSA. In severe OSA, following UPPP failure, lingualplasty reduces AHI to less than 20 events/h in 70% of patients. Using laser, complication rates approaches 25% and included bleeding, severe odynophagia, tongue edema, and taste changes. For this reason, more aggressive glossectomy techniques have been uncommonly performed. Because these procedures directly involve the airway in patients with preexisting airway risk, care was considered high and a perioperative tracheostomy historically was often performed resulting in major morbidity for the procedure. Newer technologies allow aggressive glossectomy with traumatic excision or not requiring tracheostomy and even allowing outpatient surgery in selected patients (Figure 11).

Mandibular and Bimaxillary Advancement

Mandibular advancement techniques may markedly enlarge the lower pharyngeal airway. Procedures have been described as “telegnathic” in contrast to traditional orthognathic surgery. Agressive advancement is required in sleep apnea compared with orthodontic treatment. Dentition may limit advancement in traditional techniques, and orthodontic methods alone may be inadequate to maintain a normal bite. Mandibular advancement is then required. Cosmetic changes occur and may limit application.

Molecular Biology of Squamous Cell Carcinoma

Carter Van Waes, MD, PhD

Head and neck squamous cell carcinoma (HNSCC) is the most common cancer that affects both human communication and survival. It accounts for 90% of the cancers arising in the upper aerodigestive tract, making it the most common type of cancer and cause of cancer deaths among patients with head and neck cancer. It accounts for over 40,000 new cancer cases and 11,000 deaths annually in the United States.\(^1\) Despite progress in refinement of surgery, radiation, and chemotherapeutic approaches that have enhanced organ preservation, there has been little improvement in survival of patients with HNSCC over the past 25 years.\(^1\) Recent advances in determining the identity and function of molecular events involved in the pathogenesis of HNSCC have provided a foundation for development of new methods for screening, prevention, and therapy.

Progress in understanding the molecular biology of HNSCC has been made possible through advances in technology that have permitted detection and mapping of alterations in sequence of deoxyribonucleic acid (DNA) and expression of genes throughout the human genome.\(^2\) Initially, cytogenetic analysis using special stains and fluorescence in situ hybridization (FISH) with probes for specific genes enabled detection of gross chromosomal abnormalities and altered gene copy number. Comparative genomic hybridization (CGH) is a newer technique that allows genome-wide identification and quantification of genetic alterations. Using these methods, certain abnormalities such as deletions, amplifications, and translocations have been detected in certain chromosomal regions with increased frequency in HNSCC and other cancers. In some cases, these abnormalities have led to the identification of specific genes whose deletion, amplification, or truncation is involved in development of cancer. DNA polymorphism analysis is another important tool made possible by identification of differences in DNA sequence fragments between individuals at chromosomal locations throughout the genome. With this method, different-size DNA fragments cut by enzymes from the DNA contributed by each parent are identified with electrophoresis, allowing the detection of two copies (alleles) in normal cells from the patient. In cancer cells, loss of one marker, called a loss of heterozygosity (LOH), has been used to detect nearby alterations in DNA. DNA microsatellite and LOH analyses have permitted the detection and mapping of molecular alterations in DNA that were too small to be detected by cytogenetic analysis, thereby resulting in finer maps and detection of additional submicroscopic DNA abnormalities.\(^2\) Further mapping and sequencing of these regions have been made possible by development of methods for cloning large fragments of chromosomal DNA and methods for high throughput DNA sequencing, resulting in the positional cloning of many of the mapped genes. The complete determination of the sequence and location of genes in the human genome from high throughput DNA sequencing has rapidly resulted in the identification of genes associated with abnormalities detected by genomic methods.

The identification of the sequence and isolation of genes has enabled studies of global alterations in expression of messenger ribonucleic acid (mRNAs) using complementary DNA microarrays in tumor cell lines and tissue and verification by quantitative reverse transcription-polymerase chain reaction (RT-PCR) methods.\(^3\) Determination of the mRNA sequence for the transcriptome and predicted protein sequence of the proteome has facilitated the use of quantitative RT-PCR and mass spectroscopy to identify sequences of multiple mRNAs and proteins which are aberrantly expressed in tumor specimens, serum, and saliva. The development of antibodies to many of the proteins and phosphorylated activated proteins has enabled immunostaining in multiple specimens in tissue microarrays (TMAs) and semiquantitation of hundreds of proteins in tumor extracts or sera serially diluted and spotted on slides, called reverse phase microarrays. All of these different types of microarrays provide the capability to compare simultaneously and detect differences among hundreds or thousands of different mRNAs or proteins in samples from normal and malignant tissue and body fluids. Studies to determine the relative expression and function of genes in the cell are leading to a better understanding of the molecular pathways and programs involved in the pathogenesis of cancer and their potential usefulness for molecular diagnosis and therapy. As a result of these advances, prevention and treatment of HNSCC will increasingly involve use of molecular assays for prediction of prognosis and response to therapy and targeted prevention and therapy using molecular medicine, radiation, and surgery.

**CRITICAL MOLECULAR EVENTS IN THE DEVELOPMENT OF CANCER**

Tumor development following exposure to carcinogenic agents involves molecular changes that affect key cellular functions necessary for malignant behavior.\(^4,5\) These changes include overriding the normal program for cell differentiation and death to those favoring an increase in cell proliferation and life span.\(^6,5\) Malignant tumor progression involves additional changes that result in establishment of a blood supply, migration, invasion, and metastasis within the host environment of the patient.

Weinberg has shown that molecular alteration in expression or function of at least three genes is required to alter important cellular functions and cause transformation and tumor development from normal human cells under experimental conditions.\(^6\) One important requirement for neoplastic transformation and tumor formation is an increase in cell proliferation. He showed that increased cell-cycle progression and proliferation can result
from activation of a signaling kinase called Ras. Ras may be activated by viral infection, mutation, or by upstream signal activation due to overexpression of growth factors or receptors, such as epidermal growth factor receptor (EGFR). Growth factor receptors and Ras are potent activators of the mitogen activated protein kinases (MAPKs), transcription factor activator protein-1 (AP-1), and genes involved in cell-cycle entry and proliferation, such as cyclin D1. However, Ras activation and increased proliferation alone are not sufficient as such cells eventually undergo programmed cell death or reach the end of their life span, undergoing “crisis.” Additional alterations, leading to inactivation of tumor suppressor genes that encode proteins such as p14ARF, p16INK4a, or p53, are needed. These proteins are all components of a key damage pathway that when activated induces cell-cycle arrest, repair of damaged DNA, or cell death when DNA cannot be repaired. Thus, inactivation or loss of p14ARF, p16INK4a, or p53 may result in continuous replication of cells with DNA mutations and damage and further changes in the expression and function of additional genes, leading to further increases in malignant behavior. Alteration of one or more oncogenes leading to activation of other signal transcription factor pathways, such as nuclear factor kappa B (NF-κB) and signal transduction and activator transcription factor (STAT-3), has been shown to alter the balance between life and death of cancer cells. Alterations in expression of certain genes, including decrease in p53 regulated proteins p21 and Bax and increase in NF-κB and STAT-3 regulated proteins such as and BCL-2 and BCL-XL, have been shown to be important in preventing programmed cell death of cancer cells. A third requirement for cancer development is an increase in cell life span, or immortalization. Even basilar layer stem cells from which the epithelia arise normally stop proliferating and reach the end of their life in a finite number of cell divisions. The life-span limit of normal cells has been shown to be associated with a gradual shortening of the telomeres, which are the ends of chromosomes. In contrast, cancer cells do not exhibit shortening of the telomeres, and this has been found to be attributable to increased expression of an enzyme called telomerase.

Thus, when genes provide an important regulatory brake and their loss promotes cancer development, they are termed tumor suppressor genes; whereas, when the abnormal expression of genes “turns on” transformation and growth, these genes have been called oncogenes. Genes that suppress cancer that when lost cause cancer include p53 and retinoblastoma (Rb). Genes expressed by viruses, such as E6 and E7, are called viral oncogenes. Mutated genes such as the signal kinase Ras are termed cellular oncogenes. An accumulation of alterations in the expression of different combinations of tumor suppressor genes and oncogenes may result in increased proliferation and life span and decreased cell death, leading to progressive formation of premalignant and malignant lesions.

**Pathologic and Molecular Changes during Development of Head and Neck Squamous Cell Carcinoma**

**Pathologic Events during Tumor Development**

The development of HNSCC involves a series of progressive pathologic changes in behavior of cells in squamous cell mucosa and underlying stroma of the upper aerodigestive tract, as illustrated in Figure 1A. Cells injured by exposure to physical or viral agents may undergo irreversible damage and cell death or undergo repair and survive. The surviving cells often acquire increased cellular resistance and proliferate and migrate, healing the area of injury. With repeated injury, increased numbers of cells may accumulate to produce a thickened epithelium, termed hyperplasia. With repeated exposure to mutagenic agents, irreversible genetic mutations and epigenetic changes may occur with changes in cell behavior that include a partial- or full-thickness increase in proliferating and morphologically atypical cells called dysplasia or carcinoma in situ (CIS), respectively. Dysplasia and CIS lesions are premalignant. Migration through the basement membrane into the stroma is the hallmark of invasive carcinoma, which is the stage of malignant tumor development. Hyperplasia, dysplasia, or CIS may be accompanied by hyperkeratinization, which may be visible clinically as leukoplakia. Dysplasia, CIS, or microinvasive carcinoma is accompanied by a progressive increase in inflammation, vascularity, and proliferation of fibrous stroma, which may be visible clinically as induration and vascular erythema, called erythroplasia.

**Molecular Carcinogenesis**

Development of HNSCC has been associated with repeated exposure to and injury by chemical carcinogens contained in tobacco and alcohol or chronic infection by human papillomavirus.
pressor proteins p53 and Rb, which help regulate expression of proteins encoded by viral genes called

Changes in gene expression and function can contribute to the incidence of HNSCC at specific subsites can cause DNA damage. The increased incidence of lip and skin cancer in regions nearer the equator such as in Australia and the southwestern United States is associated with sun exposure. The ultraviolet spectrum in sunlight can cause thymidine dimer formation, resulting in C to T base transitions.

Certain viruses have been associated with HNSCC, and these viruses can commandeer vital cellular control pathways and cause DNA disruption on integration. HPV types 16 and 18, which are the subtypes that cause most cervical carcinomas in women, have been shown to be prevalent in oropharyngeal carcinomas, including nonsmokers. Cells infected with HPV express proteins encoded by viral genes called E6 and E7 that can inactivate the tumor suppressor proteins p53 and Rb, which help regulate cell proliferation and death. Epstein-Barr virus has been associated with nasopharyngeal carcinoma, particularly in Asia. It encodes viral proteins such as LMP-1 (latent membrane protein-1) that activate NF-κB, a signal and DNA transcription factor, that promotes expression of genes involved in cell survival and proliferation of epithelia and lymphocytes. Epstein-Barr virus infection also carries a gene homologous to human p16, a signal and DNA repair or induction of cell death, as well as promote activation of prosurvival pathways.

Chromosomal alterations are observed with variable frequency in HNSCC. Chromosome 13q21 has been shown to exhibit increasing LOH with CIS and invasive carcinoma. This region encodes the retinoblastoma gene, another tumor suppressor gene. However, mutation of the retinoblastoma gene occurs relatively infrequently in the HNSCC studied, indicating the possible presence of another gene at this location.

Tumor Suppressor Genes in Development of Head and Neck Squamous Cell Carcinoma

A locus on the short (p) arm of chromosome 9 located at 9p21 has been found to exhibit LOH at an early stage during the development of hyperplasia. The 9p21 locus has been found to encode overlapping genes that encode proteins called p14ARF and p16INK4a, and this locus is found to be inactivated in the majority of HNSCC by homozygous deletion, mutation, or by methylation of the regulatory promoter region. The p14ARF protein is an important activator of the p53 pathway and repressor of the NF-κB pathway during programmed cell death, so its loss may be an important early event in dysfunction of both the p53 and NF-κB pathways, which are altered in dysplastic and malignant squamous cell epithelia. The p16INK4a protein is a cyclin-dependent kinase called CDKN2/MTS-1/INK4A that normally inhibits cell-cycle progression. Thus, genetic or epigenetic alteration of this locus can result in loss of p14ARF protein causing decreased programmed cell death, and loss of p16INK4a, causing increased proliferation. Consistent with this, re-expression of p16 in HNSCC cells by gene transfer suppresses cell growth in vitro. Re-expression of p14ARF has been shown to repress NF-κB mediated prosurvival gene expression and promote cell death in other cell lines.

Chromosome 17p13 encodes the p53 gene, which is itself altered with relatively low frequency in dysplasia and CIS, but with increased frequency in ~50% of primary carcinomas. Alternatively, HPV infection and E6 expression have been shown to inactivate p53, presumably at an earlier stage, particularly in oropharyngeal SCC. As described above, a variety of functions have been attributed to the p53 gene, which has been found to mediate tumor suppression by cell-cycle arrest and DNA repair or induction of cell death when damage is irreversible. Tumor suppressor p53 may also repress the activation of prosurvival genes by NF-κB, through competition for a transcriptional co-factor called CBP/p300. Thus loss of p53 can lead to dysfunction of mechanisms by which cancer cells undergo repair or cell death, as well as promote activation of prosurvival pathways.

Chromosome 3p is altered with increasing frequency with the development of dysplasia in HNSCC, and esophageal carcinomas and contains at least three putative loci. Several genes on the 3p arm have been implicated as tumor suppressors, including genes fragile histidine triad (FHIT), retinoic acid receptor-beta (RAR-β), and Ras associated domain family-1 (RASSF1). These genes have variously been implicated in checking proliferation and migration, and hence their loss can contribute to proliferation, invasion, and tumorigenesis.

LOH involving chromosomes 8p is observed later, in association with invasive HNSCC, and a locus on chromosome 8p23 is associated with poor prognosis. The putative tumor suppressor gene at the chromosome 8p23 locus has been identified and is a large transmembrane protein called cub sushic multiple domains 1 (CSMD1), another gene that infrequently undergoes mutation which results in loss of function maps to the chromosome 8p21 region in HNSCC and is a p53 regulated growth inhibitory gene that is a member of the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) family.

LOH at chromosome 10q23 is detected with intermediate frequency in primary HNSCC and has been found to reflect deletion or inactivation of a gene called phosphatase and tensin (PTEN) homologue deleted on chromosome 10. PTEN functions in the inactivation of Akt, known as protein kinase B. Akt plays an important role in activation of transcription factor NF-κB and co-activator CBP/p300 transcription of prosurvival genes, and activation of molecular target of rapamycin (mTOR), important in translation of proteins, such as angiogenesis factor, vascular endothelial growth factor (VEGF). Early activation of Akt by autocrine stimuli such as EGF and cytokine receptors, and later by loss of PTEN, could lead to increased survival and growth of HNSCC and other cancers.

Several other important chromosomal alterations are observed with variable frequency in HNSCC. Chromosome 13q21 has been shown to exhibit increasing LOH with CIS and invasive carcinoma. This region encodes the retinoblastoma gene, another tumor suppressor gene. However, mutation of the retinoblastoma gene occurs relatively infrequently in the HNSCC studied, indicating the possible presence of another gene at this location.

Tumor Oncogenes in Development of Head and Neck Squamous Cell Carcinoma

A locus alteration on the long (q) arm of chromosome 11 located at 11q13 in increasing frequency during the CIS stage is associated with amplification of a cell-cycle regulatory protein called cyclin D1. Alternatively, cyclin D1 may be overexpressed as a result of transcriptional activation by NF-κB. Cyclin D1 is required for progression of cells through the cell cycle, thereby stimulating squamous cells to proliferate. Inhibition of cyclin D1 results in inhibition of growth of HNSCC in vitro.

On chromosome 3q, amplification of a homologue of p53 was identified, and this protein, designated p40AIS (amplified in squamous cell carcinoma), was found to occur with high frequency in HNSCC and lung squamous cell carcinoma. p40AIS is a short splice variant of a related p53 family member called ΔNp53, and both lack the tumor suppressor function of p53. Expression of AIS was found to promote growth of rat cells in soft agar and in mice, indicating that it may play an early role in transformation as an oncogene. Increased p40 expression appeared to be correlated with loss of p53, and p40 may interact and...
and colleagues have also shown that increased expression of the NF-κB pathway in HNSCC are shown in Figures 1 and 2. Overexpression of Transforming Growth Factor-α (TGF-α), Epidermal Growth Factor Receptor, and Activation of the MAPK -AP-1 and STAT3 Pathways in Head and Neck Squamous Cell Carcinoma

A aberrant activation of the NF-κB pathway in head and neck squamous cell carcinoma NF-κB is a signal transcription factor found to play an important role in aberrant gene expression and the malignant phenotype of SCC. NF-κB is inducible by nicotine and chemicals contained in tobacco and betel nut, two of the most important carcinogenic agents that promote development of HNSCC. Increased nuclear activation of NF-κB has been shown to occur in premalignant dysplastic lesions and ~85% of HNSCC, indicating that it is an early event, and strong immunostaining is associated with the increased rate of malignant progression of dysplasia and decreased survival in patients with HNSCC. NF-κB was found to be constitutively activated in HNSCC cell lines and tumors, suggesting that further events contribute to sustained activation. Thus far, expression and autocrine activation by IL-1α and tumor necrosis factor (TNF) have been implicated in activation of NF-κB in HNSCC. EGFR appears to contribute weakly to constitutive activation of NF-κB pathway. Activation of NF-κB via the PI3K, Akt, and CK2 kinases appears to be important in signal activation of these pathways in HNSCC. By cDNA microarray profiling, NF-κB was found to directly or indirectly regulate ~60% of the genes aberrantly expressed with malignant progression in a murine SCC model, and genes from a 99 gene signature subset from that study were shown to group with genes aberrantly expressed in microarray gene profile found in tumor specimens from patients at high risk for malignant progression. NF-κB regulates key genes involved in cell proliferation (cyclin D1), survival (BCL-XL), migration and invasion matrix metalloproteinase 9 (MMP9), and angiogenesis (IL-8, GRO1) in cancer (see Figure 1B). Confirming this, blocking NF-κB activation inhibits these genes and cell proliferation, survival, angiogenesis, and tumorsogenesis of SCC. Recently, NF-κB mediated activation of one of the cytokines, IL-6, has been shown to be an important activator of STAT3, also important in cell survival.
importance of the HGF-cMET-EGR-1 signaling.54 In summary, HNSCC exhibits loss of tumor suppressors p14ARF, p16INK4a, and p53 and activation of ligand–receptor pairs which are tumor activators that modulate a network of signal pathways that regulate expression of target genes and proteins that mediate the phenotypic features of the malignant phenotype (see Figure 2). This includes autochthonous activation by IL-1R, TNFR, and EGFR, which contribute to activation of the MAPK-AP-1, PI3K-NF-κB, and Akt-mTOR pathway; EGFR and IL-6R which contribute to STAT3 activation; and cMET which contributes to PI3K and EGR1 pathways. Groups of genes, predominantly regulated by one or a combination of the factors AP-1 and NF-κB (cyclinD, MM Ps, IL-8), NF-κB and STAT3 (BCL-XL), AP-1, EGR1, and mTOR (VEGF) are key molecular mediators of cell proliferation, survival, invasion, and angiogenesis.

**Molecular Mediators of Tumor Progression and Metastasis of Squamous Cell Carcinoma**

The stages of cancer involve progressive tumor invasion and metastasis, which are the stages that ultimately affect vital functions and cause death in patients. Figures 1A and 2 highlight some of the intermediate and late histopathologic and molecular events associated with tumor progression and metastasis. Development of invasive carcinoma is associated with focal dissolution of the basement membrane and extracellular matrix (ECM), detachment, and migration of cells into the submucosal tissue. HNSCCs that exhibit a streaming pattern of small clusters of cells through the ECM are associated with more aggressive behavior and poor prognosis.56 Tumor progression to a size that becomes visible and has an effect on adjacent structures requires an increase in supply of oxygen and nutrients and removal of waste. Folkman established the concept that new blood vessel formation is critical in cancer.57 Enlargement of tumors to a size beyond 0.5 cm exceeds the range for diffusion of oxygen from existing vessels and necessitates new blood vessel formation, called neoangiogenesis. Such new vessel formation has been demonstrated in all cancers and is commonly associated with an increase in inflammatory cells. Increased vessel density and inflammation within tumors have been associated with more rapid growth, metastasis, and a decrease in prognosis, suggesting that the increase in vessels may somehow relate to increased access for metastasizing cancer cells. Invasion of the lymphatics and blood vessels and circulation of cells are necessary for regional and distant spread of HNSCC.

Growth of the tumor epithelia and angiogenesis is also accompanied by increased infiltration of inflammatory cells and proliferation of fibrous stroma. Several studies have suggested that tumor cells that induce host inflammatory and stromal cell responses grow, invade, and metastasize more rapidly. Chen and colleagues have shown that during progression, squamous cell carcinomas undergo additional changes needed for growth and metastasis that depend on the host.60 Y ong and colleagues have shown that inflammatory cells infiltrating human and murine squamous cell carcinomas are one of the host components that promote growth and metastasis.61 These inflammatory cells bear a stem cell marker called CD34 and appear to differentiate into granulocytes and the endothelial cells that form new blood vessels. Y ong62 and Pekarek and colleagues63 have shown that the granulocytes promote increased growth and metastasis. Granulocytes from the host can release growth factors64 and proteases65 that stimulate growth and invasion of tumor cells. Squamous cell carcinomas also induce proliferation of stromal fibroblasts. Fibroblasts also secrete factors, such as HGF, and ECM substances, that can promote growth.66 The establishment of metastases requires cell arrest and vessel formation in a new location. HNSCC shows a predilection for metastases to the lymphatics, lungs, liver, and bone marrow, suggesting that the cells and substrates of the reticuloendothelial system provide a favorable environment for arrest and formation of squamous cell carcinoma metastases.

**Molecules Involved in Cell Adhesion, Migration, and Invasion by Head and Neck Squamous Cell Carcinoma**

HNSCCs exhibit alterations in expression of a repertoire of cell adhesion molecules and ECM substances that function in attachment and migration. Increased expression of cell adhesion molecules called integrins has been detected in HNSCC by Van Waes and colleagues.67 The integrins are heterodimers comprising α and β subunits that form a superfamily of cell surface receptors involved in cell–cell and cell–ECM adhesion and recognition. The integrin α6β4, α2β1, and α3β1 heterodimers are normally expressed among proliferating layers of squamous cell epithelium but are expressed in suprabasilar layers of many squamous cell carcinomas in association with increased proliferation and immortalization that occur during early tumor development.68 Increased suprabasilar expression of α6β4, as detected by monoclonal antibody A9, was found to be correlated with a poorer prognosis in a prospective study of 80 patients with HNSCC.69 Expression of integrin α6β4 has been shown to promote aggressive tumor behavior.68 The α6β4, α2β1, and α3β1 integrins have been found to be receptors for ECM laminin, and α2β1, and α3β1 integrins also bind to collagen. HNSCCs secrete the basement membrane component laminin in vitro and in situ, and blockade of α6β4, α2β1, and α3β1 completely inhibits attachment of HNSCC to laminin and collagen.69 Monoclonal antibody to the α6 integrin has also been shown to reduce binding to activated endothelial cells. Thus, HNSCCs exhibit constitutive alterations in expression of a repertoire of integrin.

---

carcinoma (see Figure 1B). EGFR and TGF-α appear to be overexpressed owing to transcriptional activation of the genes for this receptor and ligand in most HNSCC. Patients with carcinomas expressing higher levels of these factors have been shown to have a shortened disease-free survival, independent of cervical lymph node stage. Production of TGF-α and expression of EGFR establish a potential autocrine signal pathway for continuous stimulation of proliferation of squamous cells, and the importance of TGF-α and EGFR expression in the growth of HNSCC has been established. Inhibition of either TGF-α or EGFR expression or function using antisense oligonucleotides or pharmacologic inhibitors in combination with radiation was found to decrease the proliferation and growth of HNSCC cells in vitro and of xenografts in mice in vivo. The effects of EGFR activation may be mediated through several signal transduction factor pathways, which include Ras, MAPK, or ERK that activate transcription factor AP-1 and STAT3.51 EGFR activation of STAT3 inhibits HNSCC cells from undergoing cell death (apoptosis) and stimulates proliferation. The cytokine IL-6 regulated by NF-κB has been reported to be another important factor in STAT3 activation.45 Thus, overexpression of EGFR appears to be one of several factors contributing to MAPK and STAT3 activation, the increase in proliferation, and the decrease in cell death involved in HNSCC tumorigenesis.

**Increased Activation of the Hepatocyte Growth Factor and cMET Pathway in Head and Neck Squamous Cell Carcinoma**

Murine and human SCC have been shown to express a receptor/oncogene cMET, which binds the hepatocyte growth factor (HGF), also known as the scatter factor, owing to its ability to induce separation and spreading of epithelial and endothelial cells.52,53 Consistent with this, increased responsiveness to HGF and cMET activation has been implicated in increased angiogenesis and metastasis of murine and human HNSCC. HGF/cMET activation amplifies the induction of the PI3K and Akt pathway by other growth factors and cytokines and also activates another transcription factor, EGR-1.54 The platelet derived growth factor (PDGF) and VEGF involved in angiogenesis have been shown to be among the important targets of the HGF-cMET-EGFR-1 signaling.54

**Molecular Target of Rapamycin Pathway**

The cytokine and growth factor induced activation of PI3K-Akt kinases activates another important target, mTOR, that is important in activating kinases and proteins that enhance protein translation in HNSCC.55 Activation of several targets has been associated with activation of Akt and/or mTOR. One of these, el F4 (elongation initiating factor), has been shown to be a marker in most HNSCC. This protein has been implicated in enhancing translation of angiogenesis factors such as VEGF.56 Although inhibition of mTOR by rapamycin has little effect on HN SCC lines in vitro, such inhibition sensitizes HNSCC cells to apoptosis and reduces angiogenesis in vivo in animal models.52

cell adhesion molecules, and expression of integrin α6β4 in particular is linked with aggressive tumor behavior.

Increased expression and activation of enzymes involved in remodeling of the ECM have been detected in HNSCC and are associated with increased invasiveness and pathogenicity. The MMPs comprise a family of proteases that digest ECM, which are upregulated in HNSCC (see Figures 1 and 2). HNSCC exhibits increased expression of urokinase-type plasminogen activator (uPA) and uPA receptor as well as the MMPs membrane-type MMP-1, collagenase 1,stromelysin 1, and gelatinase B. Expression of these factors and invasiveness appear to be inducible by EGF or scatter factor (SF). Invasion of EGF- or SF-stimulated cells is completely suppressed by recombinant and synthetic MMP inhibitors. These studies suggest that MMPs may be more important than the plasminogen activator–plasmin system in mediating EGF- or SF-stimulated cell invasion of interstitial matrix barriers. Inflammatory cells infiltrating tumors also can express MMPs. MMP-9 may be expressed by host-derived neutrophils, macrophages, and mast cells attracted to the tumor site. MMP-9 expressed by bone marrow derived cells appears to promote malignant tumor progression of squamous cell carcinoma in vivo.

**Cytokine and Growth Factors Involved in Inflammation and Angiogenesis in Head and Neck Squamous Cell Carcinoma**

The demonstration of the role of host inflammatory and angiogenesis responses in the development and progression of squamous cell carcinoma has led to efforts to identify the molecules involved. HNSCC have been found to express a number of cytokines and growth factors that mediate inflammatory and angiogenesis responses (see Figures 1 and 2). SCC produces a repertoire of factors in vitro and in situ that include IL-1α, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor (GM-CSF), growth-regulated oncogene-α (GRO-α), and VEGF. Tumor fibroblasts have been shown to produce SF/ HGF. IL-6, IL-8, GRO-α, VEGF, and HGF are of sufficient stability and are produced at high enough concentrations that increased concentrations have been detected in the serum of patients. Decreasing cytokine levels were associated with therapeutic response, while increasing levels were related to progression of recurrence.

IL-1 is a cytokine that can regulate NF-κB activation and expression of several of the other factors detected in SCC. IL-1 can serve as an autocrine factor to stimulate HNSCC to produce IL-6, IL-8, GM-CSF, and VEGF and as a paracrine factor to stimulate the production of HGF by stromal fibroblasts (see Figure 2). In addition, IL-1 has important systemic regulatory effects as an important mediator of acute-phase reactions, increased catabolic state and cachexia often observed in patients with aggressive HNSCC. IL-1 and IL-6 both can have direct effects as autocrine or paracrine factors that can stimulate proliferation of HNSCC cells.

IL-8 and GRO-α are also members of a related family of chemoattractant and proliferative factors that contain a cysteine-X-cysteine (C-X-C) amino acid motif. IL-8 and GRO-α have been shown to serve as chemoattractants for neutrophils, monocytes, and endothelial cells, which are major constituents of the inflammatory response in HNSCC (see Figure 2). Loukinova and colleagues have shown that expression of the murine homologues of GRO-α and IL-8 promote aggressive growth and metastases, angiogenesis, and inflammatory cell infiltration in squamous cell carcinoma. The aggressive pattern of growth is reversed in knockout mice deficient in C-X-C receptor 2, the receptor for the chemokine. These results provide direct evidence that tumor factors and the host response induced by them are critical in tumor progression and metastasis of squamous cell carcinoma. Kitadai and colleagues have shown that expression of the stromal fibroblast-inhibitor of differentiation (SDF-1) is associated with metastasis. VEGF also promotes angiogenesis and stimulates expression of αvβ3 and αvβ5 integrin heterodimers that are involved in migration of endothelial cells during angiogenesis. Inhibition of αv integrins inhibits tumorigenesis of SCC in mice.

**Molecular Diagnosis of Head and Neck Squamous Cell Carcinoma**

Progress in the determination of molecular mechanisms involved in the pathogenesis of development and progression of HNSCC, together with sensitive molecular assay methods, has expanded opportunities for use of molecular diagnosis in patients with HNSCC. Using PCR-based methods for amplification of DNA, LOH of specific markers associated with HNSCC has been shown to occur in biopsy specimens of lesions prior to development of invasive malignancy. Mutations in the p53 gene have been detected in tumor suppressor genes, have been detected in blood and saliva, and may eventually be useful for diagnosis and detection of recurrence. Using DNA microarray, quantitative RT-PCR or immunoassays, overexpression of cytokines and angiogenesis factors has been demonstrated in blood and saliva and examined as markers for diagnostic prediction of response, recurrence, and survival. These studies have established the feasibility of using molecular methods to screen patients for diagnosis, prognosis, and detection of recurrence. Further understanding of the “anatomy” of activation of pathways and target genes, as in Figure 2, will eventually offer the possibility of determining...
sensitivities or resistance of HNSCC to different therapies.

Microarray analysis of gene expression has revealed clusters of genes that group together, associated with malignant potential, decreased prognosis, recurrence, and resistance to drugs such as cisplatinum. Such gene programs related to malignant potential and clinical outcome include those associated with immortalization of HNSCC observed in cell culture, and epithelium-mesenchymal transition (EMT) and NF-κB, associated with high-risk prognostic group among patients with HNSCC. To date, these studies have been most useful in generating hypotheses about important functions of genes and identifying most unique as potential markers for study using more direct and quantitative methods.

**MOLECULAR THERAPY AND PREVENTION OF HEAD AND NECK SQUAMOUS CELL CARCINOMA**

The determination of molecular mechanisms involved in the pathogenesis of development and progression of HNSCC has enabled the development and testing of a few specific molecular therapies. Chemoprevention using inhibitors of several of these pathways are also under investigation. Figure 3 summarizes some of the targets and agents under investigation. Identification of the role of EGFR in HNSCC and other cancers led to testing of therapy with receptor antibody inhibitors, small molecule inhibitors, and DNA antisense sequence to the target gene. The anti-EGFR antibody cetuximab (Erbitux) was found to have an ~13% response rate as a second-line single agent in patients with recurrent HNSCC and, with concurrent radiation, provides an ~10 to 15% enhancement in survival over radiotherapy alone in patients with locally advanced disease. As a result, cetuximab has been approved for these indications. The EGFR tyrosine kinase inhibitor gefitinib showed limited response rates in patients with recurrent HNSCC. The relatively limited activity of EGFR inhibitors alone together with evidence for activation of downstream intermediates and of other pathways important in the malignant phenotype has highlighted the need to investigate other targets for therapy.

Xi and colleagues have shown that STAT3 decays inhibit growth of HNSCC in a xenograft model, and clinical trials are under way to determine safety in patients and effects of expression of oligonucleotides on tumor gene expression. Small molecule inhibitors of the proteasome, such as bortezomib (Velcade), can inhibit activation of the NF-κB pathway and are under study in patients with HNSCC. Early results of the first study to combine bortezomib with radiation, conducted in patients with HNSCC, showed that bortezomib can inhibit NF-κB and pro-survival target genes, and induce apoptosis in tumor biopsies postdrug infusion. Bortezomib is a first-in-class proteasome inhibitor that was initially approved for multiple myeloma. This agent may also inhibit tumor of suppressor p53 and its target gene p21, which inhibit proliferation. Nonsteroidal anti-inflammatory drug (NSAID) inhibitors of cyclooxygenase, which affect prostaglandin synthesis and NF-κB activation, are of interest for chemoprevention of HNSCC. A study of topical treatment with NSAID ketorolac showed no effect versus placebo in a randomized study of patients with leukoplakia. Natural compounds that inhibit NF-κB activation, such as curcumin from the spice turmeric (a major seasoning component of curry), are under investigation for chemoprevention.

Recent evidence that TNF inhibitors and targeting the inhibitor-κB kinase can block NF-κB activation may possibly make use of agents with greater specificity and lower toxicity than proteasome or NSAIDs with broad activities.

Preclinical laboratory and animal studies with mTOR inhibitors have shown promise and have led to initiation of clinical trials. Rapamycin induced apoptosis and tumorigenesis in HNSCC xenograft studies. A rapamycin precursor CI-779 has also been of interest. Inhibitors of Ras and MAPK have shown antiproliferative activity in HNSCC cells, and MET and PI3K inhibitors are the subject of preclinical drug development. Inhibitors of NF-κB, STAT3, MAPK, PI3K, and mTOR may be most useful together in combinations when molecular diagnostics and suitable agents make such studies feasible.

Immune evasion by cancerous cells is a key part of the carcinogenesis process. Cells displaying altered malignant phenotypes are prime targets for destruction by the host immune system unless they develop methods to avoid or block immune attacks. The phenomenon of tumor immune evasion exhibits both passive and active components. Passive components involve tumors becoming inconspicuous to the immune system, as well as becoming resistant to immune-mediated killing through manipulation of the tumor's homeostatic molecular machinery. The active components of evasion consist of tumors directly inducing cell death or dysfunction of immune effector cells or recruiting the host's normal immunosuppressive mechanisms to induce an inferior and ultimately inadequate immune response. These active evasion strategies have, in addition to local tumor and immune cell effects, global immune consequences for the host as well. Reports of opportunistic infections are abundant in patients with various cancers, especially hematopoietic malignancies. Furthermore, immunocompromised patients, due to HIV or organ transplantation, are much more susceptible to acquire cancers of many types. By becoming more inconspicuous, less vulnerable, and more virulent to the immune system, cancers can grow essentially unchecked until they lead to inevitable devastating consequences for the patient.

On the other hand, clinicians can use these immune system changes caused by malignant cells as tools to diagnose and prognosticate the advancement of cancer. For example, normal T cell activity requires the T cell receptor (TCR) to function through a variety of supportive molecules. It had been shown that patients with cancer frequently have decreased expression of the TCR molecule zeta, with resultant reduced signaling through this receptor. Others and we have now shown that this can be explained in part by tumors activating cell death machinery within T cells, causing cleavage of the zeta molecule. Importantly, zeta loss has now been shown to be important in prognosis in a variety of cancers. The ability to monitor these types of molecular changes within host immune cells and tumors has improved our understanding of the behavior of malignant disease. More importantly, understanding the various tumor immune evasion strategies can provide guidance during the development and implementation of current and future selective cancer treatment modalities.

**TUMOR IMMUNE ESCAPE VIA INVISIBILITY**

One of the most straightforward methods by which tumors evade immune attack in patients with head and neck cancer is by avoiding immune recognition in the first place. Preventing recognition allows tumors to thwart the induction of an antitumor immune response or, failing that, to avoid an effective antitumor cytotoxic attack. Because host cytotoxic cells must recognize tumor antigens within the correct molecular “context,” a tumor can sidestep the immune system by downregulating its expression of targeted antigens, reducing levels of context-supplying molecules, or preventing antigen presentation to secondary lymphatic organs, where recognition occurs (Figure 1). Attack by cytotoxic T cells or natural killer (NK) cells is prevented by loss of tumor-associated antigens (TAAs), downregulation of tumor human leukocyte antigen Class I (HLA-I) or costimulatory molecule expression, downregulation of NK-activating ligands, and upregulation of NK inhibiting ligands, or immune ignorance caused by physical separation of tumor and effector cells.

Compared to infectious agents such as viruses, tumors have the advantage of having developed from the host's own cells, thereby inheriting significant protection against attack through immune self-tolerance. The presence of self-tolerance means that tumors potentially express few antigen targets by which the innate or adaptive immune responses can distinguish neoplastic cells from adjacent normal cells. Nevertheless, intact host immune responses against tumor neo-antigens or overexpressed normal proteins have been demonstrated. The result is that many tumors either modify the expression of these recognized antigens or downregulate the processing and presentation of these antigens. More commonly, tumors can downregulate levels of context-supplying molecules, such as the human leukocyte antigen (HLA) Class I or costimulatory molecules, or prevent effective antigen presentation to secondary lymphatic organs.
machinery required for antigen presentation to immune effector cells.

**TUMOR-ASSOCIATED ANTIGEN LOSS**

Native tumors consist of a heterogeneous population of malignant cells expressing variable levels of cellular proteins. Several different categories of cancer protein antigens have been identified that can induce cytotoxic T lymphocyte (CTL) responses in vitro and in vivo. These TAAs fall into five groups: (1) cancer testis (CT) antigens, expressed in multiple malignancies and normal testis, (2) melanocyte differentiation antigens, (3) point mutations of normal genes, such as the tumor suppressor p53, (4) self antigens that are overexpressed in malignant tissues, and (5) viral antigens. Although tumors presumably benefit from producing these various oncogenic products, in the setting of T cell attack, individual tumor cells that can downregulate these TAAs and survive have a significant advantage. The result is a tumor “immunoselected” to evade host immunity. Indeed, repeated biopsies of metastatic melanoma have shown that TAA loss correlates with tumor progression. Residual tumors following vaccination with TAA peptides have also shown decreased levels of corresponding TAA expression. The presence of TAA-specific immune effector cells has little impact on these adapted cancers, and they can grow aggressively.

**HLA CLASS I LOSS**

One of the most well-characterized methods of tumor antigen loss is alteration in the cellular expression of the major histocompatibility complex (MHC) Class I proteins, also referred to as HLA. Classical HLA molecules, required for CD8 T cell recognition of antigens, are found on nearly all human cells. The loss of HLA1 has a profound effect on the ability of these cytotoxic T cells to recognize a tumor antigen, become activated, and attack tumor cells. Seven HLA1 loss phenotypes have been described, involving everything from loss of a single HLA1 allele to a total loss of all HLA1 expression. Tumors can display these phenotypes by altering one or more of the steps involved in antigen breakdown, processing, and loading onto HLA molecules. Downregulation of HLA1 levels in a human tumor relative to a normal tissue was first described in 1977. Since then, numerous investigators have found a high percentage of HLA1 loss in multiple human solid tumors, including squamous cell carcinoma of the head and neck (SCCHN). For example, Cabrera and colleagues showed loss of HLA1 in 70% of laryngeal carcinomas. Another survey of SCCHN found 15% HLA1 loss in primary tumors and 40% in metastasis, suggesting that HLA1 loss correlates with tumor aggressiveness.

Although downregulation of HLA Class I alone may help a tumor cell evade T cell cytotoxic attack, tumors must also contend with host NK cell surveillance. Classically, NK cells were understood to detect and eliminate cells that failed to express the “self” identifying protein HLA1. This NK targeting of “missing self” cells appears incompatible with successfully growing HLA1-negative tumors, suggesting that neoplasms must employ additional methods to inhibit NK cell function. Although still an area of ongoing investigation, it appears that NK cell cytotoxicity is controlled by a balance between stimulation of activating and inhibitory receptor populations on the surface of NK cells. There is recent evidence that some tumor-bearing patients express either abnormally low levels of activating receptors, on their NK cells or low levels of ligands, to these receptors on tumor cells. Theoretically, tumor-induced activation of NK inhibitory receptors, may also protect cancers from NK attack.

**IMMUNE IGNORANCE**

Tumors that express adequate levels of tumor antigens and HLA molecules can still avoid immune attack if the signals that these proteins represent never reach T cells in sufficient amounts to stimulate an antigen-specific response. This phenomenon is termed immune ignorance and is distinct from T cell anergy or deletion in that T cells capable of responding to tumor antigen in vitro are present in the host but fail to react to the tumor in vivo. These T cells act as if they do not “see” the nearby tumor cells at all. Immune ignorance is primarily a feature of solid tumors located in the periphery, which shed relatively few antigen-expressing malignant cells to the lymph nodes, where the cellular immune response is initiated. Any cells that do metastasize will themselves off from nearby T cells in these nodes by producing an isolating matrix coat. These geographical barriers prevent potentially reactive circulating T cells from encountering sufficient levels of the tumor antigen they recognize for full activation, rendering them “ignorant” of the tumor’s presence.

**COSTIMULATORY RECEPTOR LOSS**

Once a host adaptive immune response is induced, either from normal tumor cell death causing shedding of TAAs or from TAA vaccination, tumors may still prevent antigen-specific CD8 T cell destruction by modifying the expression of costimulatory molecules on their surface. Costimulation is essential for activated CD8 cytotoxic T lymphocytes (CTLs) to exhibit efficient cytotoxicity, as CD8 cells whose TCRs interact with HLA1 in the absence of the “second signal” of costimulation are quickly rendered anergic. Squamous cell carcinomas have been found universally to lack the potent costimulatory proteins CD80 and CD86, while dramatic loss of similar molecules CD40 and intercellular adhesion molecule-1 (ICAM-1) has been demonstrated as well. As the latter costimulator is also a cell adhesion molecule, tumor ICAM-1 loss may contribute to tissue invasion in addition to immune evasion. T cell anergy from lack of costimulation can be a significant barrier to effective natural induction or tumor vaccine therapy, as development of a large population of antigen-specific T cells will produce no significant CTL effect at the tumor site.

**TUMOR IMMUNE ESCAPE VIA APOPTOSIS CONTROL**

Although many human malignancies are masters of molecular disguise, they need not simply hide from the immune system. Tumors can also evade host immunity by making intracellular molecules that block cytotoxic attacks or by attacking their attackers. This is accomplished through manipulation of the normal cellular machinery responsible for the phenomenon of programmed cell death (PCD), also known as apoptosis. Apoptosis is a conserved and self-regulating pathway, operative in all eukaryotic cells. It occurs during embryonic development and is essential for successful organogenesis and the crafting of complex multicellular tissues. The evolutionary advent of differentiated cell types may have necessitated controlling cell death as well as division to keep neighboring cells interdependent and insure the proper balance of each cell lineage. For instance, apoptosis is responsible for negative selection of nonreactive leukocyte precursors and autoreactive T lymphocytes. Without this, process of immune cell selection, T cell-mediated autoimmunity would ensue. Apoptosis also operates in adult organisms to maintain normal cellular homeostasis. This is especially critical in the removal of precancerous and virally infected cells. Gain- and loss-of-function models of genes in the core apoptotic pathways indicate that the violation of this cellular homeostatic process can lead to the development of a wide range of human diseases, including cancer. Clinically, there is now strong evidence that insufficient apoptosis can manifest as cancer or autoimmunity, while accelerated cell death is evident in acute and chronic degenerative diseases, immunodeficiency, and infertility.

**Apoptotic Family of Molecules**

Within the various groups of molecules responsible for apoptotic control, there are a few key protein families. Although many molecules have an apoptotic role, the Caspase, Bcl-2, and IAPs (inhibitors of apoptosis) families are the major arbiters of this phenomenon. Also of importance are the death-receptor families and mitochondriar-based molecules, by which the two main pathways of classic apoptosis are initiated.

Caspases, a group of cysteine proteases related to mammalian ICE (interleukin-1 beta converting enzyme), play a crucial role in apoptosis. These enzymes appear to be involved in both the initial signaling events and the downstream proteolytic cleavages that characterize the apoptotic phenotype. In addition, cleavage of...
cellular proteins can change their function and cause the phenotypic changes seen in PCD. For instance, caspase-cleaved proteins are responsible for plasma membrane blebbing, cellular breakage into “apoptotic bodies,” the dissolution of cellular integrity and cellular packaging, disruption of macromolecule synthesis, and termination of survival signals. Predictably, these changes lead to the general destruction of the cell.

The apoptosis-inhibiting molecule Bcl-2 (B-cell leukemia/lymphoma 2) was first discovered as a proto-oncogene in follicular lymphomas. It is the prototype of a large family of proteins, with both anti- and proapoptotic members that share Bcl-2 homology (BH) domains. Unlike caspases, which have no antiapoptotic counterpart, it is the ratio of these anti- to proapoptotic Bcl-2 family members that determines a cell’s fate. This may be related to their separate antagonizing functions or to the ability of the two types of family members to heterodimerize. Antiapoptotic family members, such as Bcl-2, Bcl-XL, and Bcl-w, have been found to be overexpressed in a variety of solid tumors. As would be expected, proapoptotic molecules, like Bax, Bim, and Bak, have been shown to be significantly downregulated in a host of malignancies.

Numerous mechanisms for the functions of the Bcl-2 family have been proposed. Antiapoptotic members may function as an antioxidant or redox-regulating protein, as recent data implicate Bcl-2 in the general adaptation to oxidative stress. Bcl-2 and Bcl-XL also protect against mitochondrial outer membrane permeabilization. Both pro- and antiapoptotic Bcl-2 molecules have been suggested to be channel-forming proteins that are incorporated into lipid membranes to control the movement of other important PCD regulators. The pore-producing ability of proapoptotic molecules, such as Bax and Bak, appears to be essential for the release of apoptogenic molecules from the mitochondria, initiating the intrinsic apoptosis pathway (discussed below).

IAPs are the third intracellular family of apoptosis-related molecules. Their most well-described mechanism of action involves binding to and inhibiting caspase activity. IAPs are therefore potentially involved at several points in multiple apoptosis pathways.

**Two Pathways to Apoptosis**

All of the previously described PCD control molecules function within two major apoptotic pathways. The extrinsic pathway is initiated at the cell surface through a variety of death receptors belonging to the tumor necrosis factor (TNF) receptor family. The intrinsic pathway is initiated at the level of an organelle, proto-typically the mitochondria. Ultimately, both the pathways converge on the so-called downstream caspases, which function to cleave the majority of molecules necessary to complete the PCD process. It is likely that neither pathway is independent of the other, with extrinsic/intrinsic crosstalk required for a complete death signal (Figure 2).

The extrinsic apoptotic pathway begins when cell death receptors, such as Fas, TRAIL-R1-4 (TNF-related apoptosis-inducing ligand-R1-4), and TNF-R1, bind to their corresponding ligands and form tri-molecular complexes at the cell surface. These complexes recruit adapter molecules such as FADD (Fas-associated death domain) that then activate “upstream” caspases, such as caspase-8 and -10, which cleave and activate the downstream caspases that finally kill the cell. Death receptor-ligand interactions have been shown to be important in immune system development, homeostasis, and function. Various studies have focused on manipulating either receptors or ligands in a variety of disorders. For example, inhibition of Fas prevents rejection in a mouse transplant model, as transplanted cells gain resistance to the corresponding Fas-Ligand (FasL) on host immune effector cells. The intrinsic pathway is initiated in the mitochondria, where numerous apoptogenic proteins, such as cytochrome c, reside. The pathway progresses in two steps. Initially, breakdown of the inner mitochondrial membrane diffusion barrier frees cytochrome c from the unrolling cristae to the intermembrane space. Following this, cytochrome c is released into the cytosol via pores in the mitochondrial outer membrane. This second step requires the proapoptotic Bcl-2 family proteins Bax and Bak, while cristae remodeling is regulated by a protease PARL (presenilin-associ-
dated rhomboid-like protein) and its target hetero-
globiliger OPA1 (dominant optic atrophy gene).

Ultimately cytochrome c combines with other proteins to form the apoptosome (an oligomer of procaspase-9, Apaf-1, dATP, and cytochrome c). It is the apoptosome that activates the upstream caspase, caspase-9, which in turn cleaves the downstream caspases of the common pathway.
Tumor Immune Escape via Indirect Suppression of Cellular Immunity

In addition to direct inactivation or destruction of cytotoxic effector cells, tumors recruit several populations of host immune cells with immunosuppressive functions. These suppressive cells can be generally grouped together as either T regulatory cells (Tregs) or myeloid suppressor cells (MSCs). These suppressors normally function to blunt potentially overaggressive host immune responses to inflammation and infection. In the setting of cancer, however, they have been found to prevent both effective tumor surveillance and effective immunotherapy. Importantly, these effects can be measured both within the tumor microenvironment and systemically (Figure 4).

T Regulatory Cells in Indirect Suppression

Tregs, classically identified as CD4+CD25+FOXP3+ expressing cells, normally make up 5 to 10% of peripheral CD4+ T cells in humans and play an important part in peripheral tolerance of effector T cells to self antigens. Increased numbers of several different subtypes of Tregs have been found in many different human cancers, including cancers of the head and neck, both as tumor infiltrating lymphocytes (TILs) and as peripheral blood lymphocytes (PBLs). Treg populations have also been shown to correlate with tumor stage in gastric and esophageal cancers. It appears that malignancy predominately increases the number of active Tregs rather than increasing each cell’s suppressive activity.

Cancers display several different methods for producing expanded Treg populations. Precise delineation of these methods has been somewhat limited by the lack of reliable cell surface markers distinguishing Treg subtypes; nevertheless, in vitro and mouse in vivo evidence suggests potential mechanisms likely active in cancer patients. Tumor secretion of local growth factors and cytokines such as VEGF, TGFβ, and IL-10 can prevent dendritic cell (DC) maturation and result in myeloid DCs that stimulate the expansion and activation of thymus-derived natural Tregs. These cytokines and immature DCs can also convert normal T cells into CD4+ (Treg-1-type) Tregs or CD8+ Treg-2 both within the tumor microenvironment and in tumor-draining lymph nodes. Finally, Treg may be recruited to the tumor site by cancer cells expressing chemokine ligands such as macrophage-derived chemokine CCL2.

As Treg accumulate in the patient with tumor, they cause both antigen-specific and nonspecific suppression of the host immune system. Treg-like tumors can produce TGFβ and IL10, cytokines which suppress the activation and function of antigen presenting cells (APCs), NK cells, and effector T cells. In addition, Treg can directly kill T cells and APCs through release of cytokotoxic granzyme B and perforin or expression of FasL.

Since Treg express IL-2 receptors at much higher levels than other T cells, it has been suggested that
Tregs outcompete effector T cells for this important growth factor, especially within the tumor microenvironment where Tregs vastly outnumber effector T cells. Finally, Tregs constitutively express transforming growth factor β (TGFβ), which blocks costimulation of effector T cells and suppressing T cell activation. Moreover, Tregs express inducible nitric oxide synthase (iNOS), which depletes L-arginine required for T cell zeta chain expression, IL-2 receptor function, and IFNγ (interferon-gamma) production. Moreover, ARG1 induces iNOS expression, and the two enzymes work synergistically. MSCs have been shown to further assist tumor growth and invasion through production of matrix metalloproteases that stimulate angiogenesis and facilitate tissue invasion. The end result is increasingly robust tumor growth and an immunosuppressive environment that predictably frustrates systemic anticancer therapies.

### Strategies to Address Tumor Immune Evasion in Cancer Therapy

Immune-based therapies are a promising new line of treatment for cancer, treatment that is potentially much more tumor-specific than the traditional modalities of surgery, chemotherapy, and radiotherapy. Current immunotherapy includes both active strategies that seek to induce and support a robust host antitumor response and passive administration of tumor targeted cytotoxic cells or antibodies. Some encouraging clinical responses have now been reported and, as these tailored therapies are improved with genetic engineering, their effectiveness will likely greatly increase. Successfully using any of these methods will require therapies that address the central problem of tumor immune evasion described previously, that is, immunotherapy must make cancer more visible, more vulnerable, and less virulent to the immune effectors that target malignant cells both within the tumor microenvironment and throughout the patient’s body.

Because of immunoselective pressure, malignancies tend to downregulate TAAs targeted by immunotherapy. One method for limiting this escape is to target TAAs vital to cancer growth and survival, forcing cancerous cells to pay a price for antigen loss. This strategy is, by definition, limited to TAAs of known function. However, the presence of alternate intracellular pathways within tumor cells may still allow downregulation of individual “vital” TAAs. Targeting multiple TAAs at the same time is likely to be more successful, which has stimulated an extensive search for novel TAA targets. An intriguing alternative is the use of gene therapy to force TAA expression by tumor cells, potentially bypassing internal gene suppression mechanisms.

The discovery of tumor-specific effector T cells in cancer patients showed that the host immune system has the theoretical potential to treat malignancies. On the other hand, the presence of self-tolerance and the fact that tumors are poor antigen presenting cells prevent most patients with established cancers from achieving immune-mediated cures. Tumor vaccines attempt to sidestep these limitations by providing TAA

MSCs, like Tregs, are a group of normally occurring immune regulatory cells co-opted by malignancies to avoid immune attack. MSCs include undifferentiated myeloid cells, macrophages, dendritic cells, and granulocytes that exhibit immature cell surface markers such as CD34 and can be differentiated into functional APCs in vitro. Human cancer MSCs were first identified in head and neck tumors. They are concentrated at the tumor site, where they mediate local immunosuppression primarily through enzymatic factors. These cells may also be present throughout lymphoid tissues and contribute to the global immunosuppression of malignancy. Mouse studies suggest that MSCs mediate a reversible block of effector T cell function rather than destruction or anergy, as surgical removal of tumor and its associated MSCs restores tumor-specific T cell function. Prognostically, clinical studies have shown an association between MSC accumulation in tumor with disease stage and duration.

MSCs are induced by various tumor secreted cytokines, in particular IL-10, VEGF, IL-6, IL-13, CSF-1, and high-dose GM-CSF. These factors block maturation of MSCs and stimulate them to suppress effector T cells, stimulate Tregs, and encourage tumor growth. MSCs in the tumor microenvironment express inducible nitric oxide synthase (iNOS), which suppresses T cell proliferation and induces T cell apoptosis by producing high levels of superoxide and nitric oxide. MSCs also target T cell cytotoxic function though the enzyme Arginase 1 (ARG1), which depletes the amino acid L-arginine required for T cell zeta chain expression, IL-2 receptor function, and IFNγ (interferon-gamma) production. Moreover, ARG1 induces iNOS expression, and the two enzymes work synergistically. MSCs have been shown to further assist tumor growth and invasion through production of matrix metalloproteases that stimulate angiogenesis and facilitate tissue invasion. The end result is increasingly robust tumor growth and an immunosuppressive environment that predictably frustrates systemic anticancer therapies.
targets in an optimized immunogenic format. By providing host APCs with tumor antigens in an inflammatory context, vaccines can overcome immune ignorance, allowing induction of endogenous effector T cells. Alternatively, vaccination with activated, TAA-peptide-loaded DCs prevents immune escape due to tumor downregulation of HLA Class I molecules, as DCs express high levels of TAA-presenting HLA-I. The structure of these HLA-restricted peptides can also be modified, producing “heteroclitic” peptides that exhibit enhanced binding to the TCRs of low-affinity T cells. Finally, gene therapy can re-establish tumor immunogenicity by forced re-expression of downregulated proteins in the HLA-I pathway of tumor cells.

Vaccination has been shown to induce successfully functional tumor-specific cytotoxic T cells in a variety of malignancies. However, the lack of a costimulatory signal at the tumor site can still prevent efficient killing. To address this, expression of costimulatory molecules, such as B7, has been induced in several carcinomas and sarcomas. In addition, squamous cell carcinoma and melanoma xenograft models have shown that costimulatory signals can be provided by infusing agonist antibodies specific for human T cell costimulatory receptors. Engineered antibodies that recognize multiple targets represent a third alternative. Each “bi-specific” antibody binds both a TAA and a T cell activation molecule, such as CD3, and provides a novel method of cytotoxic targeting combined with T cell stimulation at the tumor cell surface.

Suppressive cells co-opted by cancers have been found to be potent obstacles to immunotherapy. Treg and MSCs work together to create an immunosuppressive cytokine environment in the host, and strategies directed at reversing these effects are vital for successful treatment. Control of Treg number and function has been attempted through numerous methods: blocking chemokine-mediated Treg trafficking to tumor sites, removing stimulation provided by both MSCs and mature DCs; decreasing available IL-2; blocking CTLA-4 molecules expressed on Treg, and depleting Treg with low-dose cyclophosphamide or CD25-targeted toxins. It is clear from the toxic autoimmuneresponses induced by many of these methods that selective depletion of Treg subsets is preferable. This will require further investigation into the markers and behavior that characterize different Treg populations in patients with tumors. To address MSC immunosuppression, investigators have targeted the enzymes ARG1 and iNOS with inhibitory drugs such as nitroaspirins. In addition, MSCs can be forced to mature into functional APCs by stimulatory cytokines, all-trans retinoic acid (ATRA), or Vitamin D3. Forced maturation is a potentially powerful strategy, as refinements of this method would produce mature APCs ideally placed to capture and present TAA to effector cells for a robust tumor-specific immune response.

Immunomodulation must also address innate tumor resistance to immune attack. Aiding malignant tissues to make them more susceptible to chemotherapy and radiotherapy has been extensively studied. Similar strategies can be used to make cancer cells more susceptible to cytotoxic immune effector cells. Administration of exogenous cytokines, especially IL-2, 7, and 12, can cause direct cell death of cancer, as well as improve the potency of both nonspecific NK cells and tumor-specific cytotoxic T cells. The ability of these activated cells to destroy both tumors and tumor-associated vasculature has been clearly demonstrated in animals; however, the results in humans have been disappointing. In addition, the clinical application of cytokine therapy may be limited by the unacceptable systemic side effects. Consequently, methods to improve clinical efficacy and reduce side-effect profiles are key to future use of cytokine-based therapies. Transfection of tumors with cytokine genes may help focus cytokine action at the tumor site. Manipulation of cytokine structure also shows promise. Certain cytokine molecules can be linked to bacterial toxins to poison tumors expressing high levels of specific cytokine receptors. Furthermore, as the cytokine components responsible for producing side effects become more defined, they could be removed to decrease these specific effects. Other components that improve cytotoxic activity or protect immune cells might be enhanced to optimize their effectiveness and allow them to survive in the harsh tumor microenvironment.

The tumor microenvironment actively induces apoptosis of immune effector cells. It is, therefore, vital to protect effector cells, whether induced or administered, from attack. Many studies have confirmed that cytokine therapy, in addition to having antitumor effects, also reduces the susceptibility of immune effector cells to undergo apoptosis. These cytokines upregulate factors that inhibit caspases and downregulate pro-apoptotic Bcl-2 family members. Less studied are strategies, such as RNA interference, that reduce tumor virulence through decreasing tumor expression of death-inducing ligands such as Fas, or B7-H1. By reducing these immune-killing molecules, most likely several concurrently, the process of cancer “counter attack” can be thwarted, and the balance of cytotoxicity can be shifted in favor of the immune system.

Strategies of immune protection are particularly potent when combined with adoptive T cell therapy. Because the T cells are activated and expanded ex vivo, immunologists can tailor these lymphocytes to improve tumor recognition, as well as their resistance to tumor-induced apoptosis. Although most work to date has used patients’ own T cells, derived from either TILs or PBLs, it is now known that lymphocytes taken from patients with advanced cancer are functionally compromised due to the general immunosuppressive state of malignancy. Furthermore, they often exhibit limited persistence after adoptive transfer due to poor proliferation and rapid depletion. Tumor recognition and cytolytic function can be augmented through genetic engineering strategies that provide the T cells with high expression of TAA-specific TCR molecules or block intracellular inhibitory pathways. Lymphocyte persistence is improved with cytokine stimulation of proliferation and could also benefit from genetically engineered overexpression of anti-apoptotic molecules, such as Bcl-2 or IAPs. Finally, pro-apoptotic

Figure 4: Tumor direct and indirect counterattack. Direct attack of cytotoxic T cells by tumor utilizes inhibitory cytokines, costimulatory molecules (B7-H1), and membrane-bound or soluble death receptor ligands (FasL or sFasL). Indirect attack occurs when tumors produce soluble factors that recruit or induce regulatory T cells (Treg) or myeloid suppressor cells (MSCs). These suppressor cells then contribute their own cytokines to an effector counterattack.
molecules might be reduced with novel small molecule inhibitors and RNA interference strategies, prior to transfer into tumor-bearing patients. 

CONCLUSIONS

The human immune system and programmed cell death machinery may prevent the vast majority of aberrant cells from ever becoming life-threatening malignancies; however, those cells that do survive to establish growing tumors are masters of immune evasion. The multiple pressures of innate and adaptive host immunity produce cancers that are weakly immunogenic, resistant to cytotoxic attack, and capable of twisting normal immune defenses to their own ends. In particular, tumors use components of the homeostatic apoptosis pathways to evade destruction and mount a counterattack against effector cells that enter their microenvironment. The challenge of immunotherapy is to tip successfully the balance in this “arms race” toward immune induction and potency without producing unacceptable levels of autoimmune disease or inflammatory side effects. Current immune modalities such as vaccination, cytokine administration, and adoptive lymphocyte transfer have produced some promising clinical results to date. The addition of novel molecular and genetic strategies has the potential to increase treatment specificity and effectiveness even more. In the future, combinations of these therapies will allow clinicians to attack a cancer from multiple sides at once while protecting and enhancing immune cells tailored to that tumor’s particular methods of immune evasion.

Molecular Diagnostic Approaches to Head and Neck Cancer

Ian M. Smith, MD
Joseph A. Califano, MD

Each year approximately 40,000 people in the United States and 500,000 people worldwide are diagnosed with head and neck squamous cell carcinoma (HNSCC). Despite significant improvements in the last few decades in the treatment of this disease, the 5-year survival rate has remained essentially unchanged at 50%. HNSCC continues to be a treatment challenge because of an advanced stage at presentation and a high rate of disease recurrence. Early stage at diagnosis continues to be the strongest factor in predicting survival. Coupled with emerging biomedical technologies, there has been a large push to develop early screening and noninvasive diagnostic tests for HNSCC.

These molecular diagnostic approaches are often based on the developing understanding of the genetic and epigenetic alterations and viral agents that have been implicated in the tumorigenesis of head and neck neoplasms. Efforts have been focused on leveraging these advances in our understanding of tumor molecular biology into relevant applied management.

Investigators have analyzed body fluids and margins for the presence of cancer cells. Improved molecular characterization of primary tumors, surgical margins, and body fluids may allow clinicians to detect and treat earlier lesions, predict a tumor’s response to treatment, tailor treatment to specific molecular alterations, and ultimately improve clinical outcomes related to HNSCC.

To date, many biomarkers have been studied that show promise: human papilloma virus (HPV) positivity, p53, cyclin D1, p16, cyclooxygenase-2 (Cox-2), epidermal growth factor (EGF), and vascular endothelial growth factor (VEGF). This chapter presents the findings on potential molecular biomarkers for HNSCC and discusses their malignant potential as well as their genetic background and may be associated with varied histological evidence of dysplasia.

HNSCC is highly correlated with environmental exposures such as cigarette smoke or smokeless tobacco, and most theories concerning the etiology of HNSCC are derived from accumulated heritable changes that are inflicted by DNA damaging, carcinogenic exposures. Ultimately, survival rates are highly dependent on stage at presentation, so early diagnosis should lead to improved overall survival of those with head and neck cancer.

EARLY DETECTION AND SCREENING

HNSCCs have a tendency toward late-stage presentation. This is because these growing neoplasms are often asymptomatic. Taken as a whole, the noted exception is that of laryngeal lesions which can often arise on the vocal folds and cause hoarseness which often leads to an earlier medical presentation, as well as anterior oral cavity lesions that may be easily visualized by the patient or primary care medical or dental professionals. Other head and neck cancers will present with dysphagia, odynophagia, or a mass, symptoms associated with late-stage presentation. While the proposed molecular model of cancer progression is new, cancers have long been noted to arise from premalignant precursors. This chapter will cover areas of investigation in molecular diagnostics, which include tests that may be adapted to screen high-risk populations without previous symptoms or findings, and the development of tests that may be used

for detection of occult, persistent, or recurrent disease in patients who have already been diagnosed with HNSCC.

**Issues with Molecular Detection**

Molecular assays for disease can be divided into two uses: population-based screening tests and molecular detection. Population-based screening tests do benefit from well-outlined risk factors including tobacco and alcohol use but suffer because of the difficulty in producing tests with adequate sensitivity so that they are useful in detection and adequate specificity to not generate large numbers of false positives in the setting of low incidence. Molecular detection strategies studied to date include molecular margin detection, detection of nodal metastasis, and disease surveillance after treatment. These techniques require reasonable sensitivity over and above the current guidelines for disease surveillance, physical examination, and imaging.

Tests developed in the laboratory for molecular diagnosis must be validated in clinical trials. To date few of the approaches for molecular screening and diagnosis have been taken to clinical trials with the notable exceptions of tests for loss of heterozygosity (LOH) used for prognosis and toluidine blue as a detection means.

**Sample Collection**

Unlike other fields where screening approaches have worked with more traditional clinical pathology approaches, such as cytology, head and neck cancer diagnosis still relies on physical examination, imaging, and biopsy. Much controversy exists regarding the application of oral cytology, but this technique generally suffers from low specificity. However, many types of clinical samples exist for testing patients. Samples for screening and diagnostic studies can come from various sources and be collected in a variety of fashions. Efforts to use fractions of the blood for molecular diagnosis will be discussed in this chapter. Studies utilize either blood plasma, the liquid component of blood, or the serum, blood plasma in which clotting factors, for example, fibrin, have been removed.

From the oral cavity, several collection methods exist. Salivary rinses refer to sample collection in which a patient simply expels their saliva and oral liquid into a specimen cup. Oral rinses are commercially available liquids that patients swish and then spit into a cup. Oral brushes can be made from commercially available cytology kits in which a patient’s oral mucosa, particularly an area of interest can be brushed which yields markedly more cells.

**Human Papilloma Virus**

Over the past few years, the body of literature implicating the HPV in the carcinogenesis of HNSCC has been building. HPV has long been a well-characterized primary cause of cervical cancer that has yielded one of the most effective forms of cancer screening, early detection, and increased cure rates. HPV is now recognized as a likely cause of head and neck cancer. There are numerous subtypes of this virus (>120), but most have not been shown to be carcinogenic. HPV subtypes 16 and 18 are the best-studied subtypes, but the majority of evidence in head and neck cancer has implicated HPV subtype 16 as an etiologic agent.

HPV contains two key proteins E6 and E7 that have the potential to transform human cells. These viral oncoproteins have been shown to inactivate two crucial human tumor-suppressor genes p53 (E6) and retinoblastoma protein (pRb or E7). This inactivation results in loss of cell-cycle control, impaired cell differentiation, increased mutations, and chromosomal instability.

Overall in HNSCC, HPV genomic DNA can be detected by real-time PCR-based methods in 26% of all cancers. However in head and neck cancer, this virus has a predilection for the lingual and palatine tonsils of the oropharynx. Data looking at only the subset of the oropharynx suggest 50% or more of these tumors are HPV positive.

Interestingly HPV-associated cancers have been shown to have increased survival and outcomes. Schwartz and colleagues found HPV 16-positive patients had significantly reduced mortality and disease-specific mortality compared with HPV 16-negative patients after adjustment for age, stage, treatment, smoking, alcohol, education, and comorbid disease.

New studies show promising molecular screening approaches that have increased sensitivity for detection. Real-time PCR of HPV-associated DNA is now the standard for detection at low thresholds. However, employment of these technologies as screening tests suffers from low sensitivity. Zhao and colleagues studied the utility of saliva screening for HPV and found that in a cohort of patients with HNSCC with a 45.6% incidence of tumor HPV positivity only 57% of the positive patients with tumor had detectable saliva rinse HPV 16 which resulted in a sensitivity of 32.6% for the saliva rinse test for head and neck cancer. Depending on the threshold for HPV 16 positivity in the assay, specificity only increased slightly, from 97.2 to 98.7% at the higher cutoff and the authors conclude that 99% specificity would be required for population-based screening.

HPV seropositivity has also been an intriguing risk-factor for the development of head and neck cancer, and the largest study examining HPV 16 seropositivity found an odds ratio of 2.2 for developing head and neck cancer in a cohort of 292 patients followed in a screening study who had eventually developed HNSCC, 50% of the oropharyngeal and 14% of tongue cancers contained HPV-16 DNA, according to PCR analysis. The diagnostic utility is again poor, related to the number of HPV seropositive patients who will not develop head and neck cancer or have seropositivity from any number of other sources. Technologies such as competitive PCR coupled with mass spectrometry have promise to yield more specificity compared to real-time PCR, detecting with accuracy a single copy of DNA, but the issue of false-positive nonpathologic detection of HPV remains.

In a case-control study examining HPV16 in the saliva, 19% of head and neck cancer patients (201 total) were saliva-positive, and 10% of control subjects (333 total) were positive, with an odds ratio of 2.6. While the utility in population-based screening is still being evaluated, HPV positivity may eventually play a role in disease monitoring and surveillance.

**Microsatellite Instability**

Microsatellite instability (MSI) is an additional molecular alteration discovered initially in colon cancer that has been found in head and neck cancer. MSI refers to alterations in copy number of small repeats of a short nucleotide motif, that is, usually one to five nucleotides long. For example, a mononucleotide repeat might be a stretch of 17 adenines and the most common microsatellite in humans is a dinucleotide repeat of cytosine and adenine, which occurs in tens of thousands of locations in our genome. In MSI, these areas are aberrantly replicated leading to expansion or contraction of the specific area. In colon cancer, MSI has been linked to errors in DNA replication and DNA repair enzymes. After their discovery, efforts were made to utilize microsatellite alterations to detect cancer cell DNA in a background of normal cells. Microsatellite analysis can reveal either MSI or LOH in a given amplified microsatellite repeat locus (Figure 2). Head and neck cancers have been found to have MSI at a variety of loci in the genome.

For screening and diagnostic purposes, these tumor-specific alterations have been found in the saliva and plasma of patients with these changes. A specific subset of alterations was initially reported in the serum of 29% of patients with HNSCC. Subsequently, these alterations were studied in the saliva samples of patients with HNSCC in a screening feasibility study to detect tumor-specific genetic alterations in exfoliated oral mucosal cell samples from 44 patients with HNSCC and 43 healthy control subjects. Their results showed that LOH or MSI of at least one marker was detected in 38 (86%) of 44 primary tumors with identical alterations found in the saliva samples in 35 of these 38 patients (92% of those with markers; 79% overall). MSI was detectable in the saliva in 24 (96%) of 25 patients in whom MSI was present in the tumor, and LOH was identified in the test sample in 19 (61%) of 31 patients. No microsatellite alterations were detected in any of the samples from the healthy control subjects.

These tests are just now starting to be clinically available from pathology services. The ability to detect microsatellite changes in the background of blood or saliva can reduce markedly the sensitivity of these tests and has resulted in significant limitations on the widespread adoption of the technology.
**Microsatellite Instability**

Microsatellite instability (MSI) is a genetic instability that occurs in the DNA of cancer cells. It is commonly associated with certain types of cancer, particularly colorectal cancer. MSI results from errors in DNA replication during cell division, leading to the insertion or deletion of short repeated DNA sequences. These changes can disrupt the normal function of genes, contributing to the development of cancer.

**Figure 2** Microsatellite instability (MSI) in cancer, example coding sequence, and example diagnostic DNA gel. A rea of MSI have been noted in many places in the genome. On a given chromosome, one area can be tested with specifically designed primers that flank the area. Differences in the lengths of the products are seen by the distance of migration on the gel. PCR = polymerase chain reaction; DNA = deoxyribonucleic acid; CA = cytosine and adenine.

**p53**

p53 is a powerful tumor-suppressor gene found altered in many cancers and the inherited Li-Fraumeni cancer syndrome of cancer susceptibility. p53 is a transcription factor, that is, binds to a gene’s promoter and upregulates transcription of mRNA, that is activated in normal cells for a variety of reasons when DNA has been damaged. p53 induces cell-cycle arrest in response to DNA damage, as well as either DNA repair activation or activation of apoptosis, depending on the context of the DNA injury (Figure 3).

Mutations, specifically missense, in p53 have been found in many human cancers and are present in around 50% of head and neck cancers. Detecting these mutations in body fluids in patients with HNSCC has been the subject of a variety of studies. Early efforts used plaque hybridization approaches to identify known p53 mutation in salivary rinses from patients with corresponding p53 mutation in primary HNSCC in five of seven patients.

Other approaches involve the observation that patients with cancer often generate p53 antibodies. Investigators have found that 27% (7/26) of patients with head and neck cancer who had recurrent cancer had p53 autoantibodies detected, versus none of the sera in the controls. In addition, these p53-positive patients had noticeably poorer prognosis (p < .005), and overall survival rate at 5 years of the p53-positive group was 24% (half that of the p53-negative group).

Clinical utilization of p53 protein detection strategies and p53 mutation detection strategies for screening has not seen implementation although efforts continue to be made to link treatment response to p53 mutation.

**Mitochondria**

Mitochondria are the source of aerobic energy to meet a cell’s demands for adenosine triphosphate (ATP). Mitochondria are critically involved in the production of ATP, and they are also involved in the regulation of apoptosis, generation of free radicals, and source of cellular energy in rapidly dividing cells using increased energy. Their role in tumorigenesis has been hypothesized in head and neck cancer. Mitochondria have their own genome (Figure 4) that includes genes encoding mitochondrial DNA (mtDNA) and cytochrome c oxidase.

**Figure 3** Function of the transcription factor and human cancer tumor-suppressor gene p53. DNA damage from a variety of source leads to a tetramerization and activation of p53 that causes activation of DNA repair, arrest of the cell cycle, and activation of apoptosis. In head and neck cancers, missense mutations can occur at almost any point in the coding sequence, but the majority are in the DNA binding domain.

**Figure 4** Map of the human mitochondrial genome. Shown here are the seven subunits of nicotinamide adenine dinucleotide (NADH) dehydrogenase-2 (ND2), one unit of the coenzyme Q oxidoreductase (ND), and two subunits of ATP synthase (A), and the protein synthesis genes (12s and 16s). Also shown are the genes for the 22 transfer RNA (tRNA) genes. mtDNA = mitochondrial DNA.

**CD44**

The soluble adhesion molecule CD44 has been implicated in the pathogenesis of head and neck cancer. It is an attractive molecular alteration for molecular diagnosis because of its cell-surface location and its availability for clinically employable approaches such as ELISA. In an important study of 81 patients with head and neck cancer and 20 controls, the levels of soluble CD44 standard (sCD44), soluble CD44 variant 5 (sCD44v5), sCD44v6, soluble intercellular adhesion molecule (sICAM-1), and soluble vascular cell adhesion molecule (sVCAM-1) were considered before and after treatment of HNSCD diagnosis, age, and smoking with increasing mtDNA/nuclear DNA for cytochrome C oxidase I (Cox I) and Cox II.

This group found that levels of all five of these markers were significantly higher in the HNSCC group than those of the control group. Coupled
with this was the finding that sCD44s, sCD44v5, sCD44v6 median serum level was significantly diminished after treatment. However, a separate group considering CD44 isoforms in the serum utilized ELISA to show that, “there was no significant difference between the serum levels of sCD44v6 in HNSCC and healthy smokers. Nor was there a correlation between the serum level of sCD44v6 and UICC (International Union Against Cancer) stage, TNM stage or histologic grading.”

E G F R

HNSCC have been shown to have upregulated EGF pathways. These growth factors fit within the molecular tyrosine-kinase family of cell-surface receptors that have been implicated in the pathogenesis of many forms of cancer. EGFR receptor (EGFR) overexpression is observed in 42 to 80% of head and neck cancers. In fact in a meta-analysis of eight trials, seven trials showed a poorer outcome for patients with EGFR overexpression. Promising clinical trials of tyrosine kinase inhibitors such as cetuximab have demonstrated the role these signaling pathways can play in the treatment of head and neck cancer.

V E G F

VEGF is also a promising serum biomarker. A group at the University of Michigan studied the utility of measuring serum VEGF levels via ELISA in a group of controls versus patients with cancer of the larynx and found that for the healthy control group the level was 47.83 ± 0.13 pg/mL, compared with the mean s-VEGF level of 317.22 ± 25.46 pg/mL in the cancer patients. This elevation was statistically significant (p < .001), and in a univariate analysis, elevated s-VEGF correlated with poor Karnofsky performance status for all patients with advanced laryngeal carcinoma (p < .008).

M ethylation

Heritable alterations in head and neck cancer have broadened from the early understanding of changes such as gene mutation, for example, missense or deletion, LOH, genomic deletions, amplifications, and translocations to epigenetic changes. Epigenetics is the study of DNA alterations that do not affect the coding of bases but do affect the regulation of genes. Examples of these changes that are inherited by cells in a clonal fashion include promoter hypermethylation, acetylation, and histone modifications. By far the most useful to date and best studied of these in HNSCC is gene promoter hypermethylation. This phenomenon takes place in the regulatory units of the genome (the promoters) in areas called CpG islands. CpG (cytosine-guanine dinucleotides) can be modified at the 5’ carbon of the carbon ring of cytosine (Figure 5), by the addition of a methyl group from s-adenyl methionine (SAM) by the DNA methyl-transferase enzyme family (DNMT). Although this phenomenon was initially shown to be the cause of X-chromosome inactivation and genetic imprinting, inactivation of tumor-suppressor genes in this manner has been increasingly shown to play a role in tumorigenesis. This keeps with the basic principles of the Nudson two-hit hypothesis which suggests that tumor-suppressor genes are inactivated by two separate hits to a gene’s alleles. Methylation has been shown to be sufficient to cause a “hit” to one allele in many cases. Once both alleles have been silenced, the cell undergoes changes in its phenotype that are more malignant, for example, cell-cycle alterations, inhibition of apoptosis. Tumors have been shown to preferentially shed DNA, and one large advantage of methylation is its ready use for screening, as DNA is stable in the blood or saliva, and small levels of methylation can be detected by sophisticated means, including bisulfite sequencing, quantitative or standard methylation-specific PCR (Figure 6) in a background of other DNA products.

Early molecular biology work in head and neck cancer on methylation examined a panel of four putative tumor-suppressor genes whose inactivation was associated with a cancer phenotype. These genes, p16, MGMT (methylguanine-DNA methyltransferase), GST-π (glutathione-S-transferase Pi), and DAPK (death-associated protein kinase) exhibited significant promoter hypermethylation in at least one of the four genes in 42% of primary tumors. Other genes epigenetically silenced include RASSF1A, hMLH1 (DNA mismatch repair gene), E-cadherin, and recently, a group has found that HNSCC shows promoter hypermethylation of at least one of the four genes in 42% of primary tumors. Other genes being studied include ATM (ataxia-telangiectasia).

Once these molecular changes were identified, screening for these hypermethylated promoters was undertaken in the laboratory. In screening for these genes in body fluids and tissues, recent studies have shown correlation in the presence of methylation of p16 among tumors, saliva, and serum with methylation-specific PCR (MSP) noting no methylation in normal controls. In an attempt to look at the presence of methylation in premalignant lesions, a group found methylation in the oral rinses of patients with premalignant lesions corresponded to that of reported cancer oral rinse methylation rates; and p16 and MGMT were observed to be methylated with MSP in 44 and 56% of the oral samples, respectively. To date it has been difficult to develop assays with sufficient sensitivity (HNSCC tumors are heterogeneous in their genetic changes) and specificity (normal cells may have methylated alleles) for clinical application.

Gene Expression Microarray

Expression microarrays utilize a small silicon chip embedded with thousands of gene-specific oligonucleotides to study the simultaneous mRNA expression of many genes in a sample. This technology affords an unmatched ability to compare large numbers of gene expressions in many samples to establish differences in gene expression patterns between, for example, tumor tissues and normal tissues. In the field of molecular diagnostics, scientists have used this technology to create a gene expression signature that can differentiate normal aerodigestive mucosa from HNSCC. One of the prominent examples for the use of gene expression microarray in clinical oncology is from the breast cancer literature where gene expression array clustering analysis has a proven efficacy in determining treatment effects and prognosis proven in clinical trials. In head and neck cancer, this approach has been employed for screening and diagnosis. These techniques have been applied to saliva and blood serum to look for early detection markers. Despite the inherent advantages of this technique, the inherent instability of RNA in the blood or saliva makes these techniques tenuous.

Efforts to examine the mRNA expression differences in the saliva have been promising. A group at the University of California Los Angeles (UCLA) found 1,679 genes had differing expression levels in saliva of patients with HNSCC and controls (p < .05). These potential salivary RNA biomarkers were interleukin-8 (IL8), IL-B, dual specificity phosphatases (DUSP1), hemoglobin 3 (HA3), ornithine decarboxylase antizyme 1 (OAZ1), S100P, and SAT, and in combinations yielded sensitivity (91%) and specificity (91%) in distinguishing squamous cell carcinoma. These findings have yet to be validated in an independent set, and recent results have brought up questions about the efficacy of this technique. A recent feasibility study concluded: “The combination of (a) a minimal microarray signal, which was unaffected by RNase treatment, (b) the presence of a conventional RT-PCR
been applied in the field of head and neck cancer at widespread protein expression in a sample. These techniques are in the category of "proteomic," a study that looks at large numbers of proteins. These techniques include two-dimensional SDS-PAGE, which uses primers specific to methylated versus unmethylated CpGs, and quantitative MSP (does the same with real-time PCR).

These proteomic techniques have just recently been applied in the field of head and neck cancer. Methylated cytosine residues are protected from the bisulfite reaction, and changes from cytosine to thymine can be seen in unmethylated bases. Methylated cytosines can be differentiated from unmethylated ones in this manner. After bisulfite treatment, methylation can be studied by bisulfite sequencing, methylation-specific PCR (MSP) which uses primers specific to methylated versus unmethylated CpGs, and quantitative MSP (does the same with real-time PCR).

Proteomic Approaches

Beyond expression microarray, new proteomic techniques that compare protein expression between cancer and normal tissues promise the possibility of identifying in the blood or saliva, new markers that would be amenable to clinical tests in the form of ELISAs. Techniques include two-dimensional SDS-PAGE (sodium dodecyl sulfate-polyacrylamide gel electrophoresis) that separate proteins based on size, charge, and isoelectric point, also the improvements of mass spectrometry and SELDI-TOF (surface-enhanced laser desorption and ionization time-of-flight) mass spectrometry as well as MALDI-TOF (matrix-assisted laser desorption ionization time-of-flight) mass spectrometry techniques that look at large numbers of proteins. These techniques are in the category of "proteomic," a study of whole-genome protein expression in a sample. Protein-based microarray technologies with chips embedded with a library of known antibodies (>10,000 is now possible) are also available to look at widespread protein expression in a sample.

These proteomic techniques have just recently been applied in the field of head and neck cancer research. The most recognized and promising study is from Soltys and colleagues, which implemented SELDI-TOF mass spectrometry to look at the plasma of patients with head and neck cancer (57 vs 52 controls). In this study, they generated a total of 37,356 data points representing the protein profile for each sample, and from these two groups significant differences in protein expression were isolated to 65 specific SELDI-TOF peaks. This study also included a blinded "validation set" of 57 cancer patients and 52 normal controls, with an attempt to predict from the plasma if the patient has cancer based on this "discovery pattern." These results were promising and showed correct identification of 39 of 57 patients with HNSCC and 40 of 52 noncancer controls, a sensitivity of 68% and specificity of 73%. Interestingly, their model tended to overpredict cancer in control smokers. These types of high-throughput molecular marker discovery techniques will be critical for finding diagnostic and predictive detectable changes in the blood or saliva.

In addition, a group at the University of Pittsburgh recently used simultaneous testing using a multiplexed immunonuclease-based panel to assay in the serum 60 biomarkers simultaneously in 116 patients with HNSCC before treatment, 103 patients successfully treated, and 117 smoker controls. The highest diagnostic power was composed of 25 biomarkers, including EGF, EGFR, IL-8, TPA (tissue plasminogen activator) inhibitor-1, α-fetoprotein, MMP-2 (matrix metalloproteinase-2), MMP-3, IFN-α (interferon-α), IFN-γ, IFN-inducible protein-10, regulated on activation normal T-cell expressed and secreted (RANTES), macrophage inflammatory protein-1 α, IL-7, IL-17, IL-1 receptor-α, IL-2 receptor, granulocyte colony-stimulating factor, mesothelin, insulin-like growth factor binding protein 1, E-selectin, cytokeratin-19, VCAM, and cancer antigen-125. This study had a remarkable sensitivity of 84.5% and specificity of 98%, and 92% of patients in the active disease group correctly classified from a cross-validation serum set. This is extremely promising data that suggests that utilizing many markers in tandem may enable adequate sensitivity and specificity for molecular detection.

These technologies do have difficulties producing reproducible results in validation sets, but there are significant signs that this type of approach will eventually afford new molecular markers that could be used in diagnosis and prognosis of HNSCC.

MOLECULAR IMAGING

Radiological imaging has recently joined the array of molecular techniques being employed to diagnose head and neck cancer. Radiologists now offer molecular-based physiologic and functional imaging that boasts an ability to improve the diagnosis and staging of head and neck cancer. Of these techniques, combined positron emission tomography-computed tomography (PET-CT) imaging or conventional PET has been the most utilized in the clinic. PET works by detecting gamma radiation emitted from a tracer that is designed to be a biological component that will undergo specific interactions. By far the most commonly used tracer is fluorodeoxyglucose (FDG) which is a molecular marker, an analog of part of the glucose pathway, and this produces signal most strongly in cells metabolizing large amounts of glucose. This tracer is also the most commonly used imaging tracer in the diagnosis and staging of HNSCC; and, while sensitivity is often excellent, this technology has many false positives caused often times by benign inflammation. Yet in the clinical setting, PET scans are now routinely used to define the extent of primary disease, the presence of lymph nodal spread, and distant metastasis. PET is also routinely used for follow-up, to assess response to chemotherapy or radiation therapy, and to detect disease spread.

In addition to this typical use, PET scientists now offer more advanced tracers that can molecularly target specific epitopes. Researchers are working on utilizing PET tracers that bind to the VEGF receptor that has been shown to be upregulated in HNSCC. Researchers have also used DNA precursors, which are incorporated into DNA during repair or division, which identifies areas of cell proliferation. Imidazole agents can identify areas under hypoxic conditions. PET scans are already quite sensitive, but improvements in molecular targeting of tracers will invariably lead to improved diagnostic capabilities that will be used by physicians in the clinic.

Figure 6: Bisulfite treatment. Bisulfite treatment is the foundation for technologies that assess promoter and CpG island methylation status. Methylated cytosine residues are protected from the bisulfite reaction, and changes from cytosine to thymine can be seen in unmethylated bases. Methylated cytosines can be differentiated from unmethylated ones in this manner. A bisulfite treatment, methylation can be studied by bisulfite sequencing, methylation-specific PCR (MSP) which uses primers specific to methylated versus unmethylated CpGs, and quantitative MSP (does the same with real-time PCR).
Molecular diagnostics also encompasses the prediction of which premalignant lesions will become cancer. Diagnosis of oral premalignant lesions is currently based on clinical information: histopathologic features, lesion site, and staging. Many recent advances in the diagnosis and prediction of malignant progression have been made.

Loss of Heterozygosity

Recently, promising advances in molecular methods offer to change the evaluation and diagnosis of oral premalignant lesions and squamous cell carcinoma (Figure 7). Early changes in HNSCC include LOH at two specific chromosome sites (sites 3p14 and 9p21). These changes are correlated to clinical outcome, with a study of 48 oral squamous cell carcinomas (OSCCs) showing that patients with allelic imbalance (AI) at 3p24-26, 3p13, and 9p21 having a 2.5-times increase in their mortality rate. Increased frequencies of AI at more loci (p = .022), without consistent patterns, were found in the three grades of dysplasia: mild, moderate, and severe that developed into cancer (39 cases) compared with case-matched controls (26 cases), with at least one marker.51 These changes are correlated to clinical outcome, with a study of 48 oral squamous cell carcinomas (OSCCs) showing that patients with allelic imbalance (AI) at 3p24-26, 3p13, and 9p21 having a 2.5-times increase in their mortality rate.52

Aneuploidy

In 2001, Sudbo and colleagues published an impressive study in the New England Journal of Medicine evaluating the prognostic value of chromosomal copy changes, that is, aneuploidy, in HNSCC. His group found a substantial link between cancer progression in premalignant lesions and chromosomal aneuploidy. This assessment was impressive and ground breaking, but this publication has recently been the source of considerable controversy, with a subsequent publication in the same journal questioning the validity of one of the primary figures, and ultimately a retraction printed because of an oversight group finding fabrication of data. At this time, further work is being conducted to validate if there is any promise of the effect of chromosomal aneuploidy on the progression of premalignant lesions.

Toluidine Blue

The primary nonmolecular tools use vital tissue staining with toluidine blue (TB) and exfoliative cytology. Toluidine blue is a metachromatic dye that stains mtDNA. The use of TB to stain premalignant lesions in the clinical office has been a promising new advance in the diagnosis of head and neck cancer. Studies employing toluidine blue for evaluation of suspicious oral lesions have demonstrated impressive sensitivity, low false negatives and good positive predictive values. This stain is used in the oral cavity to differentiate dysplasia from carcinoma, and clinical studies are in progress to affirm its widespread application. From a molecular diagnostic point of view, this technology was recently compared to a panel of loci that have known LOH in head and neck neoplasms. The study considered biopsy specimens (14 hyperplastic, 25 dysplastic), 14 of which were TB-negative. TB-positive samples had a higher frequency of LOH (panel of 10 microsatellite loci on 3p, 9p, or 17p was used) than TB-negative cases at 3p (p = .013) and 17p (p = .049). More TB-positive samples demonstrated LOH at multiple arms (>2 arms, p = .015), which was found to be associated with markedly increased cancer risk. An additional study considering TB-stained lesions found that all of the patients with SCC or carcinoma in situ cases showed LOH, but more than one-half (59%, 13 of 22) of the normal epithelia also harbored LOH in at least one marker.51

Surgical Margins and Lymph Nodes

Surgical margins and lymph nodes are an area requiring the development of molecular methods for the detection and diagnosis of head and neck cancer. Methods that detect residual disease would be helpful in reducing local recurrences and regional metastasis and lead to improved staging and better outcomes. Several studies have been conducted in this area, and they use many of the techniques and targets discussed previously, for example, p53, VEGF, cyclin D1, methylation. In a study of surgical margins and lymph nodes, negative surgical margins were positive based on p53 mutation in 13 of 25 cases, and negative lymph nodes actually harbored a mutation in 6 of 28 cases.54 Differentiating at surgical margins which lesions are genetically identical to the primary lesion in contrast to separate lesions that are part of an overall field effect, for example, genetic changes affecting a large area of tissue caused by tobacco smoke, have complicated this field greatly. In a small study that wished to address this, 61% of lesions studied that had recurred appeared to be part of a field effect cancerization which underscores the importance of close follow-up for these patients and the difficulty in relying on molecular means at the margin of a resection to diagnose direct cancer extension in the absence of histological proof.55

Other techniques used for molecular margin analysis include methylation detection strategies: quantitative MSP (QMS) to look for promoter methylation in operative margins during resection and a pilot study doing this found methylation at the margins in 50% of cases where the primary tumor was also methylated.56 A second study looking at immunohistochemical expression of p53 and the proto-oncogene eEF4E (4E) found a significant difference in the disease-free interval between patients with 4E-positive and 4E-negative margins (p = .003), but not significant with p53 multivariate analysis.57 The results provide promise that molecular detection at the margin will eventually prove to have prognostic significance and possibly guide surgical management.

Molecular detection of occult tumor cells in lymph nodes is made easier by the facts that there is no background of field cancerization nor the genetic changes of dysplastic lesions to confound the molecular results. This field does struggle with
trying to show that there is a survival difference or staging difference for micrometastasis, as well as the type of detection molecular analysis that lymph nodes avail in the setting of grossly negative nodes. In the M. D. Anderson Cancer Center retrospective study considering selective neck dissection failures, they found selective neck dissection was definitive if all the nodes are negative based on standard pathological assessment; but, if the node was invaded with cancer, postoperative radiation offered benefit. Other efforts to find micrometastasis considered whether p53 mutations could be detected in lymph nodes and found that 5 of 33 (15%) nodes examined showed metastases by light microscopy, but 11 of 33 (33%) were found to be tumor positive with molecular diagnosis.

Other work on squamous cell carcinoma antigen (SCCA) mRNA expression in 198 historically metastasis-negative lymph nodes found SCCA mRNA expression in 37 (18.7%) by nested PCR and micrometastatic foci were found in 9 of these nodes (4.6%), with additional sectioning. Other subsequent studies have considered the M UC1 gene, EGFP, cytoketin-14 (CK14), CK 20 primarily using RT-PCR. Each study has been shown to uncover successfully patients with negative lymph nodes; but because clinical management of head and neck cancer dictates that patients with even a slight risk of nodal metastasis based on tumor site and staging receive therapy that treats the nodal basins of the neck with either radiation therapy or surgical node dissection; this increased detection in finding regional lymph nodal disease has not translated to improved control or survival changes.

**CONCLUSIONS**

Molecular diagnosis of head and neck cancer remains in the preclinical stages. To date, few advances have made it into the clinic. At present, there are many diagnostic markers and diagnostic techniques that show promise. Indeed, technologies, such as, mRNA expression arrays, proteomic approaches (protein microarrays, SELDI/ MALDI-TOF mass spectrometry), molecular imaging techniques (PET), RT-PCR, quantitative DNA PCR, QMSP, ELISA, all offer hope in detecting molecular changes in head and neck cancer. Changes studied include the detection of inactivation (LOH), mutations (p53, p16, cyclin D1, VEGF), expression levels, protein levels, and presence of methylation. These techniques will be applied in six areas: screening high risk patients for disease, predicting malignant progression, improvements in staging and prediction of outcome, therapy selection, adequate margin assessment, and diagnosis of metastases to lymph nodes.

Many lessons have been learned over the last few years. Studies must perform rigorous murine analyses to reach significance, often times multiple markers are needed. In every case, these diagnostic markers obtained through validation of one set of patients must be validated in new cohorts. These targets require the design of prospective clinical studies to validate and prove efficacy. There is considerable reason for optimism that, in the near future, novel molecular markers will exist that will assist in the diagnosis of patients uninvasively and predict clinical course and response to therapy.

Imaging of the Oral Cavity, Pharynx, Salivary Glands and Neck

Robert E. Morales, MD
Adam E. Flanders, MD

Imaging plays a major role in the work-up of patients with head and neck diseases. The modalities commonly utilized for the radiologic evaluation of the neck include computed tomography (CT), magnetic resonance imaging (MRI), and combined positron emission tomography with computed tomography (PET-CT). The role of the radiologic evaluation is to determine the extent of a lesion, identify associated findings and characterize these findings to stage the lesion or develop a differential diagnosis.

In evaluating the extent of a mass, the portions of the lesion “hidden” beneath the skin or mucosal surface are of particular importance as these areas are difficult to assess by clinical examination. In addition to the lesion’s dimensions and extent, critical imaging features such as osseous invasion or perineural spread must be assessed. Finally, a fundamental understanding of anatomic landmarks and spaces is essential as the resultant information may alter surgical approach or therapeutic management.

The identification of lymphadenopathy is paramount to the complete imaging interpretation. Reactive or neoplastic lymph nodes should be identified. These include enlarged lymph nodes or lymph nodes of any size that have necrosis. The margins of the lymph nodes also need to be evaluated for extranodal extension. The adjacent fat planes surrounding the primary lesion are also studied for the presence of tumor infiltration or edema. Extensive edema with overlying skin thickening usually suggests an infectious/inflammatory process although occasionally a neoplastic process can cause lymphatic obstruction resulting in a similar appearance.

The imaging evaluation of head and neck disease is not complete without a full description of the intrinsic imaging features such as density or signal intensity of a process on CT or (MRI), respectively. This includes a description of the internal architecture and composition including the presence of calcification, necrosis, cyst formation, or prominent vascularity. Imaging margins adjacent to or surrounding a process offer clues regarding growth characteristics. Irregular, infiltrative margins often suggest a more aggressive or rapidly growing lesion. When a process abuts an osseous structure, erosion of the bone is a feature more suggestive of rapid expansion whereas bone remodeling with a sclerotic margin often suggests slow growth.

This chapter will summarize the imaging approach to the various regions including the nasopharynx, oropharynx, larynx and hypopharynx, oral cavity, salivary glands, and the suprahyoid portion of the neck. There is emphasis on the anatomic approach to the involved spaces and a focus on particular anatomic landmarks that aid in description of a lesion or in developing a differential diagnosis. Where appropriate, the imaging characteristics of some of the more common lesions will be described.

SUPRAHYOID PORTION OF THE NECK

The anatomic junction of the oropharynx and hypopharynx is at the level of the pharyngeal-glossotic fold. The hyoid bone is located at approximately the same level, and it divides the neck functionally, as well as anatomically, into two distinct parts: the suprahyoid and infrahyoid portions. The three layers of the deep cervical fascia merge at the hyoid bone, functionally dividing it into these two regions.1 The suprahyoid portion of the neck extends from the skull base to the hyoid bone and surrounds the nasopharynx and oropharynx and includes the deep spaces. These spaces consist of the pre-styloid parapharyngeal space, the post-styloid parapharyngeal space (carotid space), the pharyngeal mucosal space of the nasopharynx and oropharynx, the parapharyngeal space, the masticator space, the retropharyngeal space, and the prevertebral space. In general, MRI is the modality of choice when evaluating suprahyoid neck lesions. The superior soft tissue contrast and multiplanar capability provided with MRI enable better evaluation of intracranial extension by perineural spread, in this anatomically complex region, or via direct skull base invasion.2 However, for osseous assessment of the skull base, particularly the cortex, CT imaging should also be added. MR imaging is also less prone to extensive artifact from dental hardware.

The key to developing a differential diagnosis regarding a mass in the suprahyoid portion of the neck is to identify the anatomic space from which the lesion has originated. Identifying the space of origin of a small lesion is easy; however, when the lesion is large, the distortion of the regional anatomy can make localization difficult. In the suprahyoid portion of the neck, one visual indicator which aids in the identity of the space of origin is the direction of displacement of the prestyloid parapharyngeal fat.1 The prestyloid parapharyngeal space is a useful imaging landmark because it is composed primarily of fat, and it is located in the central position relative to the surrounding anatomic spaces. Fat is markedly low in attenuation on CT and high in signal on T1-weighted MRI. Because of the unique imaging features of fat, normal anatomic structures and lesions remain distinct from the parapharyngeal fat. Since essentially all the other deep spaces of the suprahyoid portion of the neck abut the prestyloid parapharyngeal space, large masses in those spaces will usually displace the parapharyngeal fat.

On cross-sectional imaging, the prestyloid parapharyngeal fat is triangular in shape (Figure 1). In three-dimensions, the space is...
pyramidal in shape with its widest portion and base at the level of the skull base and its apex approximately at the level of the hyoid bone. In general, a lesion within the poststyloid parapharyngeal space displaces the prestyloid parapharyngeal fat anteriorly (Figure 2). A lesion within the masticator space displaces the fat posteriorly (Figure 3). A lesion within the pharyngeal mucosal space displaces the fat laterally (Figure 4), and a lesion within the parotid space displaces the fat medially (Figure 5).

The anatomic space in which a lesion originates provides clues to its identity. A differential diagnosis can be formulated by first considering lesions that can derive from normal structures contained within the space. For example, in the complex poststyloid parapharyngeal space, the traversing structures include the internal carotid artery, the internal jugular vein, cranial nerves IX through XII, the sympathetic chain, and lymph nodes. From these structures, carotid pseudoaneurysm (Figure 6), jugular vein thrombosis, schwannomas, paragangliomas, and lymphadenopathy can occur. Once the vascular are excluded, the primary diagnosis of a mass in the poststyloid parapharyngeal space is often limited to schwannomas and paragangliomas. Schwannomas are typically well circumscribed and have areas of high signal on T2-weighted images and strong enhancement. They often displace the carotid artery anteriorly as they follow the course of the involved cranial nerve (Figure 7). The marked vascularity of glomus tumors provides a distinctive appearance on MRI ("salt and pepper") attributed to flow voids and prominent enhancement within the lesion (Figure 8).

Another relatively common diagnostic dilemma is distinguishing between a deep parotid lesion and a prestyloid parapharyngeal lesion. Intrinsic lesions to the prestyloid parapharyngeal space are relatively uncommon. Ectopic salivary gland tissue, however, can be present throughout the head and neck and can be a source of neoplastic transformation. A parotid space mass displaces the prestyloid parapharyngeal fat medially. Other imaging features that suggest a deep parotid mass include an indistinct fat plane adjacent to the parotid gland, extension through the stylomandibular notch or a tissue margin which abuts the retromandibular vein (Figure 9).

Masticator space pathology is principally derived from the mandible and muscles of mastication. Odontogenic infections (see Figure 3) are the most common lesions with sarcomas of the bone and soft tissues occurring less often. Cranial nerves, course throughout the neck, and schwannomas can be found in the masticator space, arising from the branches of the trigeminal nerve and virtually anywhere within the neck. The clinical presentation, regarding signs and symptoms of possible infection, is essential to accurate interpretation of imaging studies of this region.

Although the most common malignant neoplasm of the pharyngeal mucosal space is squamous cell carcinoma (SCC), other lesions in this space also need to be considered. Rests of salivary gland tissue are common throughout much of the neck, particularly along the mucosal surfaces, so salivary gland neoplasms are occasionally encountered. The lymphoid tissue of
Waldenström ring is part of the pharyngeal mucosal space. Therefore, lymphoma and adenoidal hyperplasia, in addition to peritonsillar abscess formation or other infection, are additional processes that occur in this location.

Another important anatomic landmark in the suprahyoid neck region is the longus colli and capitis muscle complex, which is part of the prevertebral portion of the perivertebral space. These muscles form the boundary between the retropharyngeal space and the prevertebral space. Inflammatory changes and abscess formation within the retropharyngeal space often originates from mucosal space infections and retropharyngeal adenopathy, causing posterior displacement of these muscles. Alternatively, disease processes within the prevertebral space often extend from the spine, causing anterior displacement of the muscles. Finally, a potential space exists (otherwise known as “the danger space”) that can serve as a route of spread of infection into the mediastinum (Figure 10).

Nasopharyngeal carcinoma originating from the overlying pharyngeal mucosal space can invade the prevertebral fascia, the skull base, or extend intracranially via perineural spread. Yousem and colleagues reviewed the imaging evaluation of resectability criteria for head and neck cancer.1 Extension to the prevertebral fascia is one of the criteria for a T4b category. Although Hsu and colleagues found that preservation of the high signal within the retropharyngeal fat stripe on T1-weighted images is highly consistent with a lack of invasion and fixation of the lesion and the parotid gland.
tumor to the prevertebral fascia and prevertebral muscles, Lovener and colleagues found that the radiologic suggestion of invasion was not nearly as reliable. They concluded that surgical endoscopic assessment should remain the standard of care to detect invasion, whereas the observation that preservation of the fat plane, however, is a useful indicator for lack of fixation. Xie and colleagues found that MRI was more sensitive to skull base invasion than CT. MRI is also essential for the evaluation of perineural spread of tumor. Although CT imaging may demonstrate widening of the neural foramen, MRI is far superior at visualizing actual thickening and enhancement of the affected nerve (Figure 11).

**LARYNX AND HYPOPHARYNX**

The larynx and hypopharynx are primarily better evaluated with CT as motion of the respiratory structures often degrades MRI due of anatomic structures on CT. Staging of laryngeal and hypopharyngeal SCC is one of the major indications for the evaluation of this region. Staging on an imaging study is not accurate without a description of the clinical findings obtained on physical examination. Imaging can greatly assist the evaluation of the primary lesion by defining the size of the lesion and extent of spread into the subcutaneous tissues and adjacent subsites, detecting erosion of the laryngeal cartilages and identifying associated adenopathy.

Most laryngeal neoplasms originate in the mucosal surface. A mucosal lesion may be difficult to visualize radiographically when it is small. On imaging studies, it is identified by the presence of a nodular enhancing tissue that distorts the mucosal surface. Submucosal extension is represented by extension of soft tissue into the underlying submucosal fat or other structures. Loss of fat or other soft tissue planes in this region is helpful in demarcating spread of neoplasm and provides important information regarding staging of the neoplasm and surgical approach.
particularly when the tumor invades the paraglottic and preepiglottic fat. Fat serves as natural contrast against the higher density on CT and lower signal on MRI of infiltrating tumor.

The paraglottic fat is a useful landmark in distinguishing the supraglottic larynx from the soft tissue characteristically found at the level of the glottis (Figure 12). Coronal T1-weighted images are particularly helpful in evaluating for transglottic spread of carcinoma by displaying the supraglottic, glottic, and subglottic regions simultaneously with the supraglottic larynx demarcated by the extensive submucosal paraglottic fat (Figure 13). Pyriform sinus lesions that spread into the paraglottic fat can also be visualized in this manner (Figure 14). Current multidetector CT scanners acquire images that are 1 mm in thickness or less resulting in isotropic datasets, which can be reformatted into any imaging plane without inherent loss in resolution. As a result, coronal CT reconstructions can also be helpful in a similar fashion to coronal T1-weighted MR images (Figure 15). Extension of a lesion into the preepiglottic fat has important clinical staging implications and, therefore, will affect the type of surgical management (Figure 16). Lovener and colleagues found an accuracy rate of 90% with MRI evaluation of preepiglottic space invasion with attention to the high intensity fat signal on T1-weighted images in the axial and sagittal planes.7

Another critical imaging finding which has impact on staging and treatment is the identification of laryngeal cartilage erosion (Figure 17). Cortical invasion of only the inner margin of the thyroid cartilage is the principal criterion for a categorization of laryngeal SCC as T3, whereas invasion of the entire cartilage is considered category T4. Compared to MRI, CT evaluation of thyroid cartilage invasion has a higher specificity but lower sensitivity, whereas MRI is more sensitive but with lower specificity. The mean accuracy of CT for thyroid cartilage invasion is approximately 75 to 80%, and the mean accuracy of MRI is 80 to 85%.3 Nishiyama and colleagues found that single photon emission computed tomography may have an accuracy approaching 90% in detecting cartilaginous invasion.8

Chondrification/ossification of the thyroid cartilage can be irregular; however, it is usually symmetric9 (Figure 18). An important imaging feature associated with glottic carcinoma is sclerosis of the arytenoid cartilage (Figure 19). When this is seen on the side of a known glottic carcinoma, it usually is indicative of tumor extension up to the perichondrium, and this finding has been shown to represent true neoplastic infiltration of the cartilage approximately 50% of the time.10 One must also be aware, that arytenoid cartilage sclerosis can occur normally, in the absence of a carcinoma, particularly in women, in whom it is more common on the left side.11

Evaluation for a source of vocal cord paresis is also a common indication for imaging evaluation. If the left vocal cord is paretic, imaging should extend from the posterior fossa and skull base to just below the aortic arch to assess the entire course of the left recurrent laryngeal nerve as it travels around the aortic arch. At this location the nerve is susceptible to compression, particularly by lymphadenopathy in the aorto-pulmonic
window of the mediastinum (Figure 20). The inferior aspect of the right recurrent laryngeal nerve passes under the subclavian artery; and, therefore, imaging of the mediastinum is not required to evaluate the complete course of this structure. When there are other associated cranial neuropathies, a more proximal lesion is suggested. Secondary imaging findings that suggest cranial nerve dysfunction at the level of the skull base include unilateral tongue atrophy with fat infiltra-
tion (from hypoglossal nerve dysfunction) and atrophy of the sternocleidomastoid muscle (from spinal accessory nerve dysfunction) (Figure 21).

ORAL CAVITY

Lesions within the oral cavity are often small when detected on physical examination and do not always require imaging evaluation. However, CT and MRI play an important role in answering specific questions. These include determining the degree of submucosal extension of a lesion, particularly within the tongue, evaluating for possible invasion into the adjacent osseous structures, and detecting perineural spread of tumor. The tumor can spread along the palatine nerves into the pterygopalatine fossa to involve cranial nerve V2 or along cranial nerve V3 if there is violation of the inferior alveolar canal of the mandible or masticator space. Imaging also allows for the assessment of extension of the lesion into the sublingual or submandibular spaces.

Masses within the tongue are usually much better demonstrated on MRI. The submuco-
sal extent of the affected side and involvement of the contralateral part of the tongue are particularly well demonstrated on coronal imaging (Figure 22). Coronal imaging is also particularly useful to evaluate for extension of a lesion or inflammatory process from the sublingual to the submandibular space. The mylohyoid muscle, which forms the anatomic boundary between these two spaces, is easily visible, particularly on coronal imaging or reconstructions (Figures 23 and 24). Ranulas and sublingual space infections (Ludwig angina) are relatively common lesions in this area. The distinction between ranula and...
abscess or superinfection is made clinically, however, in general, radiologic clues of infection include an enhancing wall, infiltration of the surrounding fat planes with edema, and thickening of the overlying skin (Figure 25).

Identification of osseous erosion or invasion in the evaluation of malignancies is of particular importance (Figure 26). As in other areas, MR imaging is more sensitive to detection of bone invasion while CT remains more specific. Bolzoni and colleagues reported a sensitivity of 93%, specificity of 93%, and accuracy of 93% using MRI in the detection of mandibular erosion from oral or oropharyngeal SCC. Imaizumi and colleagues found that CT had greater specificity (88%) compared to MRI (54%) in detecting mandibular invasion by SCC. An early study evaluating the utility of PET-CT for mandibular invasion by Babin and colleagues reported this modality to be 100% sensitive and 83% specific.

**SALIVARY GLANDS**

This section will focus on some of the important imaging concepts regarding the salivary glands. Other superficial, palpable lesions will also be included as occasionally patients come to imaging to determine whether a palpable mass represents a primary salivary gland lesion, an adjacent lymph node or another superficial mass. Imaging can be helpful in characterizing the lesion identified by the patient or on physical examination. In younger patients, palpable masses are often of cystic origin (Figure 27). These cystic masses have characteristic imaging appearances; however, they can be complicated by superimposed infections or congenital anomalies, such as residual thyroid tissue within a thyroglossal duct cyst. Masses within the superficial soft tissues or within the salivary glands are most appropriately evaluated with MRI where they can be most accurately characterized by studying their signal.
characteristics and enhancement patterns. Infections, however, should be initially evaluated with CT imaging.

It is often difficult to discriminate lymphadenopathy from an intrinsic submandibular gland mass on physical examination alone. Imaging is extremely useful in making this distinction. Extrasalivary lesions are separated from the gland by a fat plane, and the gland is usually displaced by the lesion. Intrinsic salivary lesions are inseparable from the gland with normal salivary tissue surrounding much, if not all, of the mass. A helpful anatomic landmark is a prominent branch of the facial vein that is consistently identified along the lateral margin of the submandibular gland. This vein will be seen coursing around an intrinsic submandibular gland mass, as it expands the gland, while the vein will often course between the gland and adjacent adenopathy (Figure 28).

While virtually all intrinsic salivary gland masses are managed with surgical resection, there are imaging findings that may suggest the diagnosis preoperatively. In general, parotid masses which demonstrate high signal intensity on T2-weighted MR images are more likely to be benign; pleomorphic adenoma is the prototypical example of this feature (Figure 29). Most primary salivary gland carcinomas such as mucoepidermoid carcinoma demonstrate lower signal intensity on T2-weighted MR images (Figure 30). Another important imaging characteristic is the definition of the lesion margin as benign masses typically demonstrate sharp, well-circumscribed
margins, whereas irregular, infiltrative margins suggest malignancy. When parotid gland lesions are bilateral or multiple, consideration should be given to Warthin tumors (especially in elderly males), lymphoepithelial cysts (in HIV-positive patients), metastatic or inflammatory lymphadenopathy, and Sjögren syndrome. Clinical history is essential in separating these entities. The triad of multiple bilateral parotid lesions, prominent soft tissue in the nasopharynx and lymphadenopathy is highly suggestive of HIV infection (Figure 31).

Nonpalpable superficial parotid lesions can be biopsied easily under ultrasound guidance and deep parotid lesions are amenable to biopsy with CT guidance (Figure 32). Ultrasound is also particularly useful in characterizing masses throughout the neck, with regard to determining their cystic or vascular nature and in evaluating for lymphadenopathy. In general, regarding any palpable or superficial mass throughout the neck, unless it has unequivocal benign imaging features suggestive of a lipoma or hemangioma (Figure 33), it is managed with biopsy or complete surgical resection.

Contrast-enhanced CT is the most appropriate initial imaging study to evaluate patients with head and neck infections. CT can be used to distinguish a superficial cellulitis from a true abscess. CT is also useful in determining the source of the infection such as in secondary superficial cellulitis from sinusitis, periapical abscess formation from endodontal disease (Figure 34), or sialoadenitis secondary to sialolithiasis (Figure 35). Although MRI can be used to diagnose an abscess, it is less useful in determining the source of infection.

Evaluation for lymphadenopathy is a major indication for neck imaging. CT is the usual modality of choice if detection of pathologic lymph nodes is the only clinical question since it is more accurate in detecting necrosis in nodes of normal size. The imaging criteria for pathologic adenopathy often vary from institution to institution. In general, level I and jugulodigastric lymph nodes are considered to be pathologic if they are larger than 1.5 cm in long axis, and level II to VI nodes are considered to be pathologic if greater than 1 cm in long axis. Retropharyngeal and intraparotid lymph nodes should be considered pathologic at an even smaller size. Any lymph node that demonstrates central necrosis should also be considered pathologic. Other criteria that should suggest malignant infiltration until proven otherwise include groups of three or more borderline in size lymph nodes, any lymph node with calcification in a patient with papillary carcinoma of the thyroid and any lymph node in a patient with mucocutaneous malignant melanoma if it has different imaging characteristics from nodes on the contralateral side.

NEW TECHNIQUES

CT and MRI techniques continue to improve, and their use in specific clinical situations
continues to be evaluated. As illustrated above, prior studies have evaluated the utility of these modalities in evaluating osseous erosion. In general, MRI tends to be more sensitive than CT in this application but CT findings generally have a higher specificity. CT is particularly valuable in evaluating cortical bone for invasion. With the advent of multidetector CT scanner, isotropic (volumetric) CT datasets and sub-second data acquisitions, the entire head and neck region can be scanned in seconds instead of minutes. This improved temporal resolution can be exploited to “capture” contrast in the arterial phase and provide a three-dimensional arteriographic-like image of the vascular anatomy (CT angiography). The axial “raw data” images are evaluated similar to standard neck CT images but are much more numerous and are obtained such that peak contrast enhancement is present within the arterial lumen. Multiplanar reconstructions can be performed in any plane to visualize a segment of interest from any perspective (Figure 36). This has particular value in planning surgical resection around critical vascular structures. For example, Yousem and colleagues found a 100% positive predictive value for vascular invasion when tumor encases the carotid artery by more than 270º.17

The capability to obtain three-dimensional information on CT and MRI has led to the development of techniques to study tumor volumes as opposed to the traditional methods of estimating tumor size by utilizing calculations solely based on longest dimensions in three planes. Mukherji and colleagues reviewed the clinical applications and technique of this procedure, citing multiple studies that have shown how calculation of gross

tumor volume is extremely useful in predicting local control of SCC at different head and neck subsites.\(^\text{18}\) This information can be integrated into the treatment plan by identifying patients at higher risk of local recurrence after nonsurgical organ-preservation therapy. In addition, this technology may be proved as useful in identifying patients who may be benefited from earlier...
surveillance for recurrence, the addition of adjuvant chemotherapy or perhaps earlier surgical intervention.\textsuperscript{18}

PET is an important imaging method for estimating the physiologic activity of a lesion. PET exploits the intrinsic radiation from a radionuclide tracer that is labeled to a compound, which is taken up in greater proportion in neoplastic tissue compared to the surrounding normal tissues. Multiple tracers are available; however, 2-fluoro-2-deoxy-D-glucose is most commonly utilized. Glucose utilization is increased in tumor cells and has been suggested to be related to the malignant potential of the lesion.\textsuperscript{19} Moreover, protein synthesis and amino acid transport are also elevated in tumor cells. These observations have led to the evaluation of the efficacy of PET in determining the aggressiveness of a lesion and predicting long-term outcomes for patients with head and neck cancer.\textsuperscript{19} Previously, this technique was limited by inherently low spatial resolution and poor anatomic detail. Fusion of PET and CT or MR data has greatly improved the ability to localize anatomically areas of abnormal physiologic activity (Figure 37). PET-CT is particularly useful in detecting recurrence in the treated patient in whom postsurgical and radiation therapy changes distort the normal anatomic relationships. The combination of PET with the high-resolution spatial anatomic data provided by CT or MRI ensures improved reliability in differentiating tumor recurrence and lymphadenopathy from posttreatment scarring and inflammation (Figures 38 and 39). PET has some known inherent limitations including compromised sensitivity for neoplasms with slow growth rate, large intrinsic mucinous components, large portion that spreads superficially or large area of central necrosis.\textsuperscript{20} Additionally, the identification of a lesion is also particularly problematic if it is adjacent to structures of normally high 2-fluoro-2-deoxy-D-glucose uptake. Finally, as in all imaging modalities, there are technical factors that can result in poor image quality if optimization is not consistently utilized.

**CONCLUSIONS**

Imaging continues to be an essential tool in the evaluation and management of patients with head and neck diseases as it provides supplemental information that is not readily available on physical examination. CT and MRI remain the foundation of imaging evaluation with combined PET-CT imaging proving more and more useful in answering specific clinical questions.

Targeted Therapeutic Approaches to Head and Neck Cancer

Stephen Y. Lai, MD, PhD
Jennifer R. Grandis, MD

Head and neck squamous cell carcinoma (HNSCC) accounts for more than 500,000 new cases projected annually worldwide, representing the sixth most common cancer in the developed world. In the United States, approximately 45,000 new cases will be diagnosed, and the majority will present as locoregionally advanced disease (stage III/IV). Despite advances in surgery, radiation oncology, and medical oncology, overall survival for HNSCC patients has not improved in decades. An increased understanding of the molecular mechanisms governing the etiology and progression of HNSCC is providing a foundation for the development of targeted therapeutics. Targeted therapeutics are directed at known molecular targets that are relatively specific for tumor cells. Unlike standard radiation therapy and chemotherapy agents, targeted therapeutics are less likely to have systemic cytotoxic effects and are predicted to have minimal associated toxicities. The relative ease of access to the mucosa of the head and neck region also permits direct delivery of therapeutic agents.

A RATIONAL APPROACH TO MOLECULAR TARGETING

Specific pathways relevant to the development or progression of HNSCC serve as the basis for identifying relevant therapeutic targets. These targets include growth factor receptors, intracellular signal transduction molecules, nuclear transcription factors, and other related proteins. The challenge in molecular therapy involves distinguishing those proteins that are differentially expressed in HNSCC cells as compared to their normal counterparts. A number of criteria distinguishes specific cellular proteins for therapeutic targeting:

1. Increased expression/activity of the therapeutic target: Growth factor/cytokine receptor subunits or intracellular signaling molecules, nuclear transcription factors, and other related proteins. The higher level of expression and/or activity within cancer cells may represent potential targets. The higher level of expression in cancer cells, as compared to normal tissues, provides improved selectivity of the therapeutic molecule for the tumor.

2. Poor clinical outcome associated with the therapeutic target: Expression or overexpression of the therapeutic targets is usually associated with tumors that have poor clinical outcome. This finding supports the contribution of a specific signaling pathway/target in tumor progression.

3. Preclinical inhibitor studies demonstrate antitumor effects: Preclinical studies of small molecular inhibitors against a particular target should demonstrate antitumor effects, such as decreased proliferation and/or increased apoptosis. Typically, these antitumor effects are associated with downregulation of the target molecule.

Preclinical and Clinical Studies

Upon identification of a potential targeted therapeutic agent, rigorous preclinical and clinical studies must be performed before a novel drug becomes a valid treatment option. Initial studies are performed in vitro, usually with cell lines derived from tumors. Investigators of HNSCC are fortunate as there are a vast number of cell lines available for preclinical studies. In vitro studies examine the ability of a particular agent to inhibit tumor proliferation or to promote programmed cell death (apoptosis). These studies also demonstrate the sensitivity of tumor cells to the agent and determine whether antitumor effects are evoked at reasonably low concentrations. The selectivity or therapeutic index of a particular agent is determined by comparing its effects on tumor and normal cells. Additionally, these studies may explore the molecular mechanisms of an agent by measuring the expression and activity of signaling proteins related to the targeted molecule.

If a candidate agent demonstrates sufficient antitumor activity, preclinical testing moves forward to animal studies. In HNSCC, the model system involves human cancer cells grown in mouse hosts. Human xenograft tumors within immunocompromised mice are treated with a candidate agent, and the antitumor effects are measured. These studies often assess the ability of an agent to prevent tumor initiation or inhibit tumor growth. These studies are less than ideal as the behavior of human tumor cells within a mouse host does not always replicate tumor behavior within humans. Additionally, toxic side effects of a drug in humans may often not be detected in a mouse model. Nevertheless, this model represents the best experimental system that is currently available. A agent that has demonstrated antitumor effects in both cell lines and animal models without significant toxic effects may be promoted for testing in humans.

The evaluation of a potential therapeutic agent in humans involves three separate levels or phases. Phase I clinical trials are designed to assess the safety of a particular agent. A candidate agent is given to a small number of patients at various doses, including the presumed therapeutic dose, to evaluate toxic side effects. Dosage usually begins at a low level that is typically determined by any information available from animal studies. In a series of patients, dose levels are increased incrementally until the drug begins to induce unacceptable toxicities. Thus, a therapeutic window and maximum tolerated dose (MTD) are determined through dose escalation to guide further testing. With an acceptably low toxicity profile, a candidate agent will move to a phase II trial with a larger number of patients. Phase II trials continue not only to monitor treatment toxicities but also assess treatment efficacy. If a candidate agent demonstrates efficacy against certain types of cancer in a phase II trial, a phase III trial may be undertaken. A phase III trial typically involves many more patients than phase I or II trial and compares a treatment with a novel agent with standard treatment. These studies need to be carefully designed and conducted to determine if the measured clinical responses are statistically significant. The licensing of a candidate agent for a specific disease indication by the United States Food and Drug Administration (FDA) usually depends upon the demonstration of a therapeutic benefit that is greater than the existing standard of care.

Imatinib: A Molecular Targeting Therapy Success Story

The development of imatinib (STI-571; Gleevec) for the treatment of chronic myeloid leukemia (CML) demonstrates successful development of a targeted therapy. CML is caused by reciprocal translocation of chromosomes 9 and 22, resulting in the formation of the constitutively
active tyrosine kinase BCR-ABL. This chromosomal defect is present in more than 95% of CML patients. Imatinib was identified as a low-molecular weight antagonist of BCR-ABL that targeted the catalytic cleft of the BCR-ABL tyrosine kinase. By 1996, imatinib was found to inhibit the growth of CML cells in vitro while not affecting normal bone marrow cells. Initial clinical trials began in 1998 and demonstrated disease remissions in all of the 31 treated patients with CML. Within 4 years, 6,000 patients had been enrolled in imatinib clinical trials, and imatinib was approved by the FDA in 2002 as first-line treatment for CML. Imatinib is a shining example of rational drug design which has dramatically altered the treatment of patients with CML and represents a vastly superior alternative to any other available treatment regimen.

HEAD AND NECK SQUAMOUS CELL CARCINOMA THERAPEUTIC TARGETS

Overview

While there has not been a success story as dramatic as imatinib in the treatment of HNSCC, a number of approaches to identifying targeted therapeutic agents may significantly improve our current ability to treat HNSCC patients. This chapter will focus on a number of developing strategies that target different facets of HNSCC disease progression (Table 1). The epidermal growth factor receptor (EGFR) has emerged as an attractive therapeutic target in HNSCC and other cancers. A number of different approaches have been directed at the inhibition of EGFR ligand-binding and tyrosine kinase activity. Some progress has been made in the development of targeted therapeutics directed at EGFR in HNSCC. In 2006, FDA approval of cetuximab for HNSCC treatment represented the first new agent for this disease in nearly one-half century.

Although the development of approaches to other molecular targets may not be similarly advanced, they hold tremendous promise for improvements in the treatment of HNSCC patients. EGFR-associated signaling molecules, for example, Src or signal transduction and activator of transcription factor 3 (STAT3), have been targeted in preclinical models. G-protein–coupled receptors (GPCR), such as the bradykinin receptor, also appear to be an important target as they can activate EGFR and its signaling pathways in HNSCC. As HNSCC tumors rapidly increase in size, they must adapt to an environment low in oxygen and nutrients. Tumors initiate blood vessel formation (angiogenesis) and receive more oxygen and nutrients. Interference of vascular endothelial growth factor receptor (VEGFR) signaling that promotes angiogenesis is under active investigation. Aditionally, the hypoxic environment itself may represent an effective means of selectively targeting HNSCC cells. Finally, p53 is the most commonly mutated gene in human cancer and frequently mutated in HNSCC. A attempts to target p53-mutant HNSCC cells are under active investigation.

Epidermal Growth Factor Receptor

The human epidermal receptor (HER) family consists of four closely related transmembrane receptors: HER-1/EGFR, HER-2, HER-3, and HER-4. These receptors are structurally similar, but unique characteristics determine ligand-binding specificity and signaling properties. Activation of the EGFR signaling complex occurs with oligomerization of the various receptor subunits. The specific signaling complex that is assembled depends upon the activating ligand and the relative expression of the different HER family receptor subunits on the cell surface.

EGFR is a widely expressed 170 kDa protein composed of 1,186 amino acid residues and approximately 40 kDa of N-linked oligosaccharide. The receptor subunit consists of an extracellular ligand-binding domain, a transmembrane domain, an intracellular tyrosine kinase domain and additional receptor regulatory motifs and critical tyrosine residues within the cytoplasmic tail. Binding of ligand by the extracellular portion of the receptor results in receptor oligomerization, activation of the receptor tyrosine kinase and autophosphorylation of several C-terminal tyrosine residues (Figure 1). These phosphorylated tyrosine residues serve as docking sites for cytoplasmic signal transduction molecules. Signaling pathways activated by EGFR include the Ras/mitogen-activated protein kinase (MAPK) and phosphoryltylinositol-3 kinase (PI3K) pathways. Other important signaling molecules that interact with EGFR include Src kinase and STAT factors, including STAT3 and STAT5. Activation of these signaling pathways leads to cell proliferation, differentiation, alterations in cell adhesion and migration, enhanced survival and differentiation.

Different members of the HER family of receptors are known to be upregulated in a variety of different tumor types. EGFR is commonly overexpressed in HNSCC and increasing levels of expressing of EGFR and the ligand, transforming growth factor-alpha (TGF-α), are associated with worse patient prognosis and disease recurrence. Overexpression of EGFR appears to be a relatively early event as expression levels increase with the increasing severity of dysplasia in premalignant lesions. Furthermore, EGFR-dependent signaling pathways are activated in HNSCC and drive cellular functions critical for HNSCC disease progression, including proliferation and antiapoptosis. These findings demonstrate a significant role for EGFR in HNSCC pathogenesis that is similar to the role in EGFR in colorectal and nonsmall cell lung cancer.

The critical role of EGFR in cancer was solidified when the oncogene v-erbB was identified as a truncated form of EGFR. M endelsohn and colleagues proposed EGFR blockade to inhibit tumor growth. Preclinical studies soon demonstrated that monoclonal antibodies against EGFR could enhance the effects of standard chemotherapy in preclinical tumor models. Additionally, these inhibitors also had radiosensitizing effects. Several strategies have been developed to interfere with EGFR activity. Selective compounds were developed that targeted EGFR either through blockade of the extracellular ligand-binding region of EGFR or inhibition of the intracellular tyrosine kinase domain. Conjugated toxins that target EGFR are in preclinical development. Additionally, gene therapy strategies are being evaluated to decrease the expression of EGFR in HNSCC cells. These approaches, related compounds and their clinical status are described below.

Antibodies: Targeting the Epidermal Growth Factor Receptor Extracellular Ligand-Binding Region

A number of anti-EGFR monoclonal antibodies are in clinical trials for a variety of human epithelial malignancies, including HNSCC (see Table 1). These antibodies have a number of potentially important differences, including their structure and target EGFR epitope. These differences may influence their efficacy and toxicity.

Cetuximab. Cetuximab (Erbitux; IM C-225) is a chimeric monoclonal antibody that is approximately 65% human (35% murine). Cetuximab targets the extracellular domain of EGFR to prevent binding by its natural ligands. In preclinical studies, cetuximab demonstrated enhanced cytotoxicity with a number of chemotherapy agents, for example, cisplatin and doxorubicin, and radiation. Several phase II and III trials with patients with HNSCC have demonstrated the efficacy of cetuximab in combination with radiation therapy alone. Tumor sites were oropharynx (60%), larynx (25%), and hypopharynx (15%). Patients with oral cavity or nasopharyngeal tumors were not enrolled. These investigators demonstrated a statistically significant improvement in the median duration of locoregional control from 14.9 to 24.4 months (p = .005). Three-year survival was similar increased from 44% with radiation therapy alone to 57% with the addition of cetuximab (p = .02). Except for grade 3/4 skin reactions, the incidence of toxicity did not increase with the addition of cetuximab. Although cetuximab and radiation therapy is more effective than radiation therapy alone, assessment of radiation therapy/cetuximab versus concurrent chemoradiation still needs to be performed. A trial using cetuximab to concurrent chemotherapy may prove to be more effective than currently available treatment regimens. Clinical trials to address these issues are currently in progress.

Erlotinib. Erlotinib (ZD1839; Iressa) is a small molecule inhibitor of the intracellular tyrosine kinase domain of EGFR. Preclinical studies have demonstrated significant activity of erlotinib as a single agent with increased progression-free survival. Current studies are underway to determine if the addition of erlotinib to standard first-line therapy for metastatic colorectal cancer will improve progression-free and overall survival of these patients. Unlike cetuximab, matuzumab, and nimotuzumab which are based on a human IgG1 framework, panitumumab is constructed on an IgG2 framework. Classically, the IgG1 isotype mediates antibody-dependent cell-mediated cytotoxicity (ADCC) by natural killer (NK) cells and macrophages. Thus, the ability of panitumumab to mediate this potentially important immune function is under current investigation. Phase I clinical trials of panitumumab in combination with chemoradiation therapy in patients with HNSCC are underway.

The humanized monoclonal antibody 806 targets the EGFRvIII mutant (del2-7). Addition- ally, 806 binds the amplified wild-type EGFR in tumor cells but not in normal tissue. In preclinical studies, antibody 806 was reactive with a high proportion of differentiated epithelial cancers of the lung and HNSCC. Phase I trials are currently in progress.

Tyrosine Kinase Inhibitors

Small molecule inhibitors of the intracellular tyrosine kinase domain of EGFR are also under clinical evaluation (see Table 1). These inhibitors competitively inhibit adenosine triphosphate (ATP) binding to EGFR, preventing autophosphorylation. The currently available tyrosine kinase inhibitors (TKIs) are 4-anilinoquinazolines, 4-[(aryl)alkylamino]pyridopyrimidines, and 4-phenylaminopyrrolo-pyrimidines. Two oral agents that have shown promising antitumor effects are erlotinib (OSI-774; Tarceva) and gefitinib (ZD1839; Iressa).
A phase III trial demonstrated the additional benefit of erlotinib with gemcitabine significantly improved survival rates in patients with advanced pancreatic cancer.31 A phase III trial in patients with advanced nonsmall cell lung cancer (NSCLC) demonstrated an increase in overall survival (6.7 months vs 4.7 months; p < 0.001).34 Erlotinib was granted approval by the FDA for pancreatic cancer and second-line treatment for patients with locally advanced or metastatic NSCLC.

In patients with HNSCC, clinical trials have investigated the efficacy of erlotinib as monotherapy or in combination with chemotherapy. A phase II study of patients (n = 115) with advanced HNSCC demonstrated an overall response rate of 43.9%. Disease stabilization, median overall survival, and 1-year survival rates were comparable to current palliative chemotherapy regimens. Although the response rate was lower than chemotherapy, toxicity due to erlotinib was favorable compared to conventional therapies. A more recent phase II study of erlotinib in combination with cisplatin and docetaxel demonstrated impressive interim results in patients with advanced/recurrent HNSCC.36 In 19 patients, 16 patients demonstrated partial response and 3 patients demonstrated complete disease regression in the head and neck region. The regimen was well tolerated with only one grade 3 rash and one grade 4 febrile neutropenia.

**Gefitinib**

Gefitinib is an anilinoquinazoline that competes with ATP for its binding site on the intracellular domain of the receptor.37,38 In preclinical studies, gefitinib was effective in blocking EGFR activity and suppressing the growth of cell lines overexpressing HER.39 In 2003, the FDA granted accelerated approval of gefitinib as a third-line monotherapy for advanced NSCLC. However, two subsequent phase III trials did not demonstrate increased survival in patients with NSCLC who were treated with gefitinib in combination with two separate chemotherapy regimens.40,41 Approximately 10% of patients with NSCLC demonstrate a rapid and dramatic clinical response to gefitinib.42 Activating mutations in the ATP-binding pocket of the tyrosine kinase domain appear to increase kinase activity in response to EGF and increase sensitivity to inhibition by gefitinib. Unlike NSCLC, there is little evidence of activating mutations of EGFR in HNSCC.35

In HNSCC, gefitinib has been employed as a monotherapy and in combination with standard chemotherapy. A phase II trial in patients with HNSCC with gefitinib monotherapy demonstrated an observed response rate of 10.6% and a disease control rate of 53%.43 In combination with docetaxel and cisplatin in patients with recurrent/metastatic HNSCC, treatment with gefitinib resulted in a 62.5% overall response and a median progression-free survival of 5.1 months.44 Additionally, simultaneous targeting of EGFR by gefitinib in combination with cetuximab is being evaluated.45 The clinical future of gefitinib remains uncertain, given the negative results from the NSCLC phase III trials and the accompanying pulmonary toxicity.

Within a number of clinical trials in different types of malignancies, investigators have noted an interesting correlation between clinical benefit and the intensity of the characteristic acniform or maculopapular rash caused by anti-EGFR therapy.46 In HNSCC, the correlation between rash intensity and improved response rates as well as survival has been observed with cetuximab, gefitinib,42,43 and erlotinib.43 This intriguing observation requires additional confirmation and should be cautiously evaluated. Although the skin rash may be a surrogate marker for tumor response to an EGFR inhibitor, the rash may signal some other global biological factors, for example, immune status.47

**Other Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors**

A number of other TKIs are currently under investigation. EKB-569 is an irreversible inhibitor of EGFR.48 CI-1033 targets all four EGFR family members by binding covalently to a cysteine residue near the ATP-binding site.49 EGFR and HER2 are frequently coexpressed in HNSCC, and EGFR: HER2 heterodimers may be more potent in their signaling than EGFR homodimers.50 Lapatinib (GW572016) is a dual inhibitor of EGFR and HER2 tyrosine kinase activity.51 Finally, vanitinib (ZD6474) is a competitive inhibitor of EGFR and the vascular endothelial growth factor receptor 2 (VEGFR2) tyrosine kinase activities that have demonstrated antiangiogenesis activity in preclinical studies.52

**OTHER EPIDERMAL GROWTH FACTOR RECEPTOR TARGETING STRATEGIES**

**Toxin Conjugates**

The bacterial toxins of Pseudomonas or Diphtheria have been conjugated to EGFR-specific ligands, for example, TGF-α or EGFR-specific monoclonal antibodies.53,54 The ligand or the antibody binds to EGFR, resulting in the internalization of the toxic conjugate which mediates cytotoxic effects. This strategy has demonstrated antitumor effects in HNSCC cell lines and tumor xenografts,55,56 but no clinical trials have been initiated to evaluate safety and efficacy in patients with HNSCC.

**Gene Therapy**

Given the increased expression of EGFR in HNSCC, efforts to decrease EGFR expression have been investigated. Antisense oligonucleotides complement a portion of the mRNA of the target protein. The single-stranded oligonucleotide binds to the mRNA, resulting in a disruption in translation and activates ribonuclease (RNase) H, resulting in the cleavage of the targeted mRNA.57 Treatment with EGFR antisense oligonucleotides demonstrated a significant decrease in HNSCC cell growth in vitro.58 An EGFR antisense gene was developed from the oligonucleotides and repeated intratumoral administration resulted in growth inhibition within a murine xenograft model system.59 The authors led a phase I trial that demonstrated that intratumoral injection of the EGFR antisense gene was safe, and no significant toxicities were noted and we are preparing these data for publication. Additionally, 5 of 17 patients demonstrated significant clinical responses, including 2 patients who had complete regression of their tumor at the injection site. A phase II trial that achieves dual targeting of EGFR by combining intratumoral EGFR antisense gene therapy with cetuximab and radiation therapy is in development.

**Src FAMILY KINASE INHIBITORS**

A activation of the Src family kinases appears to be important in HNSCC development and progression. Src family kinases are activated downstream of EGFR, STAT3, and STAT5.60 Src family kinases are key intermediates in the transactivation of EGFR by G-protein-coupled receptors (GPCRs).61 Although imatinib has dramatically altered the treatment and prognosis of patients with CML, the evidence of emerging resistance to imatinib led to the development of other potential therapies.62,63 Dasatinib (BMS-354825) was identified as an oral agent with activity against BCR-ABL and a number of Src family kinase members, including Src, c-KIT, platelet-derived growth factor receptor (PDGFR), and ephrin A receptor kinases. Preclinical studies have demonstrated decreased invasion and increased apoptosis in HNSCC and NSCLC cell lines following dasatinib treatment.64 A clinical trial employing cetuximab and dasatinib is currently being developed at our institution.

**SIGNAL TRANSDUCER AND ACTIVATOR OF TRANSCRIPTION FACTORS**

The signal transducer and activator of transcription (STAT) factors are activated upon phosphorylation by Janus kinases (JAKs) or tyrosine kinase receptors such as EGFR.65 STATs can form homodimers or heterodimers that translocate to the nucleus to form transcription complexes. STAT3 is persistently activated in many human cancers and is critical for tumorigenesis in HNSCC.66,67

Strategies to target STAT3 include decreasing STAT3 levels, reducing tyrosine phosphorylation of STAT3, and interfering with STAT3 recruitment to receptor complexes and to promoter sites. AG-490 and JSI-124 (cucurbitacin I) are inhibitors that demonstrate selective inhibition of JAKs resulting in decreased STAT3 activity.66 Introduction of antisense oligonucleotides into tumors in a mouse HNSCC xenograft model resulted in decreased STAT3 activity and increased apoptosis.68 A nother promising approach has been the use of a STAT3 decoy composed of a double-stranded oligonucleotide based upon the STAT3 response element within the c-fos promoter.69 The STAT3 decoy successfully binds activated STAT3, inhibits proliferation and induces
apoptosis. The development of clinical trials is currently in progress.

**G-PROTEIN-COUPLED RECEPTORS**

G-protein–coupled receptors (GPCRs) are ubiquitously expressed in epithelial cells. Stimulation of HNSCC cells by GPCR ligands, such as lysophosphatidic acid (LPA) and thrombin results in activation of EGFR. Additionally, stimulation of the gastrin-releasing peptide (GRP) receptor activates EGFR and modulates HNSCC growth and invasion. Activation of GPCRs by prostaglandin E2 and bradykinin release EGFR ligands and transactivate EGFR through Src-mediated activation of matrix metalloproteinases. Preclinical studies with the bradykinin antagonist CU201 demonstrated growth inhibition in HNSCC cells, and additive inhibitory effects were noted when CU201 was used in combination with erlotinib. Similar findings with CU201 have also been reported in lung cancer cells.

**VASCULAR ENDOTHELIAL GROWTH FACTOR RECEPTOR**

The formation of new blood vessels is necessary for tumors to continue to grow and/or to metastasize. Vascular endothelial growth factor (VEGF) is crucial for vessel formation and is induced under hypoxic conditions. Overexpression of VEGF within HNSCC specimens has been associated with increased recurrence and decreased survival. Antiangiogenic antibodies are less likely to respond to surgery, radiation therapy, and/or chemotherapy. The adverse conditions within hypoxic regions of tumors may select for cells that are more resistant to standard therapy and behave more aggressively. Additionally, hypoxic tumors are relatively radiosensitive, requiring a larger radiation dose to achieve an equivalent log kill as cells in normal oxygen conditions. Tirapazamine (TPZ; SR-4233) is a benzotriazine compound that exhibits differential cytotoxicity for hypoxic cells. In aerobic conditions, TPZ is reduced to form a highly reactive radical species capable of inducing DNA single- and double-strand breaks. Preclinical studies demonstrated an additive effect when TPZ was used in combination with radiation or cisplatin. TPZ has been developed to improve the efficacy of radiation and chemotherapy in HNSCC.

**HYPOXIA**

HNSCCs that demonstrate regions of decreased oxygenation or hypoxia are associated with worse patient prognosis. Poorly oxygenated tumors are less likely to respond to surgery, radiation therapy, and/or chemotherapy. The adverse conditions within hypoxic regions of tumors may select for cells that are more resistant to standard therapy and behave more aggressively. Additionally, hypoxic tumors are relatively radiosensitive, requiring a larger radiation dose to achieve an equivalent log kill as cells in normal oxygen conditions.

Chemoradiation for Head and Neck Cancer

Rob McCammon, MD
Changhu Chen, MD
Mohan Suntha, MD
David Raben, MD

Radiotherapy has long played a role in the treatment of head and neck squamous cell carcinoma (HNSCC). Early-stage disease at sites such as the laryngeal glottis and base of tongue have frequently been treated successfully with radiotherapy alone. Historically, more advanced cancers were addressed by surgery as the primary modality with postoperative radiation therapy when indicated. However, tremendous strides have been made in the realm of radiotherapy and chemotherapy such that organ preservation is now the rule rather than the exception in many head and neck sites. In instances when surgery is indicated, advances have also been made in the delivery of postoperative combined modality therapy. Moreover, recent times have been witness to exciting progress in the characterization of molecular features of HNSCC with subsequent development of biologic agents targeting specific pathways responsible for tumor growth and dissemination. In spite of this progress, failure rates in locally advanced HNSCC remain high regardless of treatment modality, underscoring the need for continued research.

HISTORY OF RADIATION THERAPY

The advent of therapeutic radiation followed closely on the heels of the discovery of X-rays by Roentgen in November of 1895. In fact, within months of the discovery of the “New Light,” at least one visionary had already performed palliative “roentgentherapy” on a patient with recurrent breast cancer.1 Since those pioneering days, more than a century of experience has been attained in the treatment of cancer with radiation.

The introduction of megavoltage radiotherapy delivered via a linear accelerator, or “linac,” marked the dawn of the modern radiation era. The ability to generate high-energy photons enabled practitioners to effectively treat not only superficial lesions but also deep-seated tumors. The introduction of computed tomography (CT) has made possible three-dimensional 3-D conformal radiotherapy. Planning CT scans are now frequently merged, that is, fused, with diagnostic CT, magnetic resonance imaging (MRI), and/or positron emission tomography (PET) datasets to improve target delineation. Improvements in patient immobilization with the use of thermoplastic masks and other similar devices have allowed for reduction in uncertain margins and enabled better overall treatment accuracy. More recently, the integration into clinical practice of multileaf collimators (MLCs) has facilitated design and delivery of radiation fields with complex shapes, obviating the use of heavy and cumbersome manually cut blocks in most instances (Figure 1). Perhaps even more exciting is the use of intensity modulated radiation therapy (IMRT), which utilizes inverse planning to generate true “dose painting” to treat tumor and areas at risk for microscopic spread, while sparing critical normal structures, most notably salivary tissue. Inverse planning refers to the process by which an idealized radiation dose distribution is first defined, and an iterative computer algorithm is subsequently employed to optimally achieve that distribution. In IMRT, the overall beam intensity is defined by many smaller beams known as “beamlets.” The radiation intensity of each beamlet is carefully controlled by frequent changes in the overall conformation of the larger beam. Each conformation is known as a segment; a typical head and neck IMRT plan is composed of 50 to 100 or more segments. A broader discussion of stereotactic radiosurgery and radiotherapy is found in Chapter 36, “Stereotactic Radiosurgery and Radiotherapy.”

Figure 1. Multileaf collimators (MLCs) within the head of a linear accelerator.

PRETREATMENT EVALUATION

Prior to embarking upon radiotherapy for HNSCC, it is essential that patients undergo a multidisciplinary evaluation. This includes consultation with the following: (1) dentistry to provide fluoride trays and other prophylaxis for serviceable teeth or extraction of poor dentition, (2) nutrition to educate the patient and institute measures to minimize weight loss and dehydration during treatment, and (3) speech therapy in anticipation of future issues with speech and swallowing. Given the significant acute mucosal toxicity attendant to concurrent chemoradiation, prophylactic gastric tube placement is frequently performed at the outset, usually via a percutaneous endoscopic gastrostomy (PEG). Baseline endocrinologic evaluation is also prudent in view of the potential thyroid or pituitary dysfunction related to treatment of certain head and neck sites.

RADIATION TREATMENT PLANNING

The initial step in the treatment planning process is the “simulation.” Today, this is almost exclusively performed on a CT simulator. Patients are typically positioned supine for head and neck treatments, and immobilization is achieved with a thermoplastic mask (Figure 2). Images through the anatomic area of interest are then obtained at 3 to 5 millimeter intervals. Reference marks are made on the thermoplastic mask to reproduce day-to-day patient setup. Axial images from the CT simulation are utilized to identify tumor volumes and involved or potentially involved nodal regions, as well as critical organs at risk such as the spinal cord, salivary glands, and true vocal cords. The physician “contours” these volumes, and radiation fields are then placed by trained dosimetrist under the guidance of the radiation oncologist, to encompass the contoured volumes. While the specifics of the radiotherapy plan vary widely based on the primary site and stage of disease, a typical initial non-IMRT field arrangement for treatment of a primary tumor and the regional lymphatics employs laterally opposed 4 to 10 MV beams matched to a low...
anterior-posterior field. Due to the low threshold for potential damage to the spinal cord, doses above approximately 45 to 50 Gray (Gy) to that organ are considered unacceptable. Therefore, “off cord” lateral fields in which the posterior border of the field lies anterior to the spinal cord, for example, at the midvertebral body in the sagittal plane, are initiated prior to reaching the tolerance dose. To adequately treat potential involvement lymph nodes lying in the region posterior to the “off cord” fields, electron fields (“posterior electron strips”) are utilized. Electron therapy deposits dose superficially compared to photons, with rapid dose fall-off at depth. The lymph nodes of interest are located relatively close to the surface and receive the prescribed dose, but the spinal cord, a deep structure in the sagittal plane, is essentially spared. Finally, a 3-D “boost” field is designed to encompass only areas of gross tumor and a margin to account for setup uncertainty and internal anatomic motion. The delivery of definitive doses of radiation has, at times, been limited by the risk of normal tissue damage. Given the anatomic proximity of vital structures, tumors of the head and neck present a significant therapeutic challenge. Standard beam arrangements and treatment planning techniques are able to achieve uniform dose delivery throughout the entire anatomic region. The ability to deliver a homogeneous dose to a tumor-bearing region is desirable; however, it proves to be a disadvantage in terms of dose delivered to surrounding critical structures. The advent of CT-based planning has allowed treating physicians to gain a better understanding of the potential toxicities of radiation therapy according to the dose delivered to these structures. Recent advances such as IMRT have clearly improved the ability to safely deliver effective total doses of radiation to HNSCC while simultaneously decreasing the risk of untoward side effects. IMRT also allows for delivery of a “synchronous integrated boost” in which modifications to treatment fields such as off-cord laterals and posterior electron strips are unnecessary (Figure 3). It is not uncommon for IMRT and conventional (3-D conformal) fields to be planned in combination. One example of this approach is the use of IMRT to the primary tumor and upper neck matched to a conventional low anterior-posterior field.

**RATIONALE FOR COMBINED CHEMOTHERAPY AND RADIATION**

A litany of evidence has been attained in the clinic demonstrating enhanced tumor control with the addition of concurrent chemotherapy to radiation (Table 1). A clear rationale exists for this marriage of modalities in that chemotherapy and radiotherapy can combine in an additive, or even supra-additive fashion to enhance tumor kill by multiple mechanisms. Prior to garnering clinical experience in concurrent chemoradiotherapy, data were obtained in the laboratory to suggest treatment synergy. In general, the goal of adding concurrent chemotherapy to radiation is to improve the therapeutic ratio. That is, the addition of a drug has a differential effect on tumor and normal tissue: while the dose-response curve is shifted to the left for both tumor and normal tissue, the magnitude of the shift is greater for the tumor (Figure 4). Therefore, at a given level of normal-tissue injury, a greater likelihood of tumor control is achievable. Various techniques are available to measure the effects of chemotherapy and radiotherapy either in vivo or in vitro. In vitro methods entail subjecting cells in culture to various treatments to assess response. Examples of in vivo methods include simple tumor growth measurements, tumor cure (TCT50) assays, dilution assays, and lung colony assays.

Although cell survival curves generated by the various laboratory assays demonstrate the effect of combined modality treatment, they say nothing regarding its mechanism. The possible interactions of combined chemotherapy and radiation were promulgated by Steel in a classic paper. The conceptual cornerstones of the interaction were spatial cooperation and toxicity independence, referring to the targeting of different anatomic sites by the respective modalities without overlapping toxicity. While providing a rationale for combined treatment, the original framework outlined by Steel did not propose a direct interaction of the modalities on common tissues nor provide an explanation for the supra-additive effect on tumors when delivered in combination. Decades of subsequent research have helped elucidate the interaction of chemotherapy and radiation, although much remains incompletely understood. The proposed mechanisms by which chemotherapy is radiosensitizing are numerous, and it is instructive to examine the more commonly utilized agents in HNSCC individually.

Cisplatin has been administered more frequently with radiotherapy than any other agent in HNSCC. The water-soluble drug is converted intracellularly to its active agent, which subsequently reacts with nuclear DNA to form interstrand and intrastrand crosslinks. Crosslink formation triggers a cascade involving signaling pathways, checkpoint activation, DNA repair activity, and apoptosis. Several mechanisms have been proposed to account for the synergy of cisplatin and radiation (Figure 5), but the explanation given most currency is that cisplatin inhibits repair of radiation-induced DNA damage. Other mechanisms have been inferred, including: enhanced formation of toxic platinum intermediates via radiation-induced free radicals, increased permanence of DNA damage by way of cisplatin mediated free electron scavenging, increased cellular uptake of cisplatin in the presence of radiation, and cell-cycle disruption. 5-Fluorouracil (5-FU) is another agent frequently administered in HNSCC. The drug is converted to its cytotoxic form by multiple pathways resulting in depletions of thymidine 5'-monophosphate and thymidine 5'-triphosphate with subsequent derangement of DNA synthesis and repair. The combination of 5-FU and radiation can clearly be synergistic, although the exact mechanism eludes our full understanding. It has been proposed that the linchpin of the interaction derives from rapid progression of cells through S-phase (when they are relatively resistant to radiation) due to presence of the drug. Other studies have suggested that 5-FU synergizes with radiation by eliminating the radiation-induced G2 phase arrest, thereby reducing the overall time for sublethal damage repair or directly inhibiting repair of DNA double-strand breaks from radiation.

Taxanes have proven to be potent radiosensitizers with resultant use in treating cancers of various sites, including the head and neck, esophagus, lung, breast, bladder, pancreas, and female urogenital systems. The success of taxanes in combination with radiotherapy highlights the influence of the cell cycle on radiation sensitivity, as first described by Terasima and Tolmach nearly half a century ago. Generally speaking, cells are most radiosensitive in G2 and M phases, whereas they are most radioresistant in S phase. Therefore, any agent that promotes the accumulation of cells in the sensitive phase of the cell cycle and/or selectively eradicates cells in the resistant phase will optimally combine with radiotherapy. Taxanes, which bind to β-tubulin and thereby increase polymerization to promote
stable microtubule generation, arrest cells in the radiosensitive G2/M phases.

**CHEMORADIATION CLINICAL TRIALS**

One of the seminal studies evaluating the feasibility of organ preservation in the treatment of head and neck cancer was the Department of Veterans Affairs Laryngeal Cancer Study Group trial (VALSG). This phase III multicenter trial randomized medically operable patients with resectable stage III or IV laryngeal SCC to either conventional laryngectomy and postoperative radiation or induction chemotherapy followed by radiation. Patients in the induction chemotherapy arm received two cycles of cisplatin and 5-FU prior to assessment of tumor response. Responders went on to a third cycle of chemotherapy followed by definitive radiotherapy to a dose of 66 to 76 Gy. Nonresponders underwent laryngectomy. The results revealed no difference between the two arms in estimated 2-year overall survival at a median follow-up of 33 months. Moreover, the larynx was preserved in 64% of patients in the nonsurgical arm. The trial included quality of life studies and functional assessments regarding communication, swallowing, and eating. At 6, 12, and 24 months, the patients with a preserved larynx reported better communication scores, although there was no statistical difference in swallowing function.

![Figure 4](image1.png)

**Figure 4** The effect of the addition of chemotherapy to radiation on both tumor control and normal tissue damage. Note that the improvement in tumor control when drug is added exceeds the increase in normal tissue damage; ie, the therapeutic ratio is improved.

![Figure 5](image2.png)

**Figure 5** Proposed interactions of radiation and cisplatin. (Published with permission from reference 5.)
A study of similar design to the VA trial was conducted by the European Organization for Research and Treatment of Cancer (EORTC) in patients with locally advanced HNSCC of the hypopharynx. Patients were randomized to either immediate surgery and postoperative radiation or induction chemotherapy followed by definitive radiation. In contrast to the VA trial, immediate surgery was deferred only in those patients who had a complete response to induction chemotherapy. Like the VA trial, the chemotherapy regimen in the EORTC trial was cisplatin and 5-FU for three cycles. Organ preservation in chemotherapy responders was 64%, virtually identical to that seen in the VA trial. Although there was an apparent initial survival advantage in the nonsurgical arm at 3-year follow-up (57% vs 43%), there was no statistically significant difference noted at 5 years (30% in the induction chemotherapy arm vs 35% in the surgery arm). Nevertheless, the organ-preservation approach was heralded as the new standard of care against which future treatment regimens would be judged.

In an effort to better delineate the exact contribution of the chemotherapy to radiation in the treatment of HNSCC, as well as the optimal treatment sequencing, the Radiation Therapy Oncology Group (RTOG) conducted a randomized trial, RTOG 91-11. This three-arm trial randomized 547 patients with resectable stage III and IV SCC of the glottic or supraglottic larynx to radiotherapy alone, induction chemotherapy (cisplatin/5-FU as per the VA trial) followed by radiation, or concurrent chemoradiation (cisplatin 100 mg/m² on days 1, 22, 43). Patients with T1 primaries or large-volume T4 disease were excluded. The primary endpoint was larynx preservation. Radiation to gross disease was 70 Gy in 35 fractions; all patients received elective treatment to the entire neck to a minimum of 50 Gy. The results clearly demonstrated that larynx preservation was improved in the concurrent chemoradiotherapy compared to the other two arms to a statistically significant degree. To wit: at 2 years, the larynx was preserved in 75% of patients in the concurrent arm, 75% in the induction chemoradiotherapy arm, and 70% in the radiotherapy alone arm. Likewise, the improvement in locoregional control at 2 years in the concurrent chemoradiotherapy arm reached statistical significance as compared to the other two arms (78% in the concurrent arm vs 61% in the induction arm vs 56% in the radiotherapy alone arm). As a result of successful surgical salvage, overall survival rates were similar in all three arms. Not surprisingly, acute toxicity was worse in the concurrent chemoradiation arm, predominately due to increased mucositis. Overall, 77% of patients experienced a grade 3 or higher acute toxicity in the concurrent arm, while 51% of patients experienced a similar toxicity during radiation in the sequential arm. In the radiotherapy alone arm, grade II acute toxicity was even lower at 47%. This disparity in acute toxicity is in keeping with the majority of HNSCC trials comparing concurrent with sequential chemoradiotherapy or radiotherapy alone. Long-term speech and swallowing function was also monitored; notably, 23% of patients in the concurrent arm were limited to swallowing only soft foods or liquids 1 year following treatment, and 3% were completely feeding tube dependent. In contrast, only 9% of patients assigned to induction chemotheraphy were limited to soft foods and liquids at 1 year, and all patients maintained some degree of swallowing. Among patients assigned to radiotherapy alone, 18% of patients described swallowing dysfunction at 1 year, including 3% unable to swallow even liquids. By 2 years, however, there was no significant difference in swallowing function among the cohorts. There were no differences between the three arms vis-a-vis speech at either 12- or 24-month follow-up.

Despite the fact that many trials combining chemotherapy and radiation have been conducted in the last four decades, the absolute survival benefit associated with combined modality therapy has historically remained poorly defined. To better define the potential advantage of cytotoxic therapy, four large meta-analyses have been performed comparing chemotheraphy (administered neoadjuvantly, concurrently, or adjuvantly) plus radiation versus radiation alone. The primary endpoint in each analysis was overall survival. Among the four reports, three were literature-based, and one was a meta-analysis of the VA trial. The total number of cases included in each analysis ranged from 4,292 (from 28 trials) to 10,741 (63 trials). The median follow-up for all patients varied from 2 years to as long as 6.8 years. Despite significant differences in the databases analyzed, the four meta-analyses reached similar conclusions. The results of each study confirmed a small but reproducible survival benefit favoring the addition of chemotherapy. The magnitude of the benefit ranged from an absolute survival advantage of 2.8 to 6.5%. The study by Pignon and colleagues identified an overall survival advantage at both 2 and 5 years of 4%. All four studies noted that the survival benefit was greatest when chemotherapy was administered concurrently with radiation. The magnitude of this benefit varied from 8 to 12% in the four analyses.

The benefit of adding concurrent chemotheraphy to radiotherapy has been demonstrated in other site-specific trials. For instance, one of the most marked improvements to concurrent chemoradiation was observed in the Intergroup 0099 trial. This phase III trial randomized 193 patients with stage III or IV nasopharyngeal cancer without distant metastases to either radiation alone or chemoradiation, of which 147 were evaluable for primary analysis. The radiation was delivered on a once per day schedule at 1.8 to 2 Gy per fraction to 70 Gy. Patients in the combined modality arm received cisplatin 100 mg/m² on days 1, 22, and 43; following radiation they received an additional three cycles of adjuvant cisplatin 80 mg/m² on day one and 5-FU 1,000 mg/m² on days 1 through 4, every 4 weeks. A striking difference was seen in progression-free and overall survival between the two arms. The 3-year progression free survival (PFS) rates were 24% and 69% (p < .001) in the radiotherapy alone and chemoradiotherapy arms, respectively; overall survival was 47% versus 78% (p = .005) at the same interval. In fact, the outcomes were so disparate that the data activated an early stopping rule. Acute toxicity was dramatic, however: and only 62% of patients received all three cycles of concurrent chemoradiotherapy. Moreover, one-third of patients in the combined modality arm received no adjuvant chemotherapy, with an additional 11% receiving less than the full three cycles. Additional nasopharynx trials have demonstrated comparable outcomes with the delivery of fewer cycles of chemotherapy as well as other regimens such as weekly cisplatin. The French Head and Neck Oncology and Radiotherapy Group conducted a randomized trial in stage III and IV SCC of the oropharynx comparing conventionally-fractionated radiotherapy alone with the same radiotherapy and concurrent 5-FU and carboplatin given every 3 weeks for three cycles, with 5-year outcomes published in an updated report. Five-year overall survival, disease-free survival, and locoregional control rates were 22% and 16% (log-rank p = .05), 27% and 15% (p = .01), and 48% and 25% (p = .002), in the concurrent chemoradiotherapy and radiotherapy alone arms, respectively.

Many chemotherapeutic agents are active in HNSCC, and several clinical trials have been conducted to assess the optimal combination of agents in concert with radiotherapy. Early trials primarily employed agents such as bleomycin and methotrexate. In fact, the first trial conducted by the RTOG following its inception in 1968 evaluated the sequential addition of methotrexate to radiotherapy in advanced head and neck cancer. Later, the use of cisplatin and 5-FU, known to be active in the metastatic setting, gained currency. Agents known to synergize with radiation, such as mitomycin or hydroxyurea, have also been frequently used. Taxanes, known to be potent radiosensitizers, have become a widely utilized component of HNSCC treatment.

RTOG 97-03 was a multicenter trial in which three different chemotherapeutic doublets were examined prospectively when given with concurrent radiotherapy. This phase II trial assigned 241 patients with stage III or IV (M0) HNSCC of the oropharynx, or hypopharynx to one of the following three regimens: (1) concurrent radiotherapy plus low-dose daily cisplatin throughout the course and continuous infusion (CI) 5-FU for the final 10 days of radiation, (2) concurrent radiotherapy plus twice daily hydroxyurea and CI 5-FU; chemoradiotherapy was delivered on an alternating 1-week on/1-week off schedule, and (3) low-dose weekly cisplatin and paclitaxel with concurrent radiation. The radiotherapy dose was identical in the three arms, with the only difference in fractionation being the alternating split-course regimen assigned to patients in arm 2. All three arms were found to be feasible, with less than ten percent of patients having unacceptable deviations from
treatment or incomplete chemotherapy. Overall, grade 4 or higher toxicity was seen in 18, 29, and 23% of patients in arms 1, 2, and 3. The most common toxicity was mucosal in nature. While not designed to directly compare the efficacy of the respective regimens, it bears mentioning that estimated 2-year disease-free survival and overall survival rates were 38.2% and 57.5% for arm 1, 48.6% and 69.4% for arm 2, and 51.3% and 66.6% for arm 3.

**POSTOPERATIVE CHEMORADIOThERAPy FOR LOCALLy ADVANCED HEAD AND NECK SQUAMOUS CELL CARCINOMA**

Surgery continues to be the primary treatment of HNSCC in certain situations. Certainly, primary resection remains the standard of care in oral cavity SCC. Moreover, advanced disease in which significant bone or deep cartilage invasion is present suggests that organ preservation is unattainable and is best addressed surgically. Nevertheless, radiotherapy is commonly indicated following resection of advanced disease. Historically, adjuvant radiation therapy was delivered without concurrent chemotherapy, as evidenced by the control arms in the VALSEG and EORTC trials mentioned previously. However, recent trials examining the postoperative treatment of advanced HNSCC have established adjuvant chemoradiotherapy as the standard of care in selected patients.

RTOG 95-01 was a phase III trial in which patients with high-risk resected HNSCC were randomized to conventionally fractionated radiotherapy to 60 to 66 Gy with or without concurrent cisplatin (100 mg/m² days 1, 22, and 43). “High-risk” was defined as any of the following features: positive margins, two or more positive lymph nodes, or evidence of involved nodal extracapsular extension (ECE). A total of 459 patients with HNSCC of the oral cavity, oropharynx, larynx, or hypopharynx were treated; at a median follow-up of 46 months, there was a statistically significant improvement in locoregional failure rate (3-year estimate 22% vs 33%, p = .01) and disease-free survival (47% vs 36%, p = .04) in the combined modality arm. While overall survival was higher in the combined modality arm, the difference did not reach statistical significance (56% vs 47%, p = .09). Eligibility for the EORTC 22931 trial was somewhat different, requiring any of the following features: tumor within 5 mm of the surgical margin, ECE, clinical involvement of level 4 or 5 lymph nodes (limited to oral cavity and oropharynx primaries), perineural involvement, or vascular embolism (Figure 6). Three hundred and thirty-four patients were enrolled and randomized to 66 Gy of radiation at conventional fractionation with or without cisplatin as in the RTOG trial. Again, locoregional control (LRC) and disease-free survival (DFS) were significantly improved in the concurrent chemoradiotherapy arm (5-year estimate, 82% vs 69% p = .007 for LRC; 47% vs

---

**INDUCTION CHEMOTHERAPY IN LOCALLy ADVANCED HEAD AND NECK SQUAMOUS CELL CARCINOMA**

Many trials have been conducted in the past three decades comparing local therapy (surgery or radiotherapy alone) with or without induction chemotherapy. With few exceptions, outcomes were not improved by induction therapy. Furthermore, several trials, including RTOG 91-11, have demonstrated improved outcomes in patients randomized to concurrent rather than sequential treatment, establishing the former regimen as the standard organ-preserving approach in locally advanced disease. However, the development of new cytotoxic agents such as the taxanes, as well as the relative increase in the rate of distant recurrences in patients treated with concurrent chemoradiotherapy, has fomented a resurgent interest in induction chemotherapy. Recent trials have established the superiority of the intensified triplet regimen of cisplatin, 5-FU, and a taxane over the combination of cisplatin and 5-FU in the induction setting. Ongoing research will compare concurrent chemoradiation with or without induction chemotherapy. At least three trials are enrolling patients to such a regimen: the Southwest Oncology Group (SWOG) 0427 trial, the Paradigm Trial spearheaded by investigators at the Dana-Farber Cancer Center, and the DeCIDE Trial at the University of Chicago.

**INTRA-ARTERIAL CHEMOTHERAPY AND RADIATION**

The concurrent application of chemotherapy and radiation is often associated with an increase in acute toxicity including mucositis and leukopenia. The incidence of these toxicities often restricts patient selection for concurrent combined modality treatment. A another approach to the delivery of chemotherapy involves the regional infusion of the primary tumor with a cytotoxic agent. Intra-arterial (IA) delivery of chemotherapy has a therapeutic advantage over intravenous administration as a result of the higher drug concentrations that can be achieved in the tumor. Advances in the field of interventional radiology now make it possible to infuse selectively chemotherapy into head and neck subsites without significant catheter-related side effects. Cisplatin is ideally suited as a cytotoxic agent delivered intra-arterially with radiation in that it has a proven role as a radiosensitizer and has systemic effects that can be mitigated by the addition of sodium thiosulfate. Single institution trials have been conducted combining IA supradios cisplatin with conventional and hyperfractionated radiotherapy (so called RADPLAT) with promising response rates. Based on these experiences, the RTOG conducted a prospective feasibility trial.
of concurrent radiation and intra-arterial chemotherapy. RTOG 96-15 enrolled 67 patients with HNSCC of the oral cavity, oropharynx, hypopharynx, or larynx. T4 disease was required for eligibility. The radiation was 70 Gy in 35 daily fractions employing a shrinking field technique. Patients received IA cisplatin at 150 mg/m² on days 1, 8, 15, and 22 of radiation. Response rates were high, with 80% of patients experiencing a complete response; 2-year estimated local control and overall survival rates were 57% and 63%, respectively. Grade 4 or higher acute toxicity was low (14%) in "experienced" centers, defined as those having treated ten or more patients previously with RADPLAT, whereas over half of all patients treated at "inexperienced" centers incurred a grade 4 (47%) or 5 (4%) toxicity.

ALTERED FRACTIONATION OF RADIATION THERAPY

While much attention has been given to combining chemotherapy and radiation in the treatment of HNSCC, there has also been avid interest in investigating the impact of altered radiation fractionation regimens on tumor control. Altered fractionation purports to improve the therapeutic ratio by exploiting the differential response of tumor cells and late responding normal tissues to fractionated radiation. For instance, hyperfractionation entails the delivery of a higher total dose of radiation via an increased number of fractions, as compared to conventional fractionation, with a smaller dose delivered per fraction. Accelerated fractionation refers to the delivery of a conventional dose in an accelerated fashion. The impetus behind accelerated fractionation is the notion, borne out by laboratory and clinical evidence, that HNSCC cells undergo accelerated repopulation approximately 3 to 4 weeks into radiation therapy. This phenomenon is so pronounced that it has been suggested that there is a need for a dose increment of 0.6 Gy each day to compensate just for repopulation of tumor cells during the 4-week mark of radiotherapy.

Several clinical trials have compared various radiation fractionation schemes in HNSCC. RTOG 90-03 was a four-arm radiation only trial designed to compare three altered fractionation regimens against standard once-daily fractionation. This prospective phase III trial enrolled 1,113 patients with stage III–IV SCC of the oral cavity, non-base of tongue (BOT) oropharynx, supraglottic larynx, and stage II–IV SCC of the BOT and hypopharynx. The control arm was 70 Gy in 35 fractions delivered once daily. The second arm was treated with pure hyperfractionation in a regimen widely employed previously at the University of Florida: 1.2 Gy two times per day to a total dose of 75 Gy at 1.25 Gy twice daily or twice daily radiation of 1.25 Gy to a reduced dose of 70 Gy with 5 days of cisplatin 12 mg/m² and 5-FU 600 mg/m² in weeks 1 and 6 of treatment. Most patients in both arms also received adjuvant cisplatin and 5-FU for two additional cycles. Improved LRC was observed in the combined modality arm (70% at 3 years vs 44% in the radiation alone arm, p = .01). Disease-free and overall survival also appeared to be better in the combined arm, but the difference was not statistically significant. While mucositis rates were comparable between the two arms, there was a higher rate of feeding tube dependence as well as sepsis in the combined arm. A similarly designed European trial was conducted in locally advanced HNSCC using low-dose (6 mg/m²) daily cisplatin without a radiation dose reduction in the concurrent arm. The results mirrored the Duke University study in that the addition of concurrent chemotherapy clearly improved outcome without significantly increased radiation-associated toxicity. In this trial, however, the improvement in overall survival (68% vs 49% at 2 years and 46% vs 25% at 5 years) was statistically significant (p = .0075).

While the Duke University and European studies aimed to assess the effect of chemotherapy added to hyperfractionated radiotherapy, the recently completed RTOG 01-29 study compared conventional fractionation versus hyperfractionation in patients receiving concurrent chemoradiotherapy. This phase III study was based upon RTOG 99-14, a single-arm phase II trial that established the feasibility of concurrent concomitant boost radiotherapy and cisplatin. RTOG 01-29 randomized patients with selected stage III-IV SCC of the oral cavity, oropharynx, hypopharynx, or larynx, to conventional fractionated radiotherapy (70 Gy in 35 fractions) and concurrent cisplatin (100 mg/m² on days 1, 22, and 43) versus concomitant boost radiation and the same chemotherapy (days 1 and 22 only). The eagerly anticipated results have not yet been published, although a successor trial, RTOG 05-22, has already opened and will compare concurrent chemoradiotherapy with or without cetuximab (an antibody to epidermal growth factor receptor (EGFR)) in the definitive setting. Notably, conventional fractionation will not be permitted in the RTOG 05-22 trial; investigators will be allowed to treat patients with either the concomitant boost approach as in RTOG 90-03 and RTOG 01-29, or IMRT with delivery of six treatments per week (www astrology.org). The IMRT fractionation scheme is adapted from the Danish Head and Neck Cancer Study Group (DAHANCA), which published the results of a phase III trial in which patients with locally advanced HNSCC were randomized to 5 versus 6 weekly radiation treatments. The total dose and dose per fraction were identical in the two arms; the only difference being the delivery of a second daily treatment once per week in the accelerated arm, that is, six total treatments per week as opposed to five. Patients with glottic primaries received radiotherapy alone, whereas those with non-glottic primaries also received the hypoxic radiosensitizer nimorazole. At 5 years, there was a statistically significant improvement in LRC (70% vs 60%, p = .0005), primary tumor control (76% vs 64%, p = .001), voice preservation (80% vs 68%, p = .01), and disease-specific survival (73% vs 66%, p = .01) in the accelerated arm.

MOLECULAR BILOGIC TARGETS

The understanding of cellular and molecular pathways responsible for tumorigenesis and malignant tumor behavior has grown exponentially in recent years. The cellular processes characteristic of all cancer cells were elegantly described by Hanahan and Weinberg in a seminal thesis to include: (1) autonomy in growth signaling, (2) evasion of apoptosis, (3) lack of responsiveness to growth inhibitory signaling, (4) limitless replication, (5) angiogenesis, and (6) invasion and metastasis. In particular, the concepts of autonomy in growth signaling and angiogenesis have impelled intense research with subsequent development of clinically useful therapeutic agents that interfere with various growth-related signaling cascades. The EGFR is a 170 kD membrane-spanning glycoprotein consisting of an extracellular ligand-binding domain, a transmembrane domain, and an intracellular cytoplasmic protein domain with tyrosine kinase activity. EGFR is a member of the human epidermal receptor (HER) family of receptor tyrosine kinases, which includes EGFR (HER1, erbB1), HER2 (neu, erbB2), HER3 (erbB3), and HER4 (erbB4). The HER
family responds to an assortment of growth factors to mediate various cell signaling pathways involved in growth and proliferation. EGFR is present in most epithelial tissues and is expressed in many solid tumors. Although there are six known ligands for EGFR, tumor growth factor-alpha (TGF-α) and EGF are the two thought to contribute most to malignant behavior. Upon binding of ligand, the EGFR forms homo- or heterodimers with resultant autophosphorylation and receptor tyrosine kinase activity. This initiates intracellular signaling cascades involving multiple pathways including Ras/MAPK, phosphatidylinositol-3′-OH (PI3) kinase, and signal transduction and activator of transcription (STAT)-3 (Figure 7). In nonmalignant tissue, regulation of EGFR activity results in controlled growth and other vital cellular functions. In tumor, EGFR is either overexpressed or aberrant, for example, manifesting constitutively activated tyrosine kinase function, and contributes to the malignant phenotypic characteristics of proliferation, angiogenesis, metastasis, and evasion of apoptosis. Agents that target EGFR are particularly appealing in HNSCC for several reasons. First, the expression of EGFR or other members of the erbB family is more prevalent in head and neck tumors than any other solid tumor (Table 2). In fact, EGFR messenger RNA and protein are frequently overexpressed in dysplastic and even histologically normal head and neck mucosa in patients with HNSCC, insinuating a role in carcinogenesis. Also, EGFR overexpression has been shown to be an independent poor prognostic factor in HNSCC.43 The correlation between EGFR expression and adverse outcome was first posited more than a decade ago, but subsequent early studies further evaluating the correlation yielded inconsistent results. More recently, Ang and colleagues reviewed tumor specimens from the RTOG 90-03 trial for EGFR expression via immunohistochemistry (IHC).44 Although approximately 95% of specimens had detectable EGFR expression, there was a wide range to the degree of expression. Contrary to several previous studies, there was no apparent correlation between tumor stage, nodal stage, or stage grouping and the degree of EGFR expression. However, there was a striking correlation between high EGFR expression and poor disease-free and overall survival independent of T and N stage. It is important to note that the examined specimens were limited to those patients randomized to the control, that is, conventionally fractionated, arm of the trial. Patterns of disease were examined in the context of variable EGFR expression in the same study. While there was no apparent correlation with distant metastases, LRC was markedly diminished in patients with high EGFR expression. This is in keeping with preclinical data, which strongly suggests that high EGFR expression renders tumor cells radioresistant in cell culture and animal xenografts. Recent data presented at the American Society of Clinical Oncology (ASCO) 2006 meeting also suggested a strong trend (p = .057) toward decreased disease-free survival in HNSCC patients with high-polyosmy or EGFR gene amplification by fluorescence in situ hybridization (FISH).45 Hence, it appears that effecting EGFR inhibition has the potential to decrease tumor radioresistance and thereby improve outcomes in patients with HNSCC.

One manifestation of increased EGFR-associated radioresistance is the finding that patients with tumors demonstrating high level EGFR expression appear to benefit particularly from accelerated radiotherapy. Bentzen and colleagues retrospectively reviewed outcomes according to EGFR expression in a series of patients with HNSCC previously treated on a prospective randomized protocol comparing continuous hyperfractionated accelerated radiotherapy (CHART), in which patients are treated three times daily, with conventional once-daily fractionation.46 Patients with relatively high EGFR expression (greater than the median for the study) had a statistically significant improvement in LRC in the CHART arm, whereas patients with relatively low EGFR expression did not seem to benefit from the accelerated course. A similar analysis was performed on the submitted tissue from three previous prospective trials conducted by the DAHANCA group in which patients with supraglottic larynx primaries were treated with definitive radiotherapy and a hypoxic radiosensitizer over 9.5, 6.5, or 5.5 weeks.47 IHC staining for EGFR as well as E-cadherin was performed.

![Figure 7](image)

**Figure 7** Possible mechanisms underlying responses to epidermal growth factor receptor (EGFR) inhibition.
on the submitted tissue. E-cadherin is a protein on the cellular membrane involved in cell-cell adhesion; decreased E-cadherin is postulated to diminish adhesion, promote tumor invasion and metastasis, and prevent terminal cell differentiation. Patients with high EGFR and low E-cadherin expression were found to have better tumor control rates when treatment was accelerated over 5.5 weeks as opposed to 6.5 or 9 weeks.

The targeting of EGFR has led to a rapid expansion of clinical investigations in recent years evaluating the utility of this approach. There are several classes of molecular-targeted agents designed to arrest EGFR-mediated pathways. Monoclonal antibodies were among the first agents designed to inhibit EGFR activity. They achieve EGFR blockade by targeting the ligand-binding domain of the receptor. Cetuximab (C-225, Erbitux, ImClone Systems/Bristol Myers Squibb) is farthest along in clinical development in HNSCC, although a host of other agents are in phase I–III trials. The small-molecule tyrosine kinase inhibitors (TKIs) is another category of agents targeting EGFR. These quinazoline- or pyrimidine-based molecules interrupt the intracellular signal transduction cascade downstream of EGFR-ligand binding. Four general categories of small-molecule TKIs exist: reversible EGFR-specific, irreversible EGFR-specific, reversible pan-HER, and irreversible pan-HER. Two reversible EGFR-specific agents in particular, gefitinib (ZD1839, Iressa, Astra-Zeneca) and erlotinib (OSI 774, Tarceva, Genentech), have been the basis of several phase II and III clinical trials in multiple solid tumors. Novel categories of agents in earlier stages of clinical development include antisense oligonucleotides directed against EGFR mRNA and EGFR ligand-toxin or immunotoxin conjugates which pair an EGFR-tropic moiety with a cellular toxin.

A multitude of HNSCC clinical trials incorporating agents targeting EGFR have been conducted in the recent past or are currently underway, although relatively few results have been published at this time. As described above, EGFR expression clearly has prognostic value; however, its utility as a predictive marker for response to EGFR blockade is considerably murkier. Interestingly, the development of the acneiform rash frequently observed in patients receiving EGFR blockade appears to serve as a surrogate marker of response to EGFR inhibition. Recent preclinical studies suggest that a transition from an epithelial to mesenchymal phenotype may also predict response to EGFR inhibitors. The results of a landmark trial affirming a role for EGFR inhibition in locally advanced HNSCC were recently reported. This randomized multicenter trial enrolled 413 patients with stage III or IV (M0) SCC of the oropharynx, larynx, or hypopharynx to either definitive radiotherapy alone or radiotherapy plus weekly cetuximab. More than half of the enrolled patients had an oropharyngeal primary; approximately 75% had stage IV disease. The radiotherapy was either conventional once-daily treatment, hyperfractionation with twice daily treatment throughout the course, or accelerated radiotherapy via concomitant boost. IMRT was not permissible, but the selection of one of the three regimens was at the treating physician's discretion. In the end, the majority (59%) of patients were treated with the concomitant boost approach. No patient received planned cytotoxic chemotherapy. In the combined modality arm, a cetuximab loading dose of 400 mg/m² was delivered 1 week prior to radiotherapy and weekly dosing was 250 mg/m² during concurrent treatment. The results revealed a significant improvement in LRC, progression-free survival, and overall survival in the radiotherapy plus cetuximab arm. The median duration of LRC was improved from 14.9 months in the radiotherapy alone arm to 24.4 months in the combined arm (p = .005). At a median follow-up of 54 months, overall survival was 49.0 months versus 29.3 months respectively in the combined modality and radiotherapy alone arms (p = .03) (Figure 8). Progression-free survival was similarly improved. Moreover, the combined treatment was well tolerated with no significant difference in mucositis rates between the two arms, a result that starkly contrasts the markedly increased acute mucosal toxicity typical of concurrent chemoradiation. Patients in the combined arm frequently experienced the acneform rash that is characteristic of EGFR blockade, but it rarely exceeded grade 2 in severity. Subgroup analysis suggested that patients with an oropharyngeal primary and those treated with hyperfractionation or concomitant boost treatment benefited the most from the addition of cetuximab. It is important to emphasize that the subgroup data should be interpreted cautiously since the trial was not powered for such analysis. Interestingly, the results in the combined arm compare favorably with previously published concurrent chemoradiotherapy data, although one obvious limitation of the trial was the absence of a chemoradiation arm. This will be addressed, in part, by the aforementioned RTOG 05-22 trial that will randomize patients in the definitive setting to chemoradiotherapy with or without cetuximab. A pilot study of concurrent radiotherapy, full-dose cisplatin, and cetuximab in the definitive setting was recently reported. Previous phase I studies reinforced the safety of such a combination, but the study in question was stopped early because of adverse events, including two toxic deaths. Nevertheless, the outcomes were very encouraging from an efficacy standpoint with 3-year progression-free and overall survival rates of 56% and 75%, respectively.

Building upon the above work, preliminary reports of several trials combining radiotherapy, cytotoxic chemotherapy, and EGFR inhibition were presented at the 2006 ASCO meeting. A small series of patients treated with cisplatin, infusional 5-FU, and cetuximab (weeks 1, 4, and 7) alternating with radiotherapy and cetuximab (weeks 2 to 3, 5 to 6, and 8 to 10) was presented by Merlano and colleagues. Kies and colleagues presented a series of 41 patients treated on a phase II protocol of induction cetuximab with pacilitaxel and carboplatin prior to either surgery and postoperative radiotherapy, radiotherapy alone, or chemoradiotherapy depending on response. A complete response to induction treatment was witnessed in 83% of patients, and no patient experienced less than a partial response. This regimen is also emblematic of the resurgent interest in exploring a role for induction treatment in organ preservation approaches to locally advanced HNSCC.

Progress in clinical trials utilizing small-molecule TKIs in locally advanced HNSCC is also evident in several recent presentations.

![Figure 8](image-url)  
Kaplan-Meier estimates of overall survival among all patients randomly assigned to radiotherapy plus cetuximab or radiotherapy alone. The dotted lines indicate median survival times. Hazard ratio for radiation plus cetuximab versus radiation alone was 0.74 (95% confidence interval, 0.57 to 0.97; p = .03). (Adapted from reference 50.)
Investigators from the Minnie Pearl Cancer Center reviewed initial results of their series of patients treated with induction gefitinib (250 mg per oral daily), taxotere, and carboplatin followed by concurrent radiotherapy, taxotere, and gefitinib.\(^5^4\) Progression-free survival was 68% and overall survival was 86% at 1 year, without unexpected toxicity. A recently conducted multi-institutional phase II trial led by investigators at the University of Colorado Cancer Center randomized patients with locally advanced HNSCC in the definitive setting to concurrent radiotherapy, cisplatin, and either 250 mg daily gefitinib, 500 mg daily gefitinib, or placebo. The results have yet to be reported, although the trial has completed accrual. The use of pre- and post-concurrent erlotinib has also been explored in the definitive radiotherapy setting in two recently reported phase I trials.\(^5^5,^5^6\) Agents which target multiple receptors in the HER family are also in clinical development. One such agent, lapatinib (Tykerb), is a small-molecule TK1 with activity against both EGFR and ErB-B2 (Her-2). A recent series of 17 patients treated in the definitive setting with radiotherapy, lapatinib, and cisplatin revealed the regimen to be well tolerated and will serve as the foundation for subsequent investigation.\(^5^7\) Anti-angiogenesis approaches are also being investigated in view of the utility of bevacizumab (A vastin) in other disease sites. A recently reported feasibility trial consisting of every-other-week radiotherapy with concurrent bevacizumab, hydroxyurea, and 5-FU demonstrated encouraging survival rates in high-risk patients, some of which were undergoing retreatment, and will be further pursued in a phase III setting.\(^5^8\) Toxicity included a fatal esophageal tumor bed bleed and a fatal carotid artery rupture, underscoring the importance of proceeding cautiously with such a combination in a clinical trial setting.

The RTOG has also investigated the combination of chemoradiotherapy and EGFR blockade in the postoperative setting. RTOG 02-34, a two arm phase II trial, has nearly completed accrual of over 200 patients following surgery for locally advanced HNSCC with high-risk pathologic features including positive surgical margins, two or more involved lymph nodes, or evidence of ECE, that is, identical eligibility criteria as RTOG 95-01. All patients receive radiotherapy and concurrent cetuximab and are randomized to either concurrent weekly cisplatin or docetaxel. The results are eagerly anticipated and will form the basis for a future phase III trial.

**ADDITIONAL PROGNOSTIC/PREDICTIVE MARKERS AND RADIOPROTETHERS IN HEAD AND NECK SQUAMOUS CELL CARCINOMA**

Yet another avenue of research in HNSCC relates to the fairly recent recognition of human papillomavirus (HPV) as an etiologic factor in a subset of HNSCC. The number of identified HPV serotypes is in excess of one hundred, with multiple low-risk constituents, for example, 6 and 11, implicated in the development of benign oral hyperproliferative lesions such as papillomas and warts. High-risk HPV serotypes, for example, 16, 18, 31, and 35, on the other hand, are thought to contribute to the malignant transformation of head and neck epithelium, particularly in the oropharynx. A mong the oncogenic serotypes, HPV16 is responsible for greater than 90% of all HPV-associated HNSCC.\(^5^9\) Evidence to support the causal role of HPV in a subset of HNSCC abounds. Case-control studies demonstrate a markedly elevated odds-ratio for developing oropharyngeal SCC in those who are seropositive for high-risk HPV. Moreover, in HPV-positive tumors, the virus is integrated and transcriptionally active in the cell nuclei, whereas it is absent in adjacent normal tissue. High-risk HPV produces the oncoproteins E6 and E7, which render the tumor-suppressor genes p53 and pRB functionally inactive. Several epidemiologic and clinical features distinguish HPV-positive from HPV-negative HNSCC. The stereotypical patient with an HPV-positive tumor is a young male or female without a significant alcohol or tobacco history presenting with a poorly differentiated or basaloid SCC of the lingual or palate tonsils. While it is highly unlikely that the typical risk factors for HNSCC are protective against the development of HPV-positive tumors, the data regarding the carcinogenic interplay of HPV and tobacco and alcohol are inconsistent, with some studies that suggest a synergism and others that do not. As is the case in cervix cancer, high-risk sexual behavior is believed to predispose patients to HPV-positive HNSCC. For the head and neck oncologist, the ramifications of the increased awareness of HPV-associated oropharyngeal cancer are numerous. First, the recognition of high-risk HPV in nodal biopsies of patients with occult primary disease clearly guides further diagnostic work-up and treatment toward the tonsillar region. Furthermore, the preponderance of data supports the notion that patients with HPV-positive tumors are ideal candidates for organ preservation in that HPV-positive tumors tend to be particularly radiosensitive. Finally, and most importantly, a vaccine approved by United States Food and Drug Administration against HPV16 exists and serves as a promising method of primary prevention of HPV-positive tumors at many sites. However, much additional time and research will be needed to assess its full role in that regard.

While a vast array of research aimed at improving patient outcomes in HNSCC has been conducted in recent decades, significant effort has also been undertaken to minimize treatment-associated toxicity. IMRT is a quantum leap forward in terms of preservation of salivary function. Preceding the conceptualization of IMRT by several decades was the notion that thiol-containing compounds could potentially lessen radiation-induced damage by way of free radical scavenging. The United States Army examined thousands of possible radioprotectors for military applications before recognizing amifostine (WR-2721, Ethyl, Medimmune Oncology) as the most promising agent, in part due to its tolerable side effect profile (primarily nausea, vomiting, and hypotension) and dense accumulation in epithelial tissue. Several small early trials suggested amelioration of mucosal and salivary gland toxicity in irradiated patients given amifostine. A double-blind trial revealed apparent protection against cisplatin-induced nephrotoxicity. More recently, a randomized phase III trial of intravenous amifostine versus placebo was conducted in patients receiving radiotherapy for HNSCC.\(^6^0\) Patients receiving amifostine experienced less acute and chronic xerostomia than those receiving placebo. Specifically, the grade 2 and higher acute xerostomia rates were 78% and 51% (p < .0001); chronic xerostomia rates were 57% and 34% respectively (p = .002). Mucositis rates were unchanged, and disease outcomes did not appear to differ, suggesting that the protection conferred by amifostine did not extend to mucosal tissue or, more importantly, the tumor.

A recent small randomized, placebo-controlled trial evaluating the role of L-alanyl-L-glutamine supports its nascent role in mucositis prevention in patients receiving head and neck radiotherapy.\(^6^1\) Thirty-two patients undergoing chemoradiotherapy received either the IV drug or placebo; statistically significant reductions in mucositis, severe mucositis (greater than 4 and higher), pain scores, and feeding tube reliance were observed in the arm receiving the study drug. The results will likely provide the impetus for a larger confirmatory trial before L-alanyl-L-glutamine becomes a component of the radiation oncologist’s armamentarium.

Another potentially protective agent generating interest is recombinant human keratinocyte-growth factor (palifermin). Palifermin is hypothesized to minimize the mucosal toxicity associated with radiotherapy by providing both a cellular growth stimulus as well as a direct cytoprotective effect. Preclinical data are strongly suggestive of a protective benefit, and there is an established role for palifermin in patients receiving stem-cell transplant conditioning regimens and other mucositis-inducing chemotherapeutic combinations. However, a previously conducted trial in patients receiving concurrent chemoradiation failed to demonstrate efficacy. Subsequent dose-response data led investigators to conclude that the lack of benefit derived from underdos- ing of the study drug. The RTOG is therefore conducting a phase III trial (RTOG 04-35) which randomizes patients undergoing chemoradiotherapy to either palifermin at the escalated dose (180 μg/kg weekly for up to eight doses) or placebo. A secondary endpoint will be disease outcome given concerns that administration of a growth factor during treatment will be counterproductive from the standpoint of tumor control, although such a finding has not been observed in previous preclinical or clinical experience with palifermin.
FUTURE DIRECTIONS

It is an exciting time to be a head and neck oncologist. HNSCC continues to pose a formidable challenge with immense room for improvement in terms of maximizing patient outcome while simultaneously minimizing treatment toxicity. However, practitioners cast an optimistic eye toward the development and selection of an ever-expanding array of targeted therapies which take aim at the myriad of cell pathways and processes that run amok in HNSCC. While the application of targeted therapies may in time lead to a sea change regarding the use of cytotoxic chemotherapy, its role today is primarily as an adjuvant to the hard-won concept of concurrent chemoradiation. New technologies such as IM RT and imaging modalities such as PET- and MRI- fusion will continue to be developed in an effort to deliver more accurate and less toxic radiotherapy. The optimal use of accelerated fractionation and hyperfractionation will be better understood as accruing trial data matures. Also, the resurgent interest in induction therapy prior to chemoradiotherapy holds promise and will be explored in ongoing and future trials.

Immunotheapy for Head and Neck Cancer

Andrei I. Chapoval, PhD
Dan H. Schulze, PhD
Scott E. Strome, MD

The term head and neck cancer embraces all malignancies that arise in the head or neck region (in the skin, nasal cavity, sinuses, lip, mouth, salivary glands, throat, larynx lymph nodes, or thyroid gland). According to recent National Cancer Institute estimates that there will be 40,500 newly diagnosed head and neck cancer cases and approximately 11,000 deaths in 2006 in the United States,1 and approximately 900,000 new cases and 240,000 deaths worldwide. Squamous cell carcinoma (SCC) represents more than 90% of all head and neck tumors. Standard therapy for advanced head and neck squamous cell carcinoma (HNSCC) includes surgery, radiotherapy, and chemotherapy. Despite available treatment options, disease recurs locally in about 40% of the cases and nearly 25% of patients develop distant metastases. Both successful surgical and medical therapy of HNSCC can result in severe cosmetic, speech, and swallowing defects, which negatively impact quality of life. Hence, the development of alternative therapies capable of improving disease-free survival and eliminating tumors not suitable for organ-sparing approaches are warranted.

Based on promising new data in both HNSCC and other histological tumor types, the possibility of developing immunotherapeutic approaches as a treatment option for HNSCC has gained interest. For example, adaptive transfer of native or genetically modified tumor-specific T lymphocytes is an effective approach to treat metastatic, immunogenic melanoma.2,3 Moreover, it is conceivable that the immune system could potentially control head and neck cancer development, and immunotherapy may be effective for the treatment of patients with HNSCC. Cellular-based therapies provide unique tumor specificity, the ability to detect and destroy micrometastases, and the potential to develop prolonged antitumor memory. In this chapter, we discuss current developments in human head and neck cancer immunotherapy including: passive immunotherapy (antibody based and adoptive T-cell transfer) and active immunotherapy (dendritic cells (DCs) based vaccine, cytokine immunotherapy and costimulation-based immunotherapy).

MECHANISTIC GOAL OF CANCER IMMUNOTHERAPY

The primary goal of cancer immunotherapy is to utilize the effector mechanisms of immunity to detect and destroy tumor targets. This can be achieved in two ways: by passive transfer of antitumor effectors generated in vitro or by inducing an antitumor immune response in vivo utilizing various vaccine approaches. Both methods have been tested in animal models and in patients with HNSCC with varied degrees of success.

Passive cancer immunotherapy can be logically divided into two categories: antibody-based immunotherapy and cell-transfer therapy. Antibody-based cancer immunotherapy became a reality after the development of techniques that can specifically recognize tumor Ags presented in the context of HLA (MHC) molecules resulting in the eliminating of Ag positive tumor cells in vivo. Many of the vaccine approaches that are currently being investigated for the treatment of cancer seek to optimize the activation of T-cells that can specifically recognize tumor Ags presented in the context of HLA (MHC) molecules resulting in the eliminating of Ag positive tumor cells.

CHALLENGES FOR IMMUNOTHERAPY OF HEAD AND NECK CANCER

One of the major challenges of HNSCC immunotherapy is the impaired immune response in patients with HNSCC and the ability of HNSCC to avoid immune surveillance. Detailed mechanisms of immunosupression in patients with HNSCC are described in Chapter 88, “Mechanisms of Immune Evasion of Head and Neck Cancer.” Here, we briefly outline possible mechanisms that permit HNSCC to avoid immune responses. It has been demonstrated that HNSCC cells completely or partially lose expression of HLA (MHC) molecules that makes this malignancy virtually invisible to T lymphocytes. Another mechanism by which HNSCC cells can circumvent immune responses is by expressing Fas ligand, which can destroy T-cells that attack neoplasms. Additionally, HNSCC can also inhibit immune cell function by producing inhibitory factors such as tumor growth factor beta (TGF-β) and IL-10.

PASSIVE IMMUNOTHERAPY OF HEAD AND NECK CANCER

Antibody-Based Immunotherapy

Monoclonal antibodies (mAb) which specifically bind to tumor surface antigens may result in tumor cell death by the following mechanisms: (1) antibody dependent cellular cytotoxicity...
expressing SCC cell lines. While it was shown specific for Her-2 can induce ADCC of Her-2 results of other recent studies indicate that mAb of patients with breast cancer, this approach has that anti-Her-2 mAb were effective in treatment (2) activation of the complement system; and (3) blocking the receptors that are essential for pro-

Figure 1 Mechanisms of antibody-based immunotherapy. Tumor-specific antibodies can kill tumor cells by (1) inducing antibody-dependent cellular cytotoxicity of natural killer cells and macrophages expressing Fc receptors, (2) complement-mediated lysis, (3) directly by inhibiting signaling of growth factor receptors.

(ADCC) mediated by NK cells or macrophages; (2) activation of the complement system; and (3) blocking the receptors that are essential for proliferation and survival of tumor cells (Figure 1).

Cancer cells often express developmental antigens that are not normally seen on mature cell types. For example, Her-2/neu, a protein proto-oncogene, was shown to be overexpressed on various types of cancer including squamous cell carcinoma. In vitro studies with human HNSCC cell lines showed that combined treatment with anti-Her-2 mAb and irradiation inhibited proliferation of Her-2 expressing HNSCC lines. The results of other recent studies indicate that mAb specific for Her-2 can induce ADCC of Her-2 expressing SCC cell lines. While it was shown that anti-Her-2 mAb were effective in treatment of patients with breast cancer, this approach has not been tested in patients with HNSCC.

Another promising antibody target for HNSCC immunotherapy may be CD44, a cell adhesion molecule. While CD44 is widely expressed in normal tissues, the expression of an abnormal CD44 variant 6 (CD44v6) has been related to aggressive behavior of various tumor types and was shown to be elevated on the cell surface of HNSCC. The therapeutic potential of anti-CD44v6 mAb was confirmed in nude mice bearing human HNSCC xenografts. Radiolabeled mAb directed against the CD44v6 antigen provided promising antitumor effects in phase I trials in patients with inoperable HNSCC.

The epidermal growth factor receptor (EGFR) is expressed on the majority of, if not all, HNSCCs, which makes it an ideal target for Ab-based immunotherapy. Cetuximab is a human-murine chimeric monoclonal Ab that binds to the extracellular domain of EGFR and is currently used for the treatment of patients with locally advanced HNSCC. Cetuximab is an example of an Ab that blocks signaling through the receptor essential for survival and proliferation of tumor cells (see Figure 1, Step 3). Binding EGFR to its ligand TGF-α induces a signaling cascade that results in tumor cell growth, invasion, angiogenesis, and metastases. Cetuximab blocks the interaction of EGFR with TGF-α and that prevents tumor pathogenesis. In a Phase III clinical trial, 117 patients with advanced head and neck cancer treated with cisplatin plus cetuximab demonstrated an improved response rate when compared to those that were treated with cisplatin alone. But treatment with cisplatin plus cetuximab did not significantly improve survival. A separate randomized study (involving 424 patients) comparing radiotherapy alone with radiotherapy plus cetuximab demonstrated that radiation plus antibody is superior to radiotherapy alone, increasing both the duration of locoregional disease control and survival. These data suggest that cetuximab mAb in combination with radiotherapy can be used for treatment of patients with HNSCC, however, additional studies are required to improve the therapeutic efficacy of cetuximab combined with radio- or chemotherapy.

Recently, it was found that 42% of HNSCCs express a mutant form of EGFR (EGFRvIII) that results in ligand-independent activation of EGFR signaling pathway that causes tumor growth. This observation may explain the limited clinical response to EGFR-targeted therapy and suggest that the antitumor efficacy of EGFR targeting strategies may be enhanced by the addition of EGFRvIII-specific blockade.

Additionally, the immunoglobulin Fc receptor polymorphism should be taken into consideration when Ab treatment is used for HNSCC immunotherapy. It was shown that the differential affinity for the IgG binding of polymorphic alleles of the human Fc receptor can influence the effectiveness of antibody immunotherapy. For example, in human Fc Gamma R IIIA (CD16) having a valine at 158 amino acid position binds to antibody better than CD16 having phenylalanine at the same position. This polymorphism was associated with a reduced response in patients with B cell malignancies treated with rituximab, an anti-CD20 human IgG1 mAb. Similarly, a polymorphic change from histidine to arginine at amino acid position 131 of the human Fc Gamma R IIa (CD32) results in reduced IgG binding affinity and therapeutic effectiveness of neuroblastoma treatment with anti-GD2 antibody. These results may be explained by variable ability of NK cells and macrophages expressing polymorphic variants of Fc receptors to bind to Ab and mediate ADCC.

Alternative methods for Ab-based immunotherapy include the use of recombinant bispecific Ab which can recognize a T-cell co-receptor like CD3 and tumor-associated antigens, for example, carcinoembryonic antigen (CEA), pan-epithelial homotypic cell adhesion molecule (EpCAM), HER2/neu, CD19, resulting in selective retargeting of cytotoxic T lymphocytes (CTLs) to tumor cells and the induction of cytotoxic effects. Such bispecific Ab represent a way to arm unique tumor specificity to the CTLs. A bispecific Ab that retarget CD3+ T lymphocytes to tumor cells expressing EpCAM membrane protein were shown to kill SCC in vitro experiments.

Adoptive T-Cell Transfer

In general, adoptive T-cell transfer is accomplished by harvesting cells from the peripheral
lymphocytes. In these studies, T lymphocytes that involved only 6 HNSCC patients showed no clinical response to adoptively transferred T-cells.23 However, a single clinical trial consisting of preclinical models that demonstrated efficacy in tumor rejection in mice immunized with DCs pulsed wt-p53 peptide.29 These results led to the development of more rapid enrichment of HPV-specific polyclonal T-cell populations for adoptive immunotherapy of cervical cancer are described.24 Recently, it was shown that HPV-specific T-cells derived from peripheral blood mononuclear cells (PBMC) of patients with oropharyngeal and laryngeal HNSCC were able to recognize and kill HPV+ SCC cells.27 It is conceivable that HPV-specific T lymphocytes can be used for adoptive T-cell therapy of HNSCC. This will require strict selection criteria for patients eligible for HPV therapy which should include the type of HPV infection and MHC haplotype of HNSCC patients.

**ACTIVE IMMUNOTHERAPY OF HEAD AND NECK CANCER**

The goal of active immunotherapy is to generate antitumor T-cell responses in patients with cancer in vivo through the development of potent antitumor vaccines. Tumor antigens are a prerequisite for non-cell-based cancer vaccine immunotherapy. So far, over 1,000 different tumor antigens including Mart-1, gp100, and NY-ESO-1 have been identified, mainly from melanoma. Tumor associated Ags can be divided into several groups: tumor-specific Ags (usually viral Ags), differentiation Ags (cancer-testis (CT) Ags), mutated normal proteins (β-catenin, caspase 8, mutated p53) and Ags overexpressed by tumors (ERβ2b, p53). Based on the evidence of tumor-specific Ags, existing experimental and clinical cancer vaccine follow two general directions: (1) immunization with unique identified tumor Ags; or (2) use of undefined tumor-derived products (Figure 3).

**Peptide-Based Antitumor Vaccine**

The recent identification of tumor-associated antigens, presented as peptides in the context of appropriate HLA molecules, which are targeted by antitumor CTL has opened the way to cancer vaccine utilizing peptide epitopes for stimulation the tumor-specific CTL. Many HNSCC express mutant or overexpress wild type p53 (wt-p53), a protein involved in cell-cycle regulation and in apoptosis. A number of investigators have identified a subset of T lymphocytes in peripheral blood of patients with HNSCC which are able to recognize and lyse HNSCC cell lines over expressing p53.28,29 These results led to the development of preclinical models that demonstrated efficacy in tumor rejection in mice immunized with DCs pulsed wt-p53 peptide.29 Based on the encouraging preclinical data, a Phase I study utilizing DCs pulsed with wt-p53 was initiated at the University of Pittsburgh for treatment HNSCC patients. In the final part of this study, patients will be immunized with HLA A*0201-restricted wt-p53 peptides loaded onto autologous, mature DCs. The study is designed to monitor the immunological status and observe tumor response in subjects after vaccine administration. A mentioned above, nearly 30% of head and neck tumors are associated with HPV infection which results in p53 mutations.

**Figure 2** Adoptive T-cell transfer. Tumor-specific T-cells can be isolated from tumor-infiltrating lymphocytes (TILs) or peripheral blood mononuclear cells (PBMC) of patients with cancer. Isolated T-cells are then expanded using high doses of IL-2. The cells are successively selected for their ability to kill autologous or allogenic HLA-matched tumor cell lines. Tumor reactivity of expanded cells is validated before adoptive transfer.
nated mice. Based on these observations, a Phase I clinical trial, led by S E Strome, is ongoing at the University of Maryland to define the feasibility and safety of MAGE-A3/HPV 16 Trojan peptide vaccine for the treatment of HNSCC. The trial demonstrated low-level toxicity and potent antitumor activity. A subsequent Phase II trial in 71 patients with HNSCC indicated that low-dose IFN-α was well tolerated. Clinical benefits of a low concentration of IFN-α were overall unimpressive. However, 2 of 29 patients treated with a high concentration of IFN-α had a complete response and 7 had stable disease. The duration of survival in patients who received high doses of IFN-α correlated with a high level of NK activity.

\[\text{Cytokine Immunostimulation} \]

Cytokines play an important role in generating and sustaining immune responses in general. IL-2, a cytokine essential for T-cell growth, has been used to activate antitumor T and NK cells both in vitro and in vivo. Injections of IL-2 were shown to cause increased antitumor responses, especially in immunogenic tumors such as melanoma and renal cancer. Other cytokines such as IFN-α, IL-12, and GM-CSF have also been used as natural adjuvants to boost the antitumor immune responses in cancer patients (Figure 4).

A preliminary trial of nonrecombinant IFN-α in patients with HNSCC was performed in 1991. This trial demonstrated low-level toxicity and potent antitumor activity. A subsequent Phase II trial in 71 patients with HNSCC indicated that low-dose IFN-α was well tolerated. Clinical benefits of a low concentration of IFN-α were overall unimpressive. However, 2 of 29 patients treated with a high concentration of IFN-α had a complete response and 7 had stable disease. The duration of survival in patients who received high doses of IFN-α correlated with a high level of NK activity.

In a series of clinical trials, IL-2 was successfully used to improve immune function of patients with head and neck cancer. The local administration of recombinant human IL-2 to patients with HNSCC demonstrated a statistically significant increase in disease-free survival as well as increased overall survival. The improved clinical response after administration of recombinant IL-2 was associated with increased numbers of activated T lymphocytes and NK cells.

A novel tumor cell immunotherapy approach utilizes the fusion of DCs with tumor cells. The fusion products retain the antigen-presenting properties of the DCs and can present protein antigens carried by the parent tumor cell. The cell fusion is usually done by exposure of cells to electric field stimulation which creates reversible membrane breakdown required for the fusion of different cell types. Vaccines prepared by this method were shown to be effective in treatment of tumors expressing model Ags (β-galactosidase). Immunization of mice bearing established pulmo-

\[\text{Whole Tumor Cell Vaccines} \]

Because only a small number of HNSCC specific Ags have been identified, whole tumor cells or their products may provide a more plausible alternative as a source of immunogen for HNSCC immunotherapy. However, immunization with tumor cells alone does not result in a meaningful therapeutic antitumor immune response due to lack of costimulatory molecule expression on the tumor cell surface and their inability to process and present adequate levels of tumor associated Ags. To overcome this problem, several strategies utilizing powerful Ag-presenting properties of DCs loaded with tumor cell products were tested in vitro and in animal models.

Whole tumor cell vaccine remains to be determined.
six times over a 28-day period. These results were obtained by direct intratumoral injections up to the tumor site, indicating that IL-2 nonviral gene therapy for head and neck cancer is safe and well tolerated when administered in a randomized, dose-escalation, phase I study shows that IL-2 can increase antitumor activity of NK and T lymphocytes. A phase II study of the administration of recombinant human IL-2 (rhIL-2) to patients with HNSCC before surgery to evaluate the immune effects on the primary tumor and regional lymph nodes was performed. After therapy with rhIL-2, an increase number of NK cells in peripheral blood and in tumors was observed. In addition, patients treated with rhIL-2 showed increased production of IFN-γ, which indicated an active immune response against tumors.

All phase I clinical trials for therapeutic use of cytokines, that is, natural or recombinant IL-2, IL-12, and IFN-α, in patients with HNSCC evaluated toxicity of cytokines and were not designed to answer the question of efficacy or to test the restoration of immune cell function in patients with cancer. Therefore, additional advanced clinical trials are required to assess the clinical outcome of cytokine immunostimulation of patients with HNSCC.

Costimulation-Based Immunotherapy

Perhaps, one of the most important recent discoveries relevant to cancer immunotherapy is the elucidation of the roles of various costimulatory molecules in antitumor immune response (Figure 5, #1). In particular, it has been demonstrated that cytotoxic T lymphocyte antigen-4 (CTLA-4), a receptor of B7-1 and B7-2 ligands, functions as a negative regulator of T-cell activation (Figure 5, #2). It has been convincingly shown that in vivo antibody-mediated blockade of the CTLA-4 expressed on T lymphocytes can greatly augment antitumor immune responses both in animal models and in patients with cancer. In fact, a fully humanized anti-CTLA-4 mAb (MDX-010) has been developed and is being tested for the immunotherapeutic treatment of specific immunity against wild-type SCC tumors. Therefore, immunotherapy utilizing the 4-1BB costimulatory pathway could be applied for treatment of head and neck cancer. One of the advantages of 4-1BB-based cancer immunotherapy is that agonistic anti-4-1BB may enhance antitumor immunity while minimizing autoimmunity. Unlike what has been observed after injection of anti-CTLA-4 mAb which stimulated the development of mild autoimmune immune reactions, anti-4-1BB mAbs have been shown to abrogate autoimmune manifestations in the mouse lupus model. Moreover, a recent report indicates that the combination of anti-CTLA-4 and anti-4-1BB mAb dramatically augmented antitumor immunity while reducing autoimmune effects.

B7-H1 ligand, a cell-surface glycoprotein belonging to the B7 family, is expressed on activated DC, epithelial and endothelial cells. Programmed death-1 protein (PD-1) is a specific receptor expressed on activated T lymphocytes that binds B7-H1 ligand. Engagement of the PD-1 receptor by B7-H1 inhibits proliferation, cytokine production and induces apoptosis of activated T lymphocytes (Figure 5, #3). Recently, it was shown that many tumors including HNSCC express B7-H1. Tumor-associated B7-H1 increased the apoptosis of T-cells interacting with tumors and antibody against B7-H1 inhibited T-cells in vivo. Therefore, it was postulated that B7-H1 may contribute to the evasion of tumor immunity in vivo. To verify the role of B7-H1 in HNSCC, the authors established a murine SCCVII cell line that was transfected with B7-H1. Combined with the adoptive transfer of activated tumor-specific T-cells, the injections of blocking anti-B7-H1 mAb significantly promote the survival of mice bearing B7-H1-expressing SCCVII tumors as compared to adoptive T-cell therapy alone. Interestingly, eight different human HNSCC tissue samples were positive for B7-H1. A more recent report confirms that many human oral SCC cell lines constitutively express B7-H1, and its expression is further up regulated by IFN-γ. This implies that altering interactions of tumor-B7-H1 with PD-1 on tumor infiltrating lymphocytes by recombinant fusion protein or neutralizing antibodies (Figure 5, #3) may have a great potential for benefit in immunotherapy of oral SCC.
CONCLUSIONS

It is clear that the immune system plays critical roles in tumor development and cancer immunosurveillance. It is also widely accepted that immunity may play a pivotal role in future cancer therapy. The immune system can recognize and destroy tumor cells that present unique antigens. However, most malignant cells possess various approaches that can evade the immune system’s attack on tumor cells. HNSCC can avoid immune cells through downregulation of HLA antigens and production of immuno-inhibitory molecules. The challenges for HNSSC immunotherapy are to understand the molecular mechanisms in play between HNSSC cells and the immune system and then to design novel approaches that can tip the balance in favor of the immune system in its fight against HNSSC cells.

Nutrition of the Patient with Head and Neck Cancer

Laurence J. DiNardo, MD
Elizabeth G. Miller, RD

About 30 to 50% of all patients with head and neck cancer are malnourished even before treatment starts. Four factors are generally responsible for calorie and protein malnutrition in these individuals. First, the tumor itself may present a barrier to deglutition through obstruction or pain. Second, tumor metabolism remains constant despite changes in nutritional status. Consequently, starvation responses such as lipolysis are not used by tumor cells, and glucose is continuously derived from protein catabolism. Third, recent evidence suggests that cancer cachexia may be induced by catabolic factors secreted by tumor cells. Finally, tumor treatment may induce anorexia through discomfort, obstruction, and loss of taste. Accelerated radiotherapy has been associated with grade 3 to 4 reactions necessitating nasogastric (NG) or percutaneous gastrosomy feedings in 26% of patients with a median weight loss of 4.1 kg. Difficulties are not limited to high-dose, large-field radiation treatments. A significant decrease in body mass index (BMI) has been observed in 80% of patients undergoing radiation therapy for early laryngeal carcinoma despite dietetic consultation and protein/calorie supplementation. Further, it has been shown that poor performance status, advanced stage disease, and a history of smoking identified those at high risk for requiring enteral feedings during definitive radiation therapy. Unfortunately, swallowing difficulties are not limited to the duration of treatment. Shiley and colleagues found that 31% of patients successfully treated for advanced oropharyngeal carcinoma with chemoradiation therapy required feeding tubes 1 year later. Tables 1 to 3 list the possible consequences of cancer treatment—surgery, radiation, and chemotherapy—that may impact a patient’s nutritional status.

Conversely, complications resulting from modern, aggressive treatment regimens for head and neck cancer are exacerbated by poor nutrition. Patients receiving accelerated fraction radiation therapy, chemoradiation, or extended resection with free flap reconstruction are particularly at risk. Preoperative weight loss of greater than 10% has been identified as the most prominent nutrition-related factor in the development of postoperative complications. In addition, preoperative weight loss of greater than 5% has been associated with higher mortality rates for men with head and neck cancer.

Recent work has identified relationships among immune function, nutritional status, and postoperative wound infection. Malnourished patients with head and neck cancer demonstrate a significantly lower human leukocyte antigen (HLA)-DR expression on monocytes than well-nourished, matched controls. Theoretically, this places these patients at a higher risk for postoperative infection. Intervention with immune-enhancing formulas has resulted in a significant decrease in the incidence of postoperative infectious complications.

NUTRITION SCREENING AND ASSESSMENT OF NUTRITIONAL STATUS

Two steps are indicated to ensure the appropriate level of nutrition intervention and follow-up: screening and assessment. Nutrition screening is used to detect the possibility of nutrient risk and whether or not nutrition follow-up is needed. Ongoing nutrition screening is indicated to determine if at any point during treatment a patient may need a more detailed evaluation due to progressive nutritional decline. Nutrition assessment is more comprehensive than screening; it includes intervention and ongoing follow-up.

Usually, nutritional status will be negatively affected in individuals diagnosed with head and neck cancer. Nutrition intervention in the patient with head and neck cancer should be initiated prior to tumor treatment and should continue even after the treatment has ended. Study has found that there is a role for dietary intervention to improve the survival of laryngeal and hypopharyngeal cancer patients. Swallowing difficulties are common prior to treatment and can continue after therapy. Early and intensive nutritional intervention is helpful in minimizing weight loss, maintaining functional status and quality of life, and in overall maintenance of nutritional status. In the head and neck cancer patient population, simply maintaining weight may be the most appropriate and achievable goal.

The initial nutritional assessment includes anthropometric, biochemical, clinical, and dietary history data.

### Anthropometric Measurements

The percentage of weight loss (% wt loss) that a patient has experienced is the most common estimate of malnutrition. The patient’s usual body weight (UBW) is defined as his or her weight 6 months prior to the assessment. Actual or current body weight is then measured. The % wt loss is calculated as follows:

$$\text{% wt loss} = \left(\frac{\text{UBW} - \text{current wt}}{\text{UBW}}\right) \times 100$$

Severe malnutrition is defined as greater than 10% weight loss in 6 months.

A patient’s height is needed to allow determination of ideal body weight (IBW), percent IBW (% IBW), and additional anthropometric measurements. IBW may be determined using reference values for a given height and frame size or by the Hamwi method:

- For men: 106 lb for the first 5 ft, with an additional 6 lb for each inch over 5 ft.
- For women: 100 lb for the first 5 ft, with an additional 5 lb for each inch over 5 ft.

<thead>
<tr>
<th>Nausea</th>
<th>Vomiting</th>
<th>Diarrhea</th>
<th>Cheilositis, glossitis</th>
<th>Pharyngitis</th>
<th>Esophagitis</th>
<th>Anorexia</th>
</tr>
</thead>
</table>

---
Percent IBW is then calculated as follows:

\[
\% \text{IBW} = \frac{\text{actual (current) wt}}{\text{IBW}} \times 100
\]

The extent of malnutrition is then estimated as follows:\(^7\):

- **Mild malnutrition** = 80 to 90% IBW
- **Moderate malnutrition** = 70 to 79% IBW
- **Severe malnutrition** = <69% IBW

Another method for assessing weight status is by determination of BMI:

\[
\text{BMI} = \frac{\text{wt(kg)}}{\text{ht}^2}\text{(m)}
\]

Once calculated, the patient’s BMI is compared to reference values:

- **Underweight**: BMI <18.5
- **Adequate weight**: BMI = 18.5 to 24.9
- **Overweight**: BMI = 25 to 29.9
- **Obese**: BMI > 30

Further assessment of a patient’s nutritional status using anthropometric data can be performed through measurement of triceps skinfold thickness and midarm muscle circumference using skinfold calipers and a measuring tape. These determine the adequacy of a patient’s fat and somatic protein or skeletal muscle status. Given inconsistency in measurements among clinicians and the influence of hydration on results, as well as time constraint, these are now uncommonly performed tests. Body fat, lean body mass, and total body water can be calculated from bioelectrical impedance analysis and may be used as a bedside measurement of a patient’s fluid status.\(^7\)

**Biochemical Assessment**

Assessment of laboratory data comprises another facet of the nutritional status evaluation. The serum proteins that are often used to assess nutritional status include albumin, transferrin, and prealbumin or transthyretin. Each have different synthesis rates and half-lives; therefore, these parameters vary in their reflection of alterations in nutritional status.

The general availability of albumin measurement renders it a useful test. It reflects visceral protein status. Since it has a long half-life of approximately 20 days, however, it does not detect early protein deficiency. Various levels of depletion have been defined:\(^8\):

- **Adequate** = >3.5 g/dL
- **Mild depletion** = 2.7 to 3.5 g/dL
- **Moderate depletion** = 2.1 to 2.6 g/dL
- **Severe depletion** = <2.1 g/dL

Albumin is influenced by many nonnutritional variables, including hydration status, liver or renal disease, sepsis, trauma, surgery, and congestive heart failure, as well as infusion of albumin, fresh frozen plasma, or whole blood. Unfortunately, this necessitates cautious interpretation of albumin values.

In protein-calorie malnutrition from cancer-related cachexia, there appears to be an insufficient supply of amino acids for liver protein synthesis, resulting in a decline in serum albumin. A decline in serum albumin is correlated with cachexia and is a predictor of mortality. In patients with cancer, postoperative complications are more frequent with serum albumin <3.0 g/dL. Decreased tube feeding tolerance has also been observed with a serum albumin <2.5 g/dL.

Transferrin is more useful than albumin as a measure of visceral protein status. Owing to its relatively short half-life (8 days), it is more sensitive to short-term changes in nutrient intake. The degree of malnutrition relative to serum transferrin levels is as follows:

- **Adequate** = 200 to 400 mg/dL
- **Mild malnutrition** = 180 to 200 mg/dL
- **Moderate malnutrition** = 160 to 180 mg/dL
- **Severe malnutrition** = <160 mg/dL

As with albumin, transferrin can be impacted by nonnutritional variables. Levels may be increased with iron deficiency anemia, some malignancies, acute hepatitis, oral contraceptive use, and pregnancy. Levels may be decreased with chronic infection, cancer, iron overload, liver disease, and protein-losing enteropathy. Despite its shorter half-life, transferrin is not as commonly used as albumin or prealbumin in evaluating malnutrition and visceral protein status.

Prealbumin, also named transthyretin or thyroxine-binding globulin, has a half-life of 2 to 3 days and therefore has replaced the transferrin assay in many institutions. Its shorter half-life makes it a sensitive indicator of visceral protein status. It is most useful when assessing a patient for acute changes in nutritional status and short-term response to nutritional support through weekly measurements. Assessment of visceral protein status based on the serum transthyretin value is estimated as follows:

- **Adequate** = 18 to 42 mg/dL
- **Mild depletion** = 13 to 17 mg/dL
- **Moderate depletion** = 8 to 12 mg/dL
- **Severe depletion** = <7 mg/dL

Prealbumin levels are also impacted by nonnutritional factors. Levels can be increased with renal dysfunction, dehydration, and blood transfusions. Levels may be decreased by stress, surgery, inflammation, cirrhosis, hepatitis, and hyperthyroidism.

Retinol-binding protein, with a half-life of 10 hours, measures acute protein deprivation or minor stress. Normal values range from 2.6 to 7.6 mg/dL.

Evaluation of immune function can also provide information relevant to the patient’s nutritional status and serves as a predictor of postoperative complications. In the past, intradermal antigen challenge for the detection of delayed hypersensitivity was used as a measure of immune competence. It has fallen out of favor owing to its lack of specificity. Total lymphocyte count (TLC) is currently the most frequently employed test of immune status in the patient with head and neck cancer. It is calculated as follows:\(^5\):

\[
\text{TLC} = \left[ \% \text{lymphocytes} \times \text{white blood count (WBC)} \right] / 100
\]

Immune competence is then evaluated as follows:\(^5\):

- **Adequate immunocompetence** = >1,800 mm\(^3\)
- **Mild depletion** = 1,500 to 1,800 mm\(^3\)
- **Moderate depletion** = 900 to 1,500 mm\(^3\)
- **Severe depletion** = <900 mm\(^3\)

The use of TLC as an indicator of nutritional status is limited since marked changes can occur in the WBC and differential counts on a day-to-day basis. Also, numerous nonnutrition-related factors can alter the value, such as severe stress, infection, corticosteroid therapy, cancer, renal failure, surgery, and cancer treatments such as radiation therapy and chemotherapy.

Several parameters have been combined to create the prognostic nutritional index (PNI), which has been defined by various formulas.\(^7\) An example:

\[
\text{PNI} = [0.14 \times \text{alb}(\text{g/dL})] + [0.03 \times \% \text{IBW}] + [0.73 \times \text{TLC}(10^9/\text{mm}^3)] - 8.90
\]

A correlation between the PNI and surgical risk in patients with head and neck cancers has been observed. A value less than 1.31 is considered below normal.

**CLINICAL DATA AND DIETARY HISTORY**

The physical examination is an important component of the nutritional status assessment. Physical findings that imply vitamin, mineral, and protein-calorie deficiencies and excesses are listed in Table 4. However, most of the physical findings are not specific for individual nutrient deficits and must be considered together, along with diet history, anthropometric data, and laboratory results.

A diet history is used to identify underlying risks for nutrition depletion or excess. Causes include inadequate intake, compromised metabolism (altered absorption, decreased use, or increased losses), and heightened requirements for nutrients. Patients with the characteristics included in Table 5 have increased susceptibility for nutritional problems.\(^8\)

The diet history of the patient with head and neck cancer should include questions about alcohol consumption. When alcohol is substituted for good nutrition, malnutrition owing to inadequate nutrient intake occurs. Alcoholic persons are prone to develop malabsorption of nutrients owing to inflammation of the gastrointestinal tract. Altered absorption or metabolism of thiamine, folic acid, pyridoxine, vitamin A, vitamin B\(_{12}\), sodium, potassium, magnesium, calcium, phosphorus, zinc, and selenium can result. Long-term alcoholism can also induce cirrhosis, with the potential development of ascites and/or hepatic encephalopathy. Glucose intolerance may
be observed in alcoholics secondary to pancreatic inflammation or injury.

Commonly used methods for obtaining a diet history include the 24-hour recall, a 1- to 7-day food intake record, and a food frequency questionnaire. A number of computer programs allow rapid estimation of nutrient intake based on these records or questionnaires. It is important to remember that in the course of the complete medical history, information elicited from the patient in all of the areas noted in Table 6 will aid in identifying possible nutrient deficits not gathered from the dietary recall.18

**ASSESSMENT OF NUTRITIONAL NEEDS**

The assessment of nutritional needs must include calorie, protein, lipid, vitamin, mineral, and water requirements. Calorie and protein needs vary depending on several factors: (1) a patient’s current nutritional status, (2) whether the need is for maintenance or repletion, (3) whether a patient is at risk for refeeding syndrome, and (4) whether a patient is in a catabolic state. Adults’ daily calorie requirements are estimated at 30 to 35 kilocalories per kilogram (kcal/kg) of body weight, with the lower end of needs being the initial aim if a patient is at refeeding risk.19 Usually, as many as 10 kcal/kg body weight may be added to regain lost weight and compensate for surgical stress. The Harris-Benedict equation was derived to estimate basal energy expenditure (BEE), the energy expended at rest.20

For men:

\[
\text{BEE} = 66.47 + [13.75 \times \text{wt} (\text{kg})] + [5.0 \times \text{ht} (\text{cm})] - [6.76 \times \text{age (yr)}]
\]

For women:

\[
\text{BEE} = 655.10 + [9.96 \times \text{wt} (\text{kg})] + [1.85 \times \text{ht} (\text{cm})] - [4.68 \times \text{age (yr)}]
\]

In general, to calculate the total calorie need of a patient with head and neck cancer, the BEE is multiplied by a stress and activity factor totaling 1.3 to 1.5, with the higher number used for sepsis or other hypermetabolic states. If weight gain or nutritional repletion is desired, approximately 500 to 1,000 calories/d is added to the total calorie need. Since these calculations are estimates and not based on actual measurement of caloric expenditure, frequent monitoring of a patient’s response to the nutrition regimen is required. It has been found through experience that calorie need for maintenance is as high as 35 to 40 kcal/kg.

Acceleration in protein turnover and derangements in protein metabolism have been observed in patients with cancer. In contrast to simple starvation, protein use increases when a patient with cancer is under metabolic stress. Protein needs are usually calculated based on actual or adjusted body weight. The approximate protein need can then be adjusted based on the degree of protein depletion and metabolic stress factors. Under normal conditions with no stress, protein requirements are estimated at 1.0 g/kg/d. For the well-nourished, mildly stressed patient with cancer the protein need may only be 1.2 g/kg/d. However, with mild to moderate depletion along with metabolic stress, up to 1.5 g/kg/d may be necessary. If a patient with head and neck cancer undergoes surgery with reconstruction, protein needs for healing may be up to 2.0 g/kg/d. The amount of protein provided may require further adjustments if renal or liver disease is present.

The best method to determine if protein needs are met in the malnourished patient is by monitoring for gradual weight gain and positive nitrogen balance. In the well-nourished patient, weight maintenance and nitrogen equilibrium are the goals. Weekly serial monitoring of a patient’s prealbumin or transthyretin level is another method for tracking protein supplementation.

Ideally, ≤30% of nonprotein calories should be derived from fat. The appropriate administration of essential fatty acids helps to blunt the insulin response by decreasing the need for infusions rich in glucose. Deriving calories from fat also has a protein-sparing effect.21 Using greater amounts of fat in combination with less glucose is especially important in patients with diabetes mellitus in whom fat can provide as much as 60% of nonprotein calories.

Although recommended daily doses of vitamins, minerals, and trace elements exist, requirements for nutritionally depleted patients with cancer have not been established. It is recommended that patients requiring prolonged parenteral nutrition receive regular doses of multivitamins and trace elements. Research indicates that the zinc status may be less than adequate in up to 50% of patients with head and neck cancer.23

### Table 5 Patients at High Risk for Nutritional Deficits

- Underweight: less than 80% standard and/or recent loss greater than 10% usual body weight
- Poor intake: anorexia, nothing by mouth more than 5 d
- Protracted nutrient loss: malabsorption, enteric fistulae, draining abscesses or wounds, renal dialysis
- Hypermetabolic state: sepsis, fever, extensive burn, or trauma
- Chronic alcohol/drug use: corticosteroids, antimetabolites, immunosuppressants
- Impoverishment, isolation, advanced age
Moreover, it has also been suggested that zinc supplementation aids in decreasing the impact of radiation therapy on taste loss and recovery. More definitive guidelines likely to evolve as knowledge is gained regarding the role of vitamins, minerals, and trace elements in critically ill patients. Experimental evidence exists in mice, for example, which demonstrates increased survival in endotoxin shock with the administration of vitamin D analogues.

There has been recent interest regarding the impact of antioxidants on cancer, cancer treatments, and treatment-related side effects. Results of a clinical trial conducted by the United States National Cancer Institute have shown that the use of vitamin E supplementation is not of help to patients with Stage I or II head and neck cancer, either in reducing the severity of radiation-induced side effects or as a chemoprevention agent. Research is underway to evaluate the impact of fruit and vegetable extracts on patients with Stages I through IVB head and neck cancer.

**NUTRITIONAL SUPPORT**

Whenever possible, nutritional support should be provided through the enteral route. The use of an intact gastrointestinal tract is not only more cost effective, safer, and more practical than parenteral nutrition, it also maintains the integrity of the gut mucosal barrier and immune function. It is also more effective, safer, and more practical than parenteral nutrition postoperatively, and have access for medications. If there is difficulty transitioning to complete oral intake, then the patient is considered for placement of a percutaneous endoscopic gastrostomy (PEG), which is more appropriate for long-term feeding. If it is anticipated that the patient will require long-term tube feeding postoperatively, a PEG tube can be placed intraoperatively. Intraoperative PEG tube placement has been associated with fewer complications than preoperative insertion.

**TYPES AND SELECTION OF FEEDING TUBES**

Enteral feeding involves the administration of nutrient solutions through a tube into the upper gastrointestinal tract. There are two major routes for tube placements: those entering the gastrointestinal tract via the nose [nasogastric (NG) and nasointestinal] and those entering the gastrointestinal tract through the abdominal wall (gastrostomy, duodenostomy, jejunoostomy). Occasionally, a feeding may be given through a tube inserted in the mouth (orogastric) or esophagus (cervical esophagostomy).

The timing and type of enteral tube feeding are largely dependent on the anticipated duration of nutritional supplementation. Placement of a pliable red rubber or Dobhoff tube for feeding is preferred if short-term nutritional support is expected. NG tube feeding should be restricted to short-term use owing to nasopharyngeal and laryngeal irritation as well as potential for necrosis of the nasal alae.

With the placement of an NG tube, the patient can be weaned quickly from intravenous hydration after surgery, receive adequate nutrition postoperatively, and have access for medications. If there is difficulty transitioning to complete oral intake, then the patient is considered for placement of a percutaneous endoscopic gastrostomy (PEG), which is more appropriate for long-term feeding. If it is anticipated that the patient will require long-term tube feeding postoperatively, a PEG tube can be placed intraoperatively. Intraoperative PEG tube placement has been associated with fewer complications than preoperative insertion.

</table>
TUBE FEEDING FORMULAS

Numerous oral and tube feeding solutions are available. Some are intended for general nutrition; others are designed to meet specific metabolic or clinical needs. Occasionally, blended foods can be used for the provision of adequate nutrition by oral or feeding tube routes.

The majority of patients with head and neck cancer is administered commercially available polymeric formulas. Polymeric formulas consist of macronutrients in the form of isolates of intact protein, fats, and carbohydrate polymers. In most of these solutions, protein makes up 12 to 20% of total calories; carbohydrates, 40 to 60%; and fats, 30 to 40%. In the standard formulas, the ratio of nonprotein calories to nitrogen is approximately 150:1. In the high-nitrogen formulas, this ratio is much lower, approximately 75:1. Table 7 provides an overview of these formulas.

Polymeric formulas contain whole proteins isolated from casein, whey, lactalbumin, and egg white. The source of carbohydrate is usually glucose polymers from starch and its hydrolysates. The fats are from vegetable sources. Essential vitamins and minerals are present in sufficient amounts so that 100% of the United States Recommended daily allowance for each nutrient is met through a daily intake of 1,500 to 2,000 calories of the formula. The amounts of minerals such as sodium and potassium vary greatly, allowing for adjustment based on requirements.

Polymeric formulas are lactose free with a caloric density between 1 and 2 cal/mL. The higher-calorie formulas allow for more calories in a smaller volume and are therefore suitable for patients requiring fluid restriction. These high-osmolality formulas often are best initiated at half strength and advanced as tolerated to full strength while maintaining appropriate hydration. Modified, more costly, polymeric formulas have been devised to suit the needs of patients with renal failure, liver failure, and diabetes.

Monomeric formulas require less digestion than do regular foods or polymeric solutions. They are suitable for patients with impaired digestion. These formulas are rarely used in patients with head and neck cancer with the exception of extremely low-fat preparations administered in the presence of a chylous fistula. Formulas with medium-chain triglycerides are also useful in the presence of a chyle leak since they enter the systemic circulation without passing through the thoracic duct.

TUBE FEEDING ADMINISTRATION

With an NG tube, placement in the stomach must be verified prior to each feeding and the head of the patient’s bed elevated. Initiation of bolus feeding may range from 100 to 200 mL every 3 to 4 hours, with the final feeding provided to the patient no later than 11:00 pm. Feedings should be administered by gravity drip over 30 to 60 minutes. Advancement of feedings by 50 to 100 mL every shift (8 hours) or daily are performed as tolerated, and residuals are monitored until the tube feeding volume goal is attained.

Initiation of tube feeding through a surgically placed gastric tube is similar to NG tube feeding except a delay of as much as 48 hours after insertion is required to allow for maturation of the stomal and return of bowel function.

After PEG or percutaneous radiologic gastrostomy feeding tube placement, feeding can often be initiated within 12 hours. If bowel sounds are present, continuous delivery of water at 50 mL/h can begin within a few hours of insertion.

If water is tolerated, feeding is initiated using a full-strength, isotonic formula infused at 50 mL/h. Residuals should be monitored every 4 hours, and feeding is advanced as with an NG or gastric tube.

Feeding into the intestine requires an intermittent or continuous pump-assisted delivery of formula since bolus amounts and hyperosmolarity can lead to diarrhea. After placement of a nasointestinal (nasoduodenal or nasojejunal) tube, feedings are administered over a 12- to 24-hour period and should be started at an isotonic level (300 mOsm) or at a low rate (10 to 15 mL/h). The rate of infusion may be increased every 8 to 24 hours as tolerated until the desired volume is reached. The rate and concentration of the formula should not be increased simultaneously.

Administration of formula through a feeding jejunostomy tube is identical to a nasointestinal feeding tube except feeding initiation may not begin for 12 to 24 hours after tube placement. With a PEG/jejunostomy, initiation is the same as for a PEG except a continuous infusion of formula is required.

FEEDING TUBE COMPLICATIONS

Tube Clogging

If a feeding tube becomes clogged, any enteral solution remaining in the tube should be withdrawn. To remove any obstruction, the following steps are attempted: (1) inject 5 mL of warm water into the tube and clamp for 5 minutes. Flush with water until tube is cleared; if the tube remains clogged, then (2) inject a bolus (20 to 30 cc) of air to dislodge the clog. If the air seems to free the obstruction, follow it with 30 to 50 mL of warm water, cola, or cranberry juice to cleanse the tube. If the tube remains clogged, then (3) crush one 324 mg sodium bicarbonate tablet. Mix the powder with the contents of one pancrelipase (Cotazym or Viokase) capsule and 5 mL of sterile water. Inject the alkalized enzyme mixture into the tube and clamp it for 5 minutes. Flush the tube with water until clear. If the aforementioned techniques fail, the tube should be replaced.
**Formula-Drug Interactions**
Formula–drug interactions resulting in delayed or diminished drug absorption are outlined in Table 8. In addition, physical incompatibilities between enteral formulas and medications may result in tube obstruction, as detailed in Table 9.

**Diarrhea**
Diarrhea is defined as an increase in the quantity and/or frequency of bowel movements. Diarrhea has been reported to occur in approximately 30% of patients receiving tube feeding. However, tube feeding itself is often not the cause. Potential causes of diarrhea include (1) an inappropriate rate of formula infusion, (2) impaired functional capacity of the gastrointestinal tract, (3) hypoalbuminemia, (4) the concurrent use of antibiotics and other medications, (5) altered bacterial flora, and (6) enteral formula contamination.

The healthy gastrointestinal tract can handle intermittent feedings of as much as 500 mL given over 10 to 15 minutes. This feeding method has routinely been used with success in patients with dysphagia owing to cancer of the head and neck. If diarrhea occurs, slower delivery of intermittent feedings or a change in the tube feeding product to one that is isotonic or contains fiber may be helpful.

Enteral nutrition-related diarrhea is often secondary to an osmotic effect, which is the result of the small intestine’s inability to absorb specific nutrients. This condition is frequently associated with a decline in intestinal blood flow and absorptive capacity. Hypoalbuminemia, which is associated with poor water absorption by the colon, can also contribute to diarrhea. This is observed in patients with edema and fluid overload. Switching the enteral solution to a more calorie-dense product (1.5 to 2.0 cal/mL) will decrease free water intake and may help correct fluid balance. When serum albumin is severely low, intravenous infusion of albumin may be indicated to correct fluid balance and promote protein repletion.

The diarrhea resulting after tolerance to an enteral formula has been achieved may be attributable to bacterial overgrowth. This overgrowth is often caused by long-term antibiotic use. If suspected, stool cultures for *Clostridium difficile* should be performed and the patient treated with oral vancomycin or metronidazole as indicated. The use of a fiber-containing formula has been helpful in correcting loose stools in these cases. Antidiarrhea medications should be used with caution if an infectious cause of diarrhea is suspected.

Another potential cause of diarrhea is fecal impaction in which loose stool can leak around the area of impaction until the bowel is cleared. Medications, especially antacids, can also induce diarrhea and should be considered.

**Refeeding Syndrome**
Refeeding syndrome is a serious metabolic disturbance that may occur with the initiation of aggressive nutrition support in a patient with severely depleted nutrition stores. Significant compartmental shifts in phosphorus, magnesium, and potassium can be induced. These shifts, as well as sodium retention with resultant expansion of the extracellular space and associated increased circulatory demands, may prove disastrous.

Hypophosphatemia is potentially the most serious single consequence in refeeding syndrome. In starvation, there is a slowing of the overall metabolic rate and, in particular, glucose oxidation. The need for phosphorus is low. When carbohydrates and glucose are reintroduced, this need dramatically rises and may surpass the rate at which phosphorus can be mobilized from bone. Cardiopulmonary failure and death may occur within days of feeding a previously starved but stable patient.

In patients at risk for refeeding syndrome, normal levels of phosphorus, potassium, and magnesium should be present prior to initiating nutrition support. Calorie repletion begins at less than 50% of need and is advanced over the course of a week to a goal of 30 cal/kg/d or less. If adequate renal and hepatic function exists, 1.5 g of protein/kg/d can also be administered. A daily multivitamin, mineral supplement, thiamine (100 mg/d), and selenium (50 μg/d) are recommended. Careful monitoring of vital signs, weight, and input and output, as well as electrolytes, is necessary during nutrition support of at-risk individuals.

**Parenteral Nutrition**
Parenteral nutrition is the intravenous administration of carbohydrates, protein, fat, vitamins, and minerals. Total parenteral nutrition involves nutrient administration into the superior vena
cava, thereby allowing for the infusion of hyper-
tonic solutions. Hyperalimentation solutions typ-
ically contain 25% glucose given at a gradually
increasing infusion rate toward a goal of 5 mg
glucose/kg/min.

Insulin requirements must be closely moni-
tored. Amino acids are administered in 2.5 to
5.0% solutions in sufficient quantity to ensure
positive nitrogen balance. The remainder of non-
carbohydrate calories is derived from fat emul-
sions. Peripheral partial nutrition supplements
enteral feeding with the administration of a 10%
glucose solution, amino acids, and fat emulsion
through a peripheral vein.

Complications from parenteral nutrition are
significantly higher than for enteral feeding and
include sepsis, hyperglycemia, hypoglycemia,
hyperlipidemia, hepatic dysfunction, electrolyte
imbalance, and thrombophlebitis. The indica-
tions for parenteral nutrition in the head and neck
patient are limited to gastrointestinal dysfunction
or intractable aspiration of tube feedings. Occa-
sionally, total parenteral nutrition is used to treat
a chyle fistula not responsive to medium-chain
triglyceride formulas.

CONCLUSIONS

Several factors conspire to induce malnutrition
in the head and neck patient. It is necessary to iden-
tify and quantify nutritional deficits to replete
losses adequately. Enteral feeding is desired with
a functioning gastrointestinal tract, and various
maneuvers exist to use an intact gut better. Nutri-
tion repletion should be carefully moni-
tored to allow the patient the potential benefits
of increased treatment tolerance and perhaps
improved survival.

Neoplasms of the Anterior Skull Base

Lawrence J. Marentette, MD
Becky L. Massey, MD
Robert M. Kellman, MD

Walter Dandy, a neurosurgeon at Johns Hopkins Hospital, described the first anterior craniofacial resection in 1941. His procedure involved an anterior craniotomy with the resection of an orbital tumor and the adjacent ethmoid sinuses. Alfred Ketcham and colleagues, in 1963, described the anterior craniofacial resection for paranasal sinus tumors in 19 patients. His subsequent paper reported the results of 32 patients with a 10-year follow-up. Although the long-term survival improved to 61%, the complication rate was 80%. All of these procedures involved frontal lobe retraction which can lead to encephalomalacia and neurologic impairment. In the 1960s, the principles of craniofacial surgery were introduced and began to serve as the basis for skull base surgery. Tessier described various periorbital osteotomies for the correction of orbital hypertelorism. Based on these principles, Raveh was 80%. All of these procedures involved frontal lobe retraction which can lead to encephalomalacia and neurologic impairment. In the 1960s, the principles of craniofacial surgery were introduced and began to serve as the basis for skull base surgery. Tessier described various periorbital osteotomies for the correction of orbital hypertelorism. Based on these principles, Raveh described the anterior craniofacial resection for cranial fossa along with the glabella and attached portion of the frontal bone exposing the anterior cranial fossa. He also described the dissection in lar osteotomies to gain access to the infratemporal fossa. He and his colleagues expanded this approach in 1993 to anterior skull base tumor surgery. Obwegeser in 1985 described various malar and mandibular osteotomies to gain access to the infratemporal fossa. He also described the dissection in the temporal fat pad, during a coronal exposure, to preserve the temporal branches of the facial nerve.

Today, advances in surgical technique, chemotherapy, and radiation therapy have led to improved survival for patients with skull base tumors. Diagnostic advances in magnetic resonance imaging (MRI), computerized tomography (CT), and positron emission tomography (PET) now allow surgeons to delineate the exact margins of the tumor, improving surgical selection of patients. In spite of these advances, however, patients often present with advanced disease as a result of minimal symptoms in the early stages of their disease process.

**EVALUATION**

**Symptoms**

An anterior skull base neoplasm is rare. These neoplasms originate from the paranasal sinuses and orbits below, the intracranial contents above and rarely in and from the bone of the cranial base. Symptoms may be vague, and the patients are often diagnosed with sinusitis. Significant delay in diagnosis may occur until attempts at medical treatment for sinusitis fail or additional symptoms present prompting an imaging study.

Common symptoms and signs in patients with anterior skull base neoplasms can be conveniently divided into early and late (Table 1). Symptoms of early skull base neoplasms may be minimal, making early diagnosis difficult. Early symptoms and signs include epistaxis, nasal obstruction, and foul smelling nasal discharge. The presence of new onset, unilateral symptoms is one of the most important indicators that helps to differentiate neoplastic from inflammatory sinonasal disease. Epistaxis is generally moderate to severe in patients with poorly differentiated neoplasms such as squamous cell carcinoma or sinonasal undifferentiated carcinoma. Well differentiated neoplasms such as esthesioneuroblastoma, may only develop nasal obstruction.

Late symptoms and signs include paresthesias, proptosis, olfactory impairment, pain on opening the mouth, hearing loss, and malocclusion. Paresthesias may result from the neoplasm invading the branches of the trigeminal nerve. The first division of the trigeminal nerve (cranial nerve V1) is often involved as a result of invasion by a neurotropic cutaneous squamous cell carcinoma. The second division (V2) may be involved in maxillary carcinomas and sarcomas. The third division (V3) is frequently involved by neoplasms arising in the infratemporal fossa. Neoplasms that exhibit neurotropism, commonly adenoid cystic carcinoma, develop retrograde spread and may invade the pterygopalatine ganglion, then follow the nerve of the pterygoid canal to the geniculate ganglion and produce facial paralysis. Proptosis results from tumor invasion into the orbit and can be an early sign in patients with lacrimal gland neoplasms or a late sign with undifferentiated carcinoma. Patients presenting with anosmia usually have bilateral involvement of the nasal cavities or may have an olfactory groove meningioma with no intranasal findings. The late symptoms include neck mass as a result of lymphatic metastasis. Pain on opening the mouth may be a late presenting symptom as a result of erosion of the posterior portion of the maxilla with extension of the neoplasm into the pterygoid muscles. Unilateral conductive hearing loss can result from the neoplasm extending posteriorly into the nasopharynx causing eustachian tube obstruction. Malocclusion may be a late complaint resulting from maxillary neoplasms extending inferiorly into the alveolar ridge causing displacement of the dentition.

**Physical Findings**

On physical examination, a nasal mass can often be readily seen either with anterior rhinoscopy or endoscopic evaluation. The finding of a friable mass is indicative of a poorly or undifferentiated malignant neoplasm. There may be restriction of the extraocular muscles, in particular the medial rectus, as a result of invasion of the neoplasm through the lamina papryacea. The extraocular muscle dysfunction may also result from retrograde spread of the tumor into a cavernous sinus. Paresthesias of the second division of the trigeminal nerve often occur with involvement of the infratemporal fossa as a result of neoplastic invasion in the retromaxillary space. These patients will also present with pain on opening the mouth. Facial paralysis in a patient with facial paresthesias results from spread of the neoplasm along the trigeminal nerve with a jump lesion.

involvement, fat saturation technique is impor-
to delineate the mass from orbital fat. This is
accomplished by eliminating the fat signal on the
gadolinium enhanced T1 image (Figure 2). CT
angioigraphy or M R angiography has been help-
any vascular involvement by the
neoplasm and is a much less invasive method than
costival angiography. Angiography is still
helpful, particularly in vascular lesions that will
require preoperative embolization, such as juve-
nile nasopharyngeal angiofibroma.

Existing Medical Records and Other Data
An important part of the patient’s overall evalu-
ation is the careful review of earlier medical
records from the referring physician. The patient
should bring actual scans in addition to reports
to be reviewed by the skull base surgeon as
as well as offi ce records indicating the duration of
symptoms and other fi ndings as well as potential
comorbid factors.

Prior biopsies should be reviewed at a tertiary
care center; and, if necessary, additional staining
techniques should be performed to confi rm the
diagnosis. The defi nitive diagnosis may depend
on the immunohistochemical profi le of the neo-
plasm. Often, a diagnosis of esthesioneuroblas-
toma is changed to sinonasal undifferentiated
carcinoma after immunostaining.

A ppropriate consultations with the neurosurg-
congenital stenosis, and radiation and
medicai oncologists should be initiated preoper-
tively to optimize patient care and offi ce
participation in clinical trials.

Special Testing
In some instances, it may be necessary to resect
the internal carotid artery to achieve tumor extir-
pation. If this is the case, a balloon test occlu-
sion is warranted to evaluate the potential for a
stroke. The catheter is inserted via the femoral
ary into the internal carotid artery and inflated.

Imaging
A CT scan is important in evaluating the extent
of anterior skull base neoplasms and in particu-
lar delineating areas of bone destruction. With
soft tissue windows the extent of the tumor can
be delineated but may not be distinguishable
from secretions in the paranasal sinuses from
ostial obstruction by the neoplastic mass. M R I
has proven invaluable for evaluating the soft tis-
sue extent of the neoplasm and also invasion of
the dura and brain parenchyma. Combined axial
and coronal T1- and T2-weighted images with
gadolinium will clearly identify areas of tumor
enhancement and also possible brain edema
which is seen on the T2 image. Retained sinus
secretions will appear hyperintense on the T2
image (Figure 1). With any question or orbital
involvement, fat saturation technique is impor-
tant to delineate the mass from orbital fat. This is
accomplished by eliminating the fat signal on the
gadolinium enhanced T1 image (Figure 2). CT
angioigraphy or M R angiography has been help-
ful in evaluating any vascular involvement by the
neoplasm and is a much less invasive method than
costival angiography. Angiography is still
helpful, particularly in vascular lesions that will
require preoperative embolization, such as juve-
nile nasopharyngeal angiofibroma.

Growth rates are variable, and symptoms may not
occur until the neoplasm has obtained large size.
Observation and limited resection are possible for
many patients. The most common benign lesions
are listed in Table 2. Benign sinonasal neoplasms
are discussed in Chapter 51, “Endoscopic Sur-
gery of the Skull Base, Orbit, and Benign Sino-
asal Neoplasms.”

The patient is evaluated for any changes in his
or her neurologic status. If the patient becomes
hemiparetic or aphasic, the balloon is deflated
and the catheter is immediately withdrawn. If the
patient can tolerate balloon test occlusion for 15
to 20 minutes, the surgeon may proceed with a
carotid resection. However, up to 22% of patients
who pass the balloon test occlusion may have
delayed ischemic complications.

PATHOLOGY

Benign Neoplasms
A variety of benign neoplasms occur in the
anterior skull base and may cause significant
Nerve Sheath Neoplasms

Peripheral nerve sheath neoplasms of the sinonasal tract are rare. Sinonasal schwannomas represent only 4% of head and neck schwannomas.1 Schwanomomas of the sinonasal tract are most common in the ethmoid sinuses where they are thought to originate from sensory branches of the trigeminal nerve and autonomic nerves. Unlike other head and neck schwannomas, sinonasal schwannomas are typically not encapsulated and may have surface ulceration.8 Schwannomas may grow to large size and may involve the orbit, skull base, and intracranial cavity by pushing rather than invading the surrounding tissue (Figure 3). Neurofibromas of the skull base are rare even in those with neurofibromatosis.

Malignant Neoplasms

Paranasal sinus cancers are the most common malignancies to involve the anterior skull base. Paranasal sinus malignancies account for only 3% of head and neck cancers, and the annual incidence is approximately one to three cases per 100,000 people. Those with skull base involvement represent an even smaller group. There is no high-level evidence to prove optimal therapy, and most patients are treated with surgery followed by adjuvant radiotherapy. Early symptoms of paranasal sinus and skull base malignancies including nasal obstruction and epistaxis may be difficult to distinguish from benign sinonasal complaints. Late signs including proptosis, diplopia, and cranial neuropathy occur after extensive local invasion and should prompt evaluation for malignancy. A diverse group of epithelial and nonepithelial malignant neoplasms with variable biologic aggressiveness may occur and are listed in Table 3. The more common tumors are described.

Squamous Cell Carcinoma. Squamous cell carcinoma (SCC) is the most common malignant neoplasm of the paranasal sinuses. Most paranasal SCCs arise in the maxillary sinuses and skull base involvement occurs late and in advanced disease (Figure 4). Primary SCC arising in the ethmoid sinus is less common, but its likelihood of invading the skull base is high. Primary SCC of the frontal or sphenoid sinuses is rare. SCC of the nasal cavity may extend directly to the skull base. Males are affected twice as often as females, which is believed to be due to greater occupational exposure to carcinogens. Multiple studies have evaluated risk factors for sinonasal malignancy. While nickel refining is most often cited as a risk for SCC, asbestos, formaldehyde and textile industry exposure have also been implicated.9,10 As in other head and neck SCC, tobacco use is a known risk factor.11 The role of chronic inflammatory sinonasal disease as a risk factor for SCC is controversial. Treatment for paranasal SCC is usually primarily surgical with adjuvant radiotherapy for all except small tumors. The incidence of regional metastases is less than 10%, and the clinically negative neck is typically not treated. While prognosis for SCC remains poor with 5-year survival less than 50%, outcomes for adenocarcinoma and esthesioneuroblastoma are much better.

Adenocarcinoma. Adenocarcinoma accounts for a third of paranasal sinus malignancies. Adenocarcinoma arises from the glandular elements of the sinonasal epithelium or from minor salivary tissue. Occupational exposure in woodworkers to both wood dust and chemicals, such as formaldehyde, used in wood preservation is a well-documented risk factor for sinonasal adenocarcinoma.12 A denocarcinomas commonly arise in the upper nasal cavity and ethmoid sinuses affecting the anterior skull base by direct extension (Figure 5). Adenocarcinomas are classified by grade based on glandular architecture and cytopathologic features. Comparison of biologic behavior is difficult due to low incidence and variable classification systems in the literature. In general, low-grade adenocarcinomas have more glandular differentiation, fewer nuclear pleomorphism and less locoregional metastases. Treatment is surgical with adjuvant radiotherapy. In contrast to SCC, 5-year survival from adenocarcinoma approaches 80%.

Adenoid Cystic Carcinoma. A denoid cystic carcinoma is the most common malignancy occurring in the minor salivary tissue in the sinonasal mucosa adjacent to the skull base. A denoid cystic carcinoma comprises approximately 10% of paranasal sinus malignancies and affects the skull base by direct extension and/or perineural spread. A denoid cystic carcinoma usually presents as a slow growing mass with early perineural involvement. A denoid cystic carcinoma has three subtypes: tubular, cribriform, and solid. Tumor grade is determined by percentage of solid growth pattern and nuclear pleomorphism. Higher grade is associated with distant metastases and poorer survival. Perineural invasion and submucosal spread are common in both low and high grades leading to a high rate of local recurrence with considerable morbidity at the skull base. Involvement of the skull base leads to poorer prognosis, and en bloc resection with negative margins is difficult. A denoid cystic carcinoma is indolent with delayed distant metastases frequent, but regional lymph nodal metastasis is uncommon. Treatment is surgical with adjuvant radiation therapy. Proton beam radiotherapy has been used for gross residual disease at the skull base with encouraging results.13 Chemotherapy is not recommended outside of a clinical trial.

Lymphoma. Lymphoma, occurring in the sinonasal region, is typically non-Hodgkin lymphoma. Lymphomas of B-cell, T-cell, T/Natural Killer (NK)-cell types may occur and have distinct biologic behavior. Surgical intervention is typically limited to biopsy. Definitive diagnosis of lymphoma subtype often requires advanced immunostaining for cell markers. Treatment is typically local radiotherapy with possible adjuvant chemotherapy with distinct differences in response rates between the subtypes. T-cell lymphomas have good response to treatment except those that also stain for NK markers. Sinonasal T/NK-cell lymphoma is an aggressive, destructive lesion formally known as lethal midline granuloma. Sinonasal T/NK-cell lymphoma presents as an angiodestructive mass causing nasal obstruction with foul odor and associated tissue necrosis. There is believed to be an association with the Epstein-Barr virus. Destruction of the nasal septum is common, and skull base destruction may be impressive with leptomeningeal spread (Figure 6).

Esthesioneuroblastoma. Esthesioneuroblastoma, or olfactory neuroblastoma, is a neural crest derived neoplasm arising directly from the olfactory neuroepithelium. Esthesioneuroblastoma is a rare neoplasm accounting for 3% of intracranial tumors and 6% of sinonasal tumors. In 1997, approximately 1,000 cases of esthesioneuroblastoma had been reported.14 Bimodal peaks of incidence occur at the second and sixth decades. There are no clear racial or ethnic predispositions or known risk factors.

Esthesioneuroblastoma may be limited to the upper nasal vault but most commonly involves the cribriform plate allowing direct intracranial extension. Like other sinonasal neoplasms, esthesioneuroblastoma often presents with unilateral nasal obstruction and epistaxis. Headache, diplopia, proptosis, and cranial nerve deficits appear as orbital and intracranial invasion occur. Anosmia occurs when both sides of the upper nasal cavity or the entire cribriform plate are replaced by the neoplasm. Esthesioneuroblastoma grows slowly and may have extensive submucosal spread. Intracranial extension occurs as the neoplasm spreads through the cribriform foramina and with overt cribriform destruction (Figure 7). Extension through the perforating vessels of the lamina papyracea allows direct access to the orbit. Cervical lymph node metastases occur in approximately 20% of patients with esthesioneuroblastomas but may not be apparent at the initial diagnosis. Local recurrences are common, and long-term follow-up is necessary. Esthesioneuroblastoma usually presents as a mass centered in the superior part of a nasal cavity. Microscopically, esthesioneuroblastoma is composed of small, blue round cells that must be differentiated from similarly appearing neoplasms including lymphoma, melanoma, neuroendocrine carcinoma, rhabdomyosarcoma, and sinonasal undifferentiated carcinoma. In low-grade esthesioneuroblastoma, histopathologic evaluation shows small, round cells arranged in a pseudorosette pattern (Figure 8). In high-grade esthesioneuroblastoma, there is more nuclear pleomorphism, and rosettes are not common. Immunohistochemistry is necessary to distinguish it from sinonasal undifferentiated carcinoma which carries a much more ominous prognosis.

Despite its rarity, esthesioneuroblastoma has a number of staging systems. The American Joint Commission on Cancer (AJCC) staging system and the Kadish staging system (Table 4) are most commonly used.15 Although it has been replaced by the AJCC staging system, the Kadish system introduced in 1976 is often used to provide adjunct information. Esthesioneuroblastoma has the best prognosis of all paranasal sinus malignant neoplasms with 5-year survival from 80 to 100%.16,17 Morbidity associated with surgical treatment and from local recurrence remains high.

Given the low incidence of esthesioneuroblastoma, adequately powered studies comparing different treatment regimens are not available. The treatment for esthesioneuroblastoma remains dynamic and controversial. There are several, single institution studies reporting excellent outcomes with variable combinations of surgery, radiation, and chemotherapy. Treatment protocols between institutions lack uniformity. Craniofacial resection has been the accepted standard at most institutions. The treatment approach reported by the MD Anderson Cancer Center includes craniofacial resection with adjuvant radiation.18 Craniofacial resection with adjuvant radiation for positive margins has been reported from the Johns Hopkins group.19 The single institutional experience reported from

the University of Virginia advocates preoperative radiation or chemoradiation therapy followed by craniofacial resection. Endoscope-assisted cranial facial resection has become more popular to limit facial and degloving incisions. For more limited neoplasms, endoscopic resection alone is becoming more commonly attempted. Despite the variety of treatment approaches, outcomes do not appear to be significantly different. 

### Sinonasal Undifferentiated Carcinoma

Sinonasal undifferentiated carcinoma (SNUC) is an uncommon, highly aggressive neoplasm of unknown etiology. It is rare with only 100 reported cases. It often presents as a rapidly enlarging mass with considerable extension to the orbital and intracranial contents (Figure 9). SNUC is associated with poor long-term survival making correct tissue diagnosis critical. SNUCs are hypercellular proliferations with prominent necrosis lacking squamous, glandular, and neuroendocrine features. Chemotherapy is typically used in an induction or primary role. Aggressive surgery and radiation therapy have been associated with decrease symptoms and modest increase in short-term survival. Multiple institutional reports with few patients per report suggest occasional patients with long-term survival. Despite aggressive multimodality therapy, 5-year survival is poor.

### Staging

The AJCC tumor, regional lymph node metastasis, and distant metastasis (TNM) staging system is most commonly used to stage paranasal sinus cancers. M axillary sinus cancers that reach the skull base structures are advanced and represent T4 disease. M ost tumors with skull base involvement are of nasal cavity or ethmoid sinus origin. There are specific T category guidelines for ethmoid and nasal cavity neoplasms (Table 5) and most patients present with at least a T3 tumor.

### SURGICAL MANAGEMENT

#### Craniofacial Resection

The standard surgical approach for patients with anterior skull base neoplasms is the craniofacial resection. This procedure involves the combined services of otolaryngology and neurosurgery. It is typically performed with a coronal incision in combination with a transfacial incision. Through the coronal incision, the neurosurgeon exposes the frontal bone. As part of the exposure, an anteriorly based pericranial flap is elevated to be employed in the reconstruction of the skull base defect. After the exposure, a bifrontal craniotomy is performed providing access to the anterior cranial fossa. The olfactory grooves are dissected bilaterally to allow retraction of the frontal lobes, thus gaining access to the orbital roof, cribiform plate, fovea ethmoidalis, and planum sphenoidale back to the sphenoid wing and anterior clinoid processes (Figure 10). From below, a lateral rhinotomy is performed or a Weber-Ferguson incision is utilized, if more access is needed to expose the mid-facial skeleton (Figure 11). At this time, the nasal bones may be cut and retracted; and, if necessary, osteotomies of the anterior face of the maxilla may be made and the anterior aspects of the maxilla may be removed. These steps allow wide access to the nasal cavity and the nasal vault up to the cribiform plate as well as the floor of the anterior skull base. The neoplasm is resected in a combined fashion with cuts being made from above in the base of the anterior cranial fossa and below in affected areas, thus allowing the specimen to be removed. This degree of exposure also allows the surgeon to obtain wide margins around the lesion accurately. The pericranial flap is inset along the floor of the skull base to seal the nasal cavity from the intracranial compartment. In patients with larger skull base defects or orbital exenteration, reconstruction with vascularized tissue decreases complications. The craniotomy is closed in a standard fashion; and, if possible the anterior maxilla and nasal bones may be replaced and secured with fixation plates. The two major advantages of this approach are wide exposure of the anterior skull base and exposure of the entirety of the nasal cavity and paranasal sinuses. However, it has the disadvantage of prolonged frontal lobe retraction which can lead to frontal encephalomalacia and permanent neurological deficits. In many patients, the disadvantage of facial incisions is avoided with endoscopic assisted craniofacial resection.

#### Subcranial Approach

The subcranial approach is derived from craniofacial surgery for congenital and traumatic deformities. The degree of exposure of the anterior skull base dictates the location of the osteotomies. This approach involves a coronal incision with dissection carried down not only over the frontal bone but the nasal bones, medial canthal ligament areas, and if necessary, the orbital rim of the zygoma, exposing the arch and the body. The supraorbital and supratrochlear neurovascular bundles are dissected from their foramina or notches and preserved. As originally described, the frontal bone segment and nasal bones were removed as a single unit. This can be modified into a two-step procedure. A bifrontal craniotomy is performed with this procedure as well. After removal of the bone flap, additional osteotomies are created in the region of the nasoethmoidal complex. These osteotomies extend vertically through the remainder of the frontal bone, down along the nasal bones and across the dorsum of the nose. A osteotomy is made from the intracranial aspect of the frontal bone through the orbital roofs and anterior to the crista galli thus allowing the removal of what is termed the frontal bar. At this point, the anterior fossa may be approached directly with minimal or no retraction of the frontal lobes. In patients with benign tumors, oflaction may be preserved on the contralateral side avoiding anosmia. The anterior cranial base defect is reconstructed with the anteriorly based pericranial flap. The flap measures approximately 15 cm in length and can extend posteriorly to the anterior clinoid processes. Care must also be taken to close all openings in the dura to ensure a water-tight seal. Any dural dehiscences above the nasal cavity will result in cerebrospinal fluid (CSF) rhinorrhea. The nasoethmoidal complex is repositioned and secured laterally to the frontal bone with microplates. The frontal bone flap is replaced and secured in position with fixation plates and screws (Figure 12).

#### Le Fort I Osteotomy

The Le Fort I osteotomy provides excellent access to the nasal cavity and nasopharynx and is particularly useful in patients presenting with juvenile nasopharyngeal angiofibroma. The procedure is started utilizing a sublabial approach extending between the first molars of the maxillae. A subperiosteal dissection exposes the faces of the maxillae with care taken to preserve the infrarostral nerves. The dissection proceeds around the lateral buttress to the pterygomaxillary fissure. The mucosa of the floor of the nose and the inferior meatus is elevated to avoid laceration during

*Maxillary sinus tumors invading cribiform plate T4.
the osteotomy. To preserve the patient’s presurgical occlusion, fixation plates are contoured to the medial and lateral buttresses of the maxillae, and holes are predrilled into the maxillae through the plate so that at the end of the procedure the maxillae are replaced into their presurgical position. After this has been accomplished, an osteotomy is made across the faces of the maxillae including the medial and lateral buttresses with care taken to avoid tooth roots. The osteotomy must extend more than 5 mm above the apices of the teeth and passes through the inferior meatus.

The nasal septum is disengaged from the floor of the nose with an osteotome. The surgeon should have a finger in the nasopharynx while making this osteotomy to avoid injury to the cervical spine. The final osteotomies are made with a curved pterygomaxillary osteotome through the pterygomaxillary fissure to disjoin the maxillary tuberosity from the anterior surface of the pterygoid plate. The surgeon must place a finger medial to the tuberosity to ensure that the osteotome has completely traversed the fissure. All osteotomies are checked for completeness, and the maxillae are gently downfractured either with a bone hook or with maxillary spreaders. Pterygoid plate fractures can result from incomplete osteotomies which may cause laceration of the internal carotid artery in the foramen lacerum. The maxillae are retracted in its downfractured position while tumor extirpation proceeds. The maxillae should be released from the retractors about every 15 to 20 minutes to ensure the viability of their blood supply. If at any time during the procedure, the gingiva becomes white or purple, vascular compromise has occurred, and the maxillae must be replaced immediately. Following tumor removal, the maxillae are replaced; and, utilizing the predrilled holes in the bone, fixation plates are applied to restore the presurgical occlusion. The incision is closed in a two-layer fashion with absorbable sutures.

Transzygomatic Approach

This approach is useful to access the postzygomatic space and, when combined with lateral mandibular osteotomies, the infratemporal fossa. The transzygomatic approach aids in removal of extensive tumors involving the maxilla, infratemporal fossa, and the anterior skull base such as a juvenile nasopharyngeal angiofibroma with intracranial extension. A coronal incision is made with the pretragal portion extending below the zygomatic articulation with the temporal bone on the surgical side. As the dissection proceeds on the lateral aspect of the skull, the superficial temporal fat pad is encountered. An incision is made in the superficial layer of the deep temporal fascia with the dissection continuing inferiorly on the undersurface of the fascia. Avoiding extensive dissection in the fat pad can minimize temporal wasting. This preserves the temporal branches of the facial nerve. The periosteum on the superior aspect of the arch is incised, and a subperiosteal dissection exposes the entire zygoma. Osteotomies are then designed to provide the necessary access for tumor removal. These may include only the arch or the entire zygoma for more extensive exposure. If a total malar osteotomy is performed in conjunction with a craniotomy, the osteotomy through the body of the zygoma should be placed lateral to the zygomaticofacial nerve. This will avoid the maxillary sinus and prevent the potential for CSF rhinorrhea. The zygoma remains pedicled on the masseter muscle, preserving its blood supply. If the infratemporal fossa must be accessed, various
osteotomies are made in the lateral portion of the mandible to access the pterygoid muscles and the deeper structures. If access to the lateral part of the infratemporal fossa is required the coronoid process may be sectioned and retracted superiorly pedicled on the temporalis tendon. For more extensive exposure, the condylar neck may be transected and the ramus of the mandible may be sectioned above the antilungal prominence and retracted superiorly. At the conclusion of the procedure, the osteotomies are stabilized with internal fixation.

**Endoscopic Resection**

With the improvement in endoscopic instrumentation and the routine availability of image guidance systems in the last decade, transnasal,
transoral, and trans-sinus endoscopic techniques have become more popular. Endoscopic-assisted craniofacial resection allows excellent visualization while avoiding facial incision. The boundaries for transnasal endoscopic resection alone are expanding, and good outcomes are reported in appropriately selected patients. Some surgeons advocate replacing virtually all "open" procedures with endoscopic techniques. However, there remain cases that we believe are better approached via an open craniofacial resection, and the complete surgeon today should be familiar with all the means necessary to provide access and exposure for both resection of these challenging neoplasms and postoperative reconstruction.

**RADIATION THERAPY**

In most malignant neoplasms of the skull base, there is a role for radiotherapy. Radiation therapy (RT) is most often delivered as adjuvant therapy in skull-based malignant neoplasms. Despite improvements in disease control, RT can have significant complications due to radiation-induced injury to the brain, visual pathway, and remaining skull base supportive tissue. Modern advances in RT technology may allow improvements in radiation delivery to tumor tissue and may decrease devastating complications such as radiation-induced retinopathy and optic neuropathy.

**Intensity Modulated Radiation Therapy**

Intensity modulated radiation therapy (IMRT) is an advanced form of three-dimensional (3-D) conformal radiotherapy. The patient, initially, undergoes a treatment planning CT scan, and the data from this scan is fed into a computer. The software reconstructs the targeted area in three dimensions that allow the radiation oncologist and radiation physicist to determine the dose of radiation to the neoplasm while relatively sparing surrounding normal tissue. The main advantage is being able to deliver the radiation dose in non-uniform beam densities that may spare critical structures while maintaining high dose delivery to the gross tumor volume. Prior to the treatment, the patient has a mask fabricated specifically to his or her facial structure. During the treatment, the mask is worn, and the head is fixed in a rigid position. Photon radiation is delivered from a linear accelerator. During the delivery, the radiation beams are conformed to the precise configuration of the neoplasm with collimator leaves that adjust the targeting area to the irregular shape of the tumor. The leaves may be adjusted to alter the specific dose from any given beam to the target area, so that radiation aimed at the neoplasm may have different doses for each beam. This technique has proved to be useful in treating patients with neoplasms in the anterior fossa, so that the radiation may be delivered to a neoplasm close to vital structures such as the optic nerve, pituitary or spinal cord while minimizing radiation that would damage these structures. While studies may not show improvement in disease control compared to conventional radiotherapy, a decrease in early radiation associated toxicity has been demonstrated.

**Proton Beam Irradiation**

Although proton beam irradiation therapy is a type of external beam radiation, it differs in that protons rather than photons are used in treating the patient with a neoplasm. Proton irradiation can be delivered in a conformal fashion so that the beam can be altered to the irregular shape of the neoplasm and to minimize or avoid radiating adjacent normal tissue. When protons are delivered to a neoplasm, the entrance dose into adjacent normal tissue is low, however, the protons themselves release high doses of radiation when they strike the neoplasm which is referred to as the Bragg peak. After the protons exit the neoplasm, there is a minimal, if any, dose delivered to normal tissue deep to the neoplasm. Proton irradiation is effective in patients with chordomas or chondrosarcomas, and the uses of this therapy are continuing to be expanded. Proton beam irradiation has been studied in skull base adenoid cystic carcinoma. Proton beam irradiation may allow higher dose radiation to the skull base with better local control without changing overall survival.

**Stereotactic Radiosurgery**

Stereotactic radiosurgery is a type of radiation which is delivered in a single dose in a one-time treatment setting. During this procedure, the patient undergoes a planning CT scan and those data are fed into a computer that uses software to determine the area of the tumor in three dimensions. Following treatment planning, a head frame is secured to the patient’s skull using pins. The positioning of this is determined by CT scan localization. Radiation, either from cobalt 60 or linear accelerator sources, is delivered from multiple beams to focus on the tumor site. In stereotactic radiosurgery, there are multiple radiation ports that all converge on the tumor so that adjacent tissue receives minimal radiation dosage; however, the tumor receives a tumoricidal dose. Stereotactic radiosurgery is most often used in treating benign intracranial neoplasms, such as vestibular schwannomas and meningiomas. It has also proved quite useful in treating arteriovenous malformations (AVMs). The role in malignant disease has expanded in not only treating primary malignant neoplasms, but also intracranial metastatic lesions. The approximate upper limit diameter of neoplasms can be treated with this modality is approximately 3 cm. After treatment, the neoplasm may either shrink or remain stable. However, with ongoing follow-up MRI scans, neoplasms usually are noted to cease their growth. In response to radiosurgery, AVMs develop thickening in their walls and usually cease to grow. Stereotactic radiosurgery is discussed in Chapter 36, “Stereotactic Radiosurgery.”

**CHEMOTHERAPY**

Generally speaking, surgery has been the mainstay for the management of resectable anterior skull base neoplasms, and chemotherapy and radiotherapy have been used primarily in an adjuvant role. A exception has been reported in 1997 by Bhattacharyya and colleagues in which 8 of 9 patients with esthesioneuroblastoma treated with cisplatin and etoposide had complete responses and were then treated with 68 Gray (Gy) of stereotactic fractionated proton therapy. Although lack of recurrence was reported, the patients were only followed for a mean of 14 months (range 2 to 26 months). Most commonly, esthesioneuroblastoma is treated with surgical resection followed by adjuvant RT adding chemotherapy in selected cases. Chemotherapy regimens may include cisplatin and etoposide, as well as vincristine, cyclophosphamide, and doxorubicin. However, one group reported excellent results using preoperative RT for Kadish stage A and B tumors and preoperative chemotherapy and RT for Kadish stage C tumors. Chemotherapy generally included cyclophosphamide and vincristine with occasional addition of doxorubicin. Only 5 of 30 patients developed complications from chemotherapy. The majority of patients (64%) had Kadish stage C.

Squamous cell carcinomas and adenoid cystic carcinomas are generally treated using surgical resection and postoperative RT. Postoperative RT is used for chordomas and sarcomas when complete resection is not possible although the quantitative benefits are not entirely clear.

SNUC is a particularly aggressive lesion with a poor prognosis. Although postoperative RT is commonly employed, we have some increased success with induction chemotherapy-RT using a SCC protocol followed by surgical resection.

In an interesting recent report from MD Anderson Cancer Center in 2007, the survivals of patients with all paranasal sinus carcinomas treated with RT (with or without surgery and/or chemotherapy) were evaluated by decade. No improvement in survival was noted, but complications of treatment have decreased significantly.

Certainly, most surgeons today would treat unresectable carcinoma with combined chemotherapy and RT for palliative intent, hoping for an occasional unexpected cure.

Samant and colleagues used intra-arterial cisplatin with concomitant RT followed by planned organ-sparing surgical resection for advanced paranasal sinus cancer. After a median follow-up of 53 months, actuarial overall survival at 2 and 5 years was 68% and 53%, respectively. Chemoradiation is discussed in Chapter 92, “Chemoradiation for Head and Neck Cancer.”

**COMPLICATIONS**

Although fairly uncommon today, craniofacial resection carries with it a risk of mortality in the perioperative period. Fortunately, with modern
skull base surgery and anesthesia techniques, death as a direct result of treatment is infrequent. Of the more common complications of craniofacial resection, the most feared has always been infection since this can quickly lead to meningitis, cerebritis, and cerebral abscess. Better methods for reconstructing the skull base using living tissue (locoregional flaps and free flaps) have resulted in better segregation of the nose and sinuses from the anterior cranial fossa, minimizing the occurrence of infection. Other complications include pneumocephalus, hematoma (intradural or epidural), cerebral contusion, edema and/or stroke, as well as cranial nerve injuries, particularly anomaia, since this may be completely unavoidable when resecting neoplasms involving the cribiform plate. CSF leaks occur as well although these are also minimized by improved flap reconstructions.

The use of lumbar spinal drainage to prevent CSF leakage is controversial, and the lumbar drains pose their own nontrivial risks, including particularly excessive CSF drainage, that may lead to increased pneumocephalus. The drains can also be a source of infection and meningitis.

Pneumocephalus is an expected finding in the early postoperative period. As the reconstructed skull base heals, separation of the nasal cavity from the intracranial cavity prevents further collection, and the intracranial air is resorbed. Airtight closure of the skull base reconstruction, nasal packing, and avoidance of nose blowing decrease troublesome pneumocephalus. CSF leak may create a ball-valve phenomenon that predisposes to tension pneumocephalus. Tension pneumocephalus is uncommon, but it must be identified early and managed, or it can be devastating. Any postoperative patient who develops a change in sensorium should have an immediate CT. Percutaneous aspiration and airway diversion can relieve tension pneumocephalus.

Late complications include encephalocoele, wound complications, and cosmetic alterations such as enophthalmos, telecanthus, nasal deformity, forehead deformity, and scar prominence including alopecia. Bone flap resorption and necrosis is more likely when postoperative RT is used. Skull base osteoradionecrosis is often difficult to distinguish from tumor recurrence.

Neoplasms of the Nasopharynx

Randall L. Plant, MD

ANATOMY

The superior border of the nasopharynx is the sphenoid bone, the inferior border is the free border of the soft palate, the posterior border comprises the clivus and first two cervical vertebrae, and the anterior border occurs at the choanae. Several key anatomic structures situated along the perimeter of the nasopharynx play an important role in the presentation and the prognosis of juvenile nasopharyngeal angiofibromas (JNAs) and nasopharyngeal carcinoma (NPC). The eustachian tube enters into the nasopharynx through a defect in the lateral wall of pharyngeal fascia known as the sinus of Morgagni. The posterior portion of the cartilaginous eustachian tube forms a ridge in the lateral nasopharynx called the torus tubarius. The recess posterior to the torus tubarius, called the fossa of Rosenmuller, is a frequent site of NPC. The foramen lacerum lies within the nasopharynx, serving as a route of perivascular tumor spread to the middle cranial fossa, the cavernous sinus, and the adjacent cranial nerves (CNs) III, IV, V1, V2, and VI. Other foramina adjacent to the nasopharynx include the foramina ovale and rotundum, the carotid canal, the jugular foramen, and the superior orbital fissure. The pharyngobasilar fascia surrounding the nasopharynx provides an initial barrier to tumor spread. Passage of the eustachian tube through this fascia allows spread of tumor into the parapharyngeal region and the cavernous sinus.

The nasopharynx has an extensive bilateral lymphatic drainage system, accounting for the high rate of neck involvement at initial presentation; up to one-half of all patients with NPC have cervical node metastasis at the time of diagnosis. The lymphatic system drains anterior to posterior toward the midline into the parapharyngeal and retropharyngeal lymph nodes. Lymphatic drainage also occurs into the deep posterior cervical chain near the mastoid tip and down along the jugulodigastric chain.

JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

JNAs are benign, highly vascular lesions that occur almost exclusively in adolescent males. The lesions are locally expansive, usually growing in a pushing fashion but also possess the ability to infiltrate local structures. They are rare, representing only about 0.05% of all head and neck tumors, but are the most common benign neoplasms of the nasopharynx.

Epidemiology and Etiology

The site of origin of JNAs is felt to be at the junction of the sphenoidal process of the palatine bone and the pterygoid process of the sphenoid bone, just superior to the sphenopalatine foramen. The main blood supply to JNAs is the ipsilateral internal maxillary artery, usually its distal branches, that is, sphenopalatine or vidian artery. There can be contributions from internal carotid artery branches, that is, mandibular artery and inferolateral trunk, in nearly 50% of cases. Other arteries may become prominent after embolization.

Presentation

JNAs are slow-growing neoplasms that can reach large size before detection. Patients with them most commonly present with nasal complaints such as nasal obstruction and recurrent epistaxis. With lateral growth, the neoplasms can erode into the pterygoid plates and extend into the infratemporal fossa via the pterygomaxillary fissure. Intracranial extension can occur in 20 to 35% of the patients in whom most spread into the middle cranial fossa, the pituitary fossa, and the anterior cranial fossa.

Histology

JNAs are unencapsulated neoplasms consisting of endothelially lined vascular spaces and fibrous connective tissue. The nasopharyngeal surface is lined by mucoepidermoid tissue, giving the tumor a deceptively nonvascular appearance. The precise histogenesis of JNAs has been subject to debate, particularly as to whether they are of angiomatus or fibromatus origin. Recent electron micrograph studies have shown that the tumor consists of an actively proliferating part and a relatively nonactive part, with a transitional zone in between. The actively proliferating part contains hyperplastic capillaries and vascular sinuses that lack muscular components (Figure 1). This tissue, seen primarily at the periphery of the neoplasm, consists of a bicellular combination of epithelial cells and pericytes. Toward the central portion of the lesion, the neoplasm is in more of a reactive state with a higher component of fibrous tissue. These findings indicate that JNA may arise as a reactive process or defective development rather than a neoplastic proliferation. In origin it, therefore, is similar to vascular hamartomas and other hemangiomatous processes.

Immunohistochemical staining has shown the presence of transforming growth factor ß-1 in JNA. This polypeptide is associated with fibroblast proliferation and angiogenesis and was found in both endothelial and stromal tissue of angiofibromas. Elevated levels of other types of growth factor, including vascular endothelial growth factor (VEGF), fibroblast growth factor, and the proliferation marker Ki67 have been found in JNA endothelium and stroma. Tumor angiogenesis may be promoted when androgens such as testosterone stimulate the secretion of these growth factors. Although JNAs have increased expression of androgen receptors, administration of the androgen blocker flutamide does not produce a significant decrease in size of these tumors.

Advanced JNAs have increased expression of the proto-oncogene C-MYC. Overexpression of C-MYC may interact with androgen receptor genes and the cytoplasmic protein ß-catenin to induce cell and tumor growth.

Evaluation

Both contrast-enhanced computed tomography (CT) scans and magnetic resonance imaging (MRI) are useful for evaluation of JNAs and their relationship with important adjacent structures. As with most other tumors, CT scans typically provide more information about bone erosion, and MRI is most useful for assessment of soft tissue structures. On CT scans, infratemporal involvement may...
produce a thinning and anterior bowing of the posterior wall of the maxillary paranasal sinus. Other signs of tumor erosion include displacement of the hard palate, erosion of the medical pterygoid plate, and orbital fissure enlargement.5 M R I has shown accuracy in detecting erosion of the pterygoid process, and is especially useful for evaluating extension into the pterygomaxillary and infratemporal fossae.4 MRI can help determine whether intracranial tumors are intradural or extradural. For follow-up studies, M R I has the advantage of avoiding radiation exposure to what is usually a young patient population.

Angiography can be performed preoperatively to define and embolize the feeding vessels. Embolization is usually done within a day or two of the operative date.

Although the combination of clinical presentation, appearance on imaging studies, and risk of bleeding typically precludes the need for biopsy, some clinicians feel that tissue diagnosis is useful to rule out other lesions. Differential diagnosis includes NPC, rhabdomyosarcoma, Kaposi sarcoma, neovascularized inflammatory polyps, teratomas, hemangiomas, and lymphoproliferative disorders.3

Staging

Many different staging systems have been proposed for J N A s; Table 1 shows two recent recommendations. The classification by Close and colleagues has used a staging system from Fisch and modified it to account for involvement of the cavernous sinus.12 However, preoperative classification based on radiological assessment of cavernous sinus involvement may overestimate the stage.13 The Radkowski and colleagues’ staging system has taken a system proposed by Sessions and modified it to emphasize the importance of extension posterior to the pterygoid plates and erosion of the skull base.3

T h e r e is evidence on imaging of invasion into the vidian canal and the sphenoid bone. Careful exploration of the basosphenoid bone may reveal invagination of tumor into the cancellous portion of the sphenoid bone. This bone, as well as the pterygoid plates and the clivus, should be drilled out to remove all remaining tumor and reduce the likelihood of recurrence.13

The risk of recurrence is increased when there is evidence on imaging of invasion into the vidian canal and the sphenoid bone. Careful exploration of the basosphenoid bone may reveal invagination of tumor into the cancellous portion of the sphenoid bone. This bone, as well as the pterygoid plates and the clivus, should be drilled out to remove all remaining tumor and reduce the likelihood of recurrence.13

Radiation therapy has been used for tumors with intracranial extension, for tumors considered unresectable due to their proximity to structures such as the optic nerve, or for tumors receiving extensive supply from the internal carotid artery. Tumor dosages range from 36 to 40 Gray (Gy) and recurrence rates from this treatment have been 10 to 15%. Presence of radiographic abnormalities after radiation therapy is not uncommon and may represent chronic inflammation rather than persistence of tumor. Further treatment, is therefore, considered necessary only if there are recurrent symptoms or new changes on imaging studies.22,23

NASOPHARYNGEAL CANCER

Epidemiology

NPC occurs with widely variable rates throughout the world. The disease is especially common among ethnic Chinese in and around the Guangdong province of China, in certain regions of southeast Asia, northern Africa, and among the Inuit (Eskimo) population of Alaska. Within China, the risk decreases in the more northern portions of the country. A verage age-adjusted incidence rates per 100,000 population are 0.75 among the general US population, 8.4 among the Alaska Native population and range as high as 20 to 30 in certain regions near Hong Kong.24 The
epithelium. Rather it is felt that overexpression of the malignant transformation of nasopharyngeal mal expression of the gene does not alone lead to p53 Expression of this gene is believed to trigger tumor ant, contains high levels of the oncogene (EBNA1). LMP1 is known to have oncogenic protein-1 (LMP1) and EBV nuclear antigen-1 Nasopharyngeal cells produce latent membrane different types of proteins are typically expressed. Eventually leading to cell death, or latent. In the event of salted fish among young children, may be having an effect on rates of NPC: the average annual incidence of NPC in Hong Kong has fallen by about 35% between 1973 and 1977 and 1993 and 1997. A mong Chinese residents in Malaysia, NPC was found to be associated with high concentration levels of salted fish, salted eggs, beer, and pork or beef liver and with low consumption of cabbage, oranges or tangerines, and shrimp. Tobacco smoking is an independent risk factor for NPC although the magnitude of the effect is less than seen in other parts of the upper aerodigestive tract. Heavy smokers have two to four times the risk of developing NPC compared to nonsmokers. High alcohol consumption has not been shown to be a risk among Chinese although a correlation was seen in some studies from the United States. Industrial exposure to formaldehyde and wood dust has also been shown to increase the risk of NPC.

In endemic regions, there appears to be an underlying genetic predisposition to development of NPC. In these areas, the rate of NPC involvement by first-degree relatives ranges from 5.8 to 19%. This familial version of NPC does not differ clinically from nonfamilial NPC.

Presentation
Early signs and symptoms of NPC are both subtle and nonspecific, and the nasopharynx is a difficult area to examine for primary care physicians. As a result, NPC is often diagnosed at a later stage than other head and neck malignancies. Due to its rich lymphatic supply and its relative inaccessibility, in many cases cervical metastases are present on initial presentation. Unlike other head and neck malignancies, there is no relationship between primary tumor size and the presence of cervical lymph node disease. Eustachian tube dysfunction from infiltration into the levator veli palatini results in formation of serous otitis media in about 40% of patients, and its presence should warrant careful examination of the nasopharynx in any individual from the endemic regions. Other symptoms related to the nasal cavity include epistaxis and nasal obstruction, seen in about 35% of patients as initial presentation.

Incidence of neurological signs and symptoms at initial presentation ranges from 13 to 25% and most often results from CN involvement rather than extension of the tumor into the cranial cavity. Tumor can extend along natural routes of spread through the foramen lacerum, the jugular foramen, or the hypoglossal canal. Infiltration along these routes normally precedes bone erosion. The most commonly involved CNs are CN V and VI, followed by III and IV. Clinical manifestations of CN involvement include partial or complete ophthalmoplegia, facial pain or paralysis, and dysphagia. Horner syndrome can develop due to tumor compression of the cervical sympathetic chain. Headaches are seen in about one-third of patients, usually indicating some sort of deep spread into the skull base. The most common sites for distant spread are the bone, lung, and liver.

Evaluation
As with most neoplasms in nonivisible regions, an accurate history and physical examination and high degree of suspicion are crucial for early diagnosis of NPC. The clinician should examine the nasopharynx with Hopkins rod telescopes or flexible nasopharyngoscope. In tumors with submucosal spread, the nasopharynx can be normal despite extensive destruction of the underlying structures. A careful neurological examination should also be performed for assessment of CN abnormalities. Biopsies of the nasopharynx can often be done under local anesthesia in the office with the use of flexible or rigid endoscopes with sensitivities and specificities of greater than 95%. If there are problems with patient tolerance or risk of bleeding, the biopsy should be performed in the operating room. The neck should also be thoroughly examined since cervical lymph node involvement is so common, and fine-needle aspiration should be performed on suspicion nodes.

Imaging studies are crucial to define the full extent of tumor spread (Figures 3 and 4). MRI with gadolinium enhancement is superior to CT scanning for distinguishing tumor from soft tissue, assessing lymph nodal metastases, and detecting new bone marrow involvement. However, CT imaging is better for detecting early signs of skull-base bone erosion and other bony destruction. A precise imaging is also necessary to define the tumor volumes to be treated during radiation therapy. CT imaging most commonly shows a mildly enhancing mass in the lateral pharyngeal recess, often with metastatic nodal disease in the neck. Presence of lateral extension into the parapharyngeal and mastoid space helps distinguish NPC from benign processes. There can also be posterior extension through the deep cervical fascia into the carotid space and subsequent intracranial extension. Tumor can pass through the defect at the entry point for the eustachian tube in the lateral pharyngobasilar fascia and travel in a retrograde fashion along V3 to the cavernous sinus. Nearly one-third of patients will have caudal extension, sometimes submucosal, along the lateral pharyngeal wall, and anterior and posterior tonsillar pillars. T1-weighted MRI images show a mass that is hypointense or isointense to muscle, with obliteration of the normal fat pad at the skull.

Figure 2 Graph showing incidence of nasopharyngeal cancer for different populations and age distributions. NPC = nasopharyngeal carcinoma.
base foramina. Skull-base lesions also produce abnormally low signal intensity. T2-weighted imaging shows moderate hyperintensity when compared to muscle. Contrast-enhanced T1 imaging shows mild homogeneous enhancement of the nasopharyngeal mass. Retropharyngeal nodes often are better seen with MRI than with CT. Distant metastases are not uncommon in NPC. The combination of chest X-ray, bone scan, and liver ultrasound has allowed detection of distant spread in 5% of patients with N2 disease and 14% of patients with N3 disease. Patients presenting with advanced stage disease should, therefore, be evaluated for metastasis. PET scans using (18)F-fluorodeoxyglucose have been shown to be valuable in detecting distant spread, especially in individuals with N2 or N3 disease. Scanning with PET is more sensitive than scintigraphy in locating spread to bones.

**Histology**

NPC is a squamous cell cancer originating in the epithelial lining of the nasopharynx. The World Health Organization (WHO) has subdivided NPC into two groups, keratinizing and nonkeratinizing. The keratinizing variant, classified as WHO type 1, is similar to squamous cell cancer seen in other parts of the upper aerodigestive tract. Microscopic examination shows intercellular bridges and keratinization (Figure 5). This variant is also typically associated with a desmoplastic reaction. It is graded as well, moderately, or poorly differentiated and typically has poorer overall survival than nonkeratinizing types although the risk of metastasis is lower.

The nonkeratinizing variant is further divided into differentiated (WHO type 2) and undifferentiated (WHO type 3, sometimes called WHO type 2b) carcinoma. WHO type 2 carcinoma makes up about 12% of all NPC. One sees a growth pattern similar to transitional cell cancer of the bladder, with stratified cells sharply delineated from the surrounding stroma (Figure 6).

The undifferentiated form of nonkeratinizing NPC (WHO type 3) is the most common throughout the world and accounts for almost all nasopharyngeal malignancies in endemic regions (Figure 7A and B). Tumor cells are uniform with round to oval vesicular nuclei and prominent nucleoli. In addition to the malignant epithelial cells, one also sees a prominent infiltrate of nonneoplastic lymphoid tissue. Although the term “lymphoepithelioma” is sometimes used to describe the nonkeratinizing variant, this term is incorrect since the tumor originates entirely from epithelial tissue and the lymphoid component typically is an associated benign process. The malignant tissue can occur in a nested, syncytial pattern, known as the Regaud type, or it can have a diffuse growth pattern without cohesion and known as the Schmincke type. Since a desmoplastic reaction is often absent, the latter pattern can be difficult to differentiate from lymphoma without the aid of immunohistochemistry. NPC can be distinguished from non-Hodgkin lymphoma by its reactivity with cytokeratin and its lack of reactivity with leukocyte common antigen (LCA).

**Staging**

The heterogeneous nature of NPC is also reflected in two distinct staging systems used to describe extent of disease (Table 2). In endemic regions, the Ho system was felt to better describe the disease and its clinical course. Most non-endemic regions use a TNM staging system.
developed by the American Joint Committee on Cancer (AJCC/UICC). To help reduce discrepancies between the systems, the fifth edition of the AJCC/UICC was based only on size and laterality, similar to other head and neck cancer sites. The newest AJCC/UICC system now takes location into account and judges nodes only as to whether they are larger or smaller than 6 cm. For T status, the key difference is that the Ho system does not have a T4 level and instead divides level T3 into four subsets, one of which the AJCC/UICC system classifies as T4. Compared to the 1988 AJCC system, the 1997 staging considers tumor confined to the nasopharynx, whether one side or two, to be T1. Invasion to bony structures classifies tumor as T3 instead of T4. The new T4 status now includes, in addition to intracranial extension and CN involvement, extension of tumor into the infratemporal fossa, hypopharynx, or orbit.

The AJCC/UICC staging system has been shown to be superior to the Ho system both in producing an even distribution of patients across different stages and in predicting cancer recurrence and death from cancer.50,51 Closer analysis of outcomes has shown that better prognosis might be achieved if the N status were modified to include a subset of patients with nodes less than 3 cm. In addition, patients with T2a disease under the current system are classified as stage II although their prognosis is similar to those in stage I.52 However, the distinction between T2a and T2b depends on whether or not there is parapharyngeal space involvement, and the precise boundaries of this space are not uniformly defined. Stratification of parapharyngeal space into an advanced region, defined as extension across a line drawn from the lateral pterygoid plate to the styloid process, has been shown to be a better predictor of survival that parapharyngeal space invasion alone.53

</table>
what timing of chemotherapy produces the highest beneficial effect. Many previous trials showed improved disease control and disease-free survival with combined treatment, but it was not until the Intergroup Study 0099 that an improvement in overall survival was also seen. That particular randomized trial compared results of stage III and IV patients from North America who received radiotherapy alone with similar patients who received both concurrent and adjuvant chemotherapy. Both arms received 35 to 39 treatments of 1.8 to 2.9 Gy/d of radiotherapy. The chemotherapy arm received in addition cisplatin (100 mg/m²) on days 1, 2, and 43 of the radiation therapy and three courses of postradiation chemotherapy (cisplatin and fluorouracil) spaced 4 weeks apart. The 3-year survival for the radiotherapy was 47%, and it was 78% in the combined treatment arm. Rates of locoregional recurrence and distant metastasis were lower in the chemoradiotherapy (CRT) arm. Results at 5 years continued to show significant improvements for the combined treatment protocol. The improved survival was seen with combined therapy despite poor overall compliance with chemotherapy: only 55% of those scheduled to receive all courses of adjuvant therapy actually completed the treatment.

Several aspects of the Intergroup 0099 raised questions as to whether the improved overall survival rates could be duplicated, especially for those patients from endemic regions. Nearly 25% of the patients in the Intergroup Study 0099 had WHO type 1 NPC, a much different distribution than seen in endemic regions. Also, the survival rate for the radiotherapy-alone treatment arm in the Intergroup 0099 study was also particularly poor when compared to other studies, increasing the relative beneficial effects of concurrent chemotherapy.

Lin and colleagues studied the role of concurrent CRT in a randomized sample of Taiwanese patients. They stratified patients into low and high risk based on neck lymph node status. Patients in the low-risk arm received combined cisplatin (20 mg/m²) and fluorouracil, both delivered as continuous 96-hour infusions, on weeks 1 and 5. Unlike the Intergroup 0099 study, the low signing and adjuvant chemotherapy was used. The combination of a substantially lower chemotherapy dose combined with continuous infusion substantially decreased its morbidity and improved compliance, such that 94% of the patients in the CRT arm completed their full regimen. The addition of concurrent chemotherapy significantly improved overall survival for patients in the low-risk group. However, no difference in survival was seen in high-risk patients. These patients often died of distant metastases, indicating that the elimination of adjuvant therapy may have increased the risk of micrometastases.

Chan and colleagues compared concurrent chemotherapy and radiotherapy alone in 350 patients in Hong Kong. Unlike the two previously cited studies, their protocol included patients with stage II disease, as well as stage III and stage IV. The chemotherapy protocol consisted of weekly infusions of cisplatin (40 mg/m²) during the radiation therapy, with no adjuvant or adjuvant chemotherapy. Patients with persistent cancer in the nasopharynx also received intracavitary brachytherapy. The overall 5-year survival for all patients receiving combined treatment was significantly better that the radiation therapy arm (70% vs 59%, p = .049). However, there was no difference in survival among those patients with T1 or T2 disease.

Woo and colleagues followed a protocol similar to the Intergroup 0099 study in patients with stage II, III, and IV NPC in Singapore and found improved survival with CRT. All of their patients had WHO type 2 or type 3 histology. Compliance with chemotherapy was problematic. Due primarily to toxicity problems, only 71% and 59% of the patients received complete concurrent and adjuvant chemotherapy treatments, respectively. CRT patients had significantly higher incidences of toxicity than the radiotherapy alone group, most notably with oropharyngeal mucositis (48% vs 32%), anorexia (22% vs 4%), and neutropenia (14% vs 0%). However, overall 3-year survival was 86% for CRT patients and 83% for the radiotherapy arm.

Not all trials have demonstrated these improved survival rates with concurrent CRT. Lee and colleagues randomized patients with WHO type 2 and type 3 NPC to receive either radiotherapy or combined treatment identical to that in the Intergroup 0099 study. All of their patients had either N2 or N3 neck disease. They found no difference in distant control or overall survival in the combined arm, though locoregional control was higher in this group (92% vs 82%). Improved radiotherapy techniques may have narrowed the survival advantage usually seen with chemotherapy: In their trial, over 50% of their patients received radiation therapy based on 3-D techniques, instead of less accurate 2-D techniques used in earlier studies.

Kong and colleagues showed a trend toward improvement in overall survival with CRT, although the difference was not statistically significant. They randomized patients into four groups: radiation therapy with and without adjuvant chemotherapy, and concurrent chemotherapies and radiotherapy with and without adjuvant chemotherapy. Using factorial analysis, they were able to determine the effectiveness of concurrent CRT and of adjuvant therapy. The chemotherapy protocol consisted of oral UFT (a fluorouracil prodrg consisting of uracil and tegafur) used for concurrent treatment and a combination of cisplatin, fluorouracil, methotrexate, vincristine, and bleomycin for adjuvant treatment. Toxicity to adjuvant chemotherapy was high, with 65% of the patients developing a grade 3 or 4 toxic reaction.

Bajaj and colleagues performed a meta-analysis of the effects on event-free survival and overall survival of adding chemotherapy to radiation therapy. The authors were able to obtain individual patient data files from eight randomized clinical trials comparing the two types of treatment. Their results showed a significant improvement in both event-free survival and overall survival with addition of chemotherapy. The hazard ratio for 5-year event-free survival was 54% in the radiotherapy groups and 63% in the combined CRT groups. The timing of the chemotherapy was not significant for this parameter. For 5-year overall survival, the hazard ratio was 18% lower for the combined group, resulting in a statistically significant increase in survival (56% for radiotherapy, 62% for combined treatment). Concurrent CRT showed better results than neo-adjuvant or adjuvant treatment.

To reduce problems with toxicity, newer chemotherapeutic agents have been used to treat patients with NPC. Zhang and colleagues used oxaliplatin, a new analog of platinum that has fewer gastrointestinal side toxicities than cisplatin and less myelosuppression than carboplatin, in a phase III study comparing radiotherapy versus concurrent CRT. Oxaliplatin was given weekly for 6 weeks, and 97% of patients were able to complete the entire course of chemotherapy. Patients in the CRT arm had significantly better overall survival, relapse-free survival, and metastasis-free survival.

Improvements in radiotherapy have also narrowed the advantages seen with concurrent treatment. In particular, 3-D conformal radiation therapy (3DCRT) and intensity-modulated radiation therapy (IMRT) allow higher dose delivery to the tumor with reduced damage to adjacent structures such as the spinal cord, brain stem, and the parotid glands. Both techniques allow finer control of dose distribution such that the planned treatment volume conforms to the tumor anatomy.

IMRT offers several distinct advantages that allow better dosimetry in treatment of NPC. In particular, IMRT allows adjustment of intensities within individual beams, called “beamlets.” For example, the intensity at tumor boundaries can be increased to account for edge effects that, in 3DCRT, require extension of radiation fields into surrounding tissue. IMRT allows both concave and convex isodose curves that can more accurately curve around critical nontumor structures. More homogeneous dosage within the target volumes can also be achieved with IMRT. Field shaping is done with computer controlled multileaf collimators (MLCs), eliminating the need for other shielding devices (Figure 8). 3DCRT uses a “forward planning” model in which the doses are calculated after the beam parameters have been specified. In contrast, IMRT uses an “inverse planning” model in which the dosage curves are defined and the treatment software designs beam parameters to produce these curves. The nasopharynx is also well suited for IMRT techniques since there is little motion in that structure during treatment and it is centrally located. Stereotactic radiosurgery and radiotherapy is discussed in Chapter 36, “Stereotactic Radiosurgery and Radiotherapy.”

There are several different methods for delivering IMRT. The static multileaf collimation technique uses standard MLCs and irregular
fields to produce a nonuniform distribution of radiation energy. A second technique, known as dynamic multileaf collimation, also uses conventional MLCs but the leaves move during the actual treatment. In a third technique, known as tomotherapy, the linear accelerator is rotated around the patient while the collimators are opened and closed depending on the trajectory of the beam. A fourth technique uses physical filters, usually made out of metal, to produce a nonuniform fluence distribution.

To date, there have been no randomized studies comparing control rates for using IMRT to those achieved with 2DRT or 3DCRT. However, nonrandomized retrospective studies tend to show higher survival than seen with historic techniques. Lee and colleagues treated 67 patients with NPC using three different methods for delivering IMRT. Fifty of these patients received concurrent chemotherapy using the Intergroup 0099 protocol, and 26 patients received brachytherapy. With a median follow-up of 31 months, there was only one locoregional failure. Mucositis requiring feeding tube placement occurred in 22% of the patients, and there was a high incidence of skin reaction. However, xerostomia was reduced, with only 1 of 41 patients reporting Grade 2 xerostomia at 24 months.

Kam and colleagues treated 63 newly diagnosed patients with NPC in Hong Kong with IMRT. Nineteen of the 36 patients with advanced stage disease also received either neoadjuvant or concurrent CRT. At 3 years, the local relapse-free survival rate and overall survival rate were 92% and 90%, respectively. Four patients, all of whom had T3 or T4 disease, recurred locoregionally, and 13 patients had distant metastases.

Wolden and colleagues used IMRT in treating 74 patients (65% WHO type 3) at Memorial Sloan-Kettering Cancer Center in New York. Patients with stage II, III, and IV disease also received concurrent and adjuvant chemotherapy according to the Intergroup 0099 protocol. The 3-year local control rate was 91%, compared with a historic rate of about 79% for those patients treated with non-IMRT techniques. The overall survival rate was 83%, with distant metastases the prominent form of failure.

The parotid-sparing properties of IMRT were directly measured by Hsiung and colleagues. The maximal excretion ratio (MER) from the gland was calculated both before and after treatment using quantitative salivary scintigraphy. Patients receiving IMRT had a drop in their MER from 53% down to 23% 9 months after treatment, compared with historic posttreatment MER of 0.6% in patients who had previously been treated using conventional techniques.

**Treatment Side Effects.** Toxicities of some degree to either radiotherapy alone or combined with chemotherapy are common. Over one-half or more of patients suffer some degree of problem such as leukopenia, vomiting, skin reaction, or mucositis. With several exceptions, the incidence of higher-grade toxicities is low. Mucositis is the most common severe side effect, with grade 3 or higher toxicities occurring in 25 to 65% of patients. Rates are higher, although not always with statistical significance, in patients receiving combined treatment. When severe, a feeding tube may be necessary to maintain nutrition.

Severe leukopenia is usually not a major problem during concurrent chemotherapy, and its frequency (~5%) matches that seen in radiotherapy alone. However, during adjuvant therapy the incidence of grade 3 or 4 toxicity rises to 30 to 57%. Rates of severe skin reaction are roughly comparable in both combined therapy and radiotherapy and range from 10 to 30%. Although seldom life threatening, xerostomia is a chronic problem after treatment, affecting up to 75% of patients. New radiation therapy techniques such as IMRT have been shown to reduce its incidence.

Hypothalamic-pituitary dysfunction, temporal lobe necrosis, and other forms of intracranial radiation injury have been seen in small numbers of patients. Pituitary hypofunction is associated with abnormal levels of serum thyroxin, cortisol, or prolactin. Retinopathy has been noted in some patients, as well as vitreous hemorrhage and ischemic neuropathy. Patients treated for NPC have an increased risk of developing otitis media with effusion due to deterioration in eustachian tube function. Placement of ventilation tubes can in some cases worsen the situation by aggravating the inflammatory process. In these patients, better results may be obtained with myringotomy, even if repeated, and local treatment.

Combined chemotherapy and radiation therapy or radiation therapy alone can produce significant ototoxic effects. In a follow-up study of 132 patients treated with radiotherapy for NPC of whom 52 also received neoadjuvant cisplatin, 24% of the patients experienced a 15 dB or greater sensorineural hearing loss. Rates were significantly higher in older male patients, with sensorineural loss in 17% of patients 30 to 50 years old and 37% of patients older than 50. The administration of neoadjuvant chemotherapy did not increase the risk for SNHL. Forty-seven percent of the patients developed sensorineural hearing loss, and this was found to be a risk factor for SNHL.

In a more recent study in which 22 patients received combined therapy using conformal radiation therapy, SNHL was found in 57% of the ears. Exposure of the ear to greater than 48 Gy increased the risk of developing hearing loss, but the effect of cisplatin on hearing loss was variable.

**Serological Markers of NPC**

A variety of serologic markers based on serum antibodies or tumor DNA have been detected and proposed as possible tools for screening for NPC and monitoring patients following treatment. Patients with NPC develop elevated levels of a wide variety of antibodies to various EBV antigens, including viral capsid antigen (VCA), early antigen (EA), a protein of the early replicating phase, and nuclear antigen (EBNA1). Prospective studies have shown that the cumulative risk of NPC in a Taiwanese male population is significantly higher for those individuals who tested positive for either antibodies for EBVCA or EBV-specific DNAse, and substantially greater for those who tested positive for both.

Serology for EA IgA has been found highly specific for NPC, but it has a sensitivity of only 70 to 80%. In contrast, VCA IgA is much more sensitive for NPC but less specific, suggesting that the optimal screening based in immunofluorescence would be achieved by tandem detection of antibodies to EA and VCA.

With polymerase chain reaction techniques, circulating EBV DNA can be detected in the serum of NPC patients. The actual mechanism for release of DNA into the circulation is not known but is believed to be related to cell death. This DNA, usually in fragmented form, has been found in over 95% of individuals with NPC but only 7% of controls. In those controls without NPC but with detectable EBV DNA, the levels are much lower than in seropositive patients with NPC. EBV DNA concentrations are also lower or nondetectable in patients who have a complete remission following radiotherapy. Patients with high levels of EBV DNA prior to treatment are more likely to relapse following treatment and to have lower overall survival. PCR has also been used to detect the LMP1 gene and the EBNA1 gene from nasopharyngeal swab samples. This technique had a sensitivity of 91% and a specificity of 98% in detecting NPC among 437 Taiwanese patients. However, the sample population chosen for the study may not have been representative since the prevalence of NPC was high (16%). Nasopharyngeal swabbing and detection of these two genes also was valuable in detecting recurrences following treatment. In one study, 11 of 12 patients with positive tests for both genes had recurrence, and all but one of 72 patients who were negative for the gene testing remained free of disease.

**Management of the Neck**

One of the principal roles for surgery in NPC is management of the neck after definitive radiotherapy or CRT. Recurrent disease often occurs...
in the upper neck nodes and is frequently more extensive than appreciated on clinical examination.92 There is a high incidence of extracapsular spread and infiltration into adjacent structures such as the sternocleidomastoid muscle, the spinal accessory nerve, or the internal jugular vein. Isolated clusters of tumor cells have been detected lying within fat or fibrous tissue in 35% of neck specimens. Radical neck dissection is, therefore, considered necessary for control of disease in this setting.93

Recurrence

Local recurrence rates in recent concurrent chemotheraphy/radiation therapy trials have ranged around 10 to 20%. In a large review of 2,915 patients treated initially for nonmetastatic NPC between 1996 and 2000, the local recurrence rate with or without synchronous regional failure or distant metastasis was 11% (recurrence was defined as the presence of disease more than 24 weeks after completion of radiotherapy).85 In 82% of these patients, the T-classification at recurrence was the same as the initial T stage. Two hundred of these patients were given salvage treatment of some sort, most often radiotherapy (79%), but also surgery (11%) and chemotherapy (9%). Multivariate analysis showed that the initial T-stage most accurately predicted overall survival, with limited benefit for those initially staged as T3 or T4.86 In certain cases, surgical resection of recurrent tumor at the primary site has been performed. Chang and colleagues reported 2-year survival rates of 94, 75, and 82%, for tumors at recurrence staged as T1, T2, and T3, respectively.87 Facial translocation approach, in some performed in conjunction with a craniotomy, was used. A attempt to achieve surgical salvage was contraindicated if there was extensive intradural invasion or cavernous sinus involvement. Fee and colleagues have used intraoral, transpalatal, and sublabial approaches to recurrent carcinomas with 5-year survival of 73 and 40% for rT1 and rT2 disease, and 14 and 0% for rT3 and rT4 disease.98 Hsu and colleagues tailored their approach to recurrent disease to the site and stage of the recurrence, with transpalatal approaches for limited disease and transaxillary and transmandibular for more extensive disease. They consider CN involvement to be an absolute contraindication for surgery.90

Chemotherapy has been used for salvage treatment, either alone or in conjunction with radiotherapy. Response rates of about 60 to 75% have been achieved, occasionally associated with a high incidence of toxicity.91,92

Surveillance

Endoscopic examination with rigid endoscopes is more sensitive and specific than CT scans and has better positive and negative predictive value. A accuracy is not at high with flexible scopes but still roughly comparable and less expensive than CT imaging.93 Nevertheless, approximately one-third of the tumors are not visible on endoscopic examinations,88 and some studies have shown that the overall sensitivity of endoscopy in predicting persistent disease is only 40%. Tumor necrosis can continue after completion of radiation therapy, such that biopsies taken too soon (within 10 weeks of treatment completion) may be falsely positive. There is a false-negative rate of about 60% with posttreatment biopsies from a single site; multiple biopsies are therefore important.89

Prognosis

In a review of treatment outcomes of 2,687 patients treated at five oncology centers in Hong Kong, multivariate analysis showed that the presenting stage was consistently the most significant factor for survival.93 Nodal failure was predicted by the presenting N status, and distant failure was predicted by the T and N categories. Male gender and increased age were associated with higher rates of disease progression and distant failure. In this group, treated between 1996 and 2000, the 5-year disease-specific survival was 92% for stage I, 87% for stage II, 79% for stage III, and 65% for stage IV. The overall 5-year disease-specific survival for all patients was 80%; the similar figure for patients treated at these same institutions between 1976 and 1985 was 52%, indicating a true improvement in tumor control.73

In addition to clinical attributes, other biomarkers have been investigated for their predictive strength. NPC expresses high levels of two proteins that inhibit cell apoptosis, survivin and livin. Patients with low levels of survivin expression have better overall survival and disease-free survival than those with high expression.96 EBV antigens expressed on NPC cells membranes, such as latent membrane protein-2, can be used as targets for cell therapy techniques. In this technique, peripheral blood mononuclear cells are harvested and transformed to produce autologous EBV-specific cytotoxic T-lymphocytes. When transfused back into patients with progressive chemotherapy- and radiotherapy-resistant NPC, a partial response was seen in 2 of 10 patients and disease stabilization occurred in 4 of 10.97

Neoplasms of the Oral Cavity

Dennis H. Kraus, MD
Mark G. Shrieve, MD

The list of neoplasms involving the oral cavity is extensive, including neoplasms of the minor salivary glands and neoplasms of lymphatic tissue and epidermoid tissue, that is, squamous cell carcinoma. Given that over 90% of neoplasms of the oral cavity are of the latter variety, they will serve as the focus of this chapter. Neoplasms of the oral cavity have significant effects on respiration, deglutition, and speech. The propensity for locoregional recurrence of cancers of the oral cavity often necessitates multimodality therapy. Consequently, appropriate treatment planning should be undertaken by a multidisciplinary team including the following specialties: head and neck surgical oncology, radiation oncology, medical oncology, prosthodontics, and speech-language pathology.

ANATOMY

The oral cavity is composed of distinct anatomic subsites. Malignancy arising at different subsites varies in behavior; as a result, recognition of this anatomic classification allows for prognostic evaluation and appropriate treatment planning.

Oral Cavity

The oral cavity is defined as the region from the skin–vermilion junction of the lips to the junction of the hard and soft palate superiorly and to the skin–vermilion junction of the lips to the junction of the hard palate inferiorly. Laterally, the oral cavity ends at the anterior face of the palatoglossal pillar. The various subsites of the oral cavity are illustrated in Figure 1, specifically the lips, the buccal mucosa, the upper and lower alveolar ridges with their attached gingiva, the retromolar trigone, the hard palate, the floor of the mouth, and the anterior two-thirds of the tongue.

The upper and lower lips begin at the junction of the skin with the vermilion border. The lips connect laterally at the oral commissure and form the anterior boundary of the oral cavity. Sensory innervation to the lower lip is provided by the mental branch of the mandibular division of the fifth cranial nerve as it exits the mandible at the mental foramen. This nerve may serve as an important pathway for spread of malignancy into the body of the mandible. Sensory innervation to the upper lip is provided by the infraorbital branch of the maxillary division of the fifth cranial nerve as it exits the infraorbital foramen adherent to bone; treatment of cancers at these subsites necessitates treatment of the bony mandible and maxilla as well.

The retromolar trigone is the triangular stretch of mucosa extending from the level of the distal surface of the upper and lower third molars to attach to the hamulus of the medial pterygoid process of the sphenoid bone. The mucosa of the retromolar trigone is tightly adherent to the underlying tendon between the buccinator and superior pharyngeal constrictor muscles and is separated from the periosteum of the ascending ramus of the mandible by the buccal fat pad. Neoplasms in this region frequently invade the mandible. The site of entry of the inferior alveolar nerve into the mandibular foramen places the nerve at risk for involvement by neoplasms of the retromolar trigone. Pain from this site may be referred to the ipsilateral ear due to sensory innervation of the retromolar trigone by branches of the ninth cranial nerve. This referred otalgia is common in cancers of the oral cavity.

The hard palate is the semilunar area within the upper alveolar ridge that includes the palatine processes of the maxillary bone and the horizontal processes of the palatine bones bilaterally. It extends from the medial surfaces of the maxillary alveolar ridge to the posterior edge of the palatine bone and forms the roof of the oral cavity. The descending palatine arteries and the anterior, middle, and posterior palatine nerves are transmitted through the palatine foramina which lie laterally near the junction of the hard and soft palate. Similarly, the incisive canal, located anteriorly at the midline junction of the palatine processes of the maxillary bone, transmits the nasopalatine nerves and branches of the maxillary division of the trigeminal nerve. The mucosa at this subsite is also tightly adherent to the bone, often necessitating treatment of the underlying maxillary bone in cancers of the hard palate. In addition, the palatine and incisive foramina serve as potential routes of spread of cancer from the hard palate to the pterygopalatine fossae and the skull base.

The floor of the mouth is the semilunar space over the mylohyoid and hyoglossus muscles, extending from the inner surface of the lower alveolar ridge to the undersurface of the anterior two-thirds of the tongue. Its posterior boundaries are the bases of the palatoglossal pillars. The floor of the oral cavity is divided into two sides by the

the accepted staging system is illustrated in multiple staging systems have been proposed,

the branches of the mandibular division of the fifth cranial nerve, providing sensation to portions of the auricle, the external auditory canal, and the tympanic membrane, which are branches of the mandibular division of the fifth cranial nerve, cancer of the floor of mouth may present with referred pain to the ipsilateral ear.

The oral tongue includes the freely mobile anterior two-thirds of the tongue, extending anteriorly from the linea terminals at the circumvallate papillae to the undersurface of the tongue at the junction of the floor of the mouth. It is composed of four areas: the tip, the lateral borders, the dorsum, and the nonvillous ventral surface of the tongue. The posterior one-third of the tongue and the lingual tonsils are considered part of the oropharynx. The hypoglossal nerve provides motor innervation to the tongue; general somatic afferents from the tongue are carried along the lingual nerve while special sensory afferents are carried along the chorda tympani branch of the facial nerve. A swift of the floor of the mouth, cancers of the oral tongue may present with referred pain to the ipsilateral ear due to involvement of the mandibular branch of the trigeminal nerve.

**Lymphatics**

Lymph nodes in the neck are grouped into various levels for ease of description. Although multiple staging systems have been proposed, the accepted staging system is illustrated in Figure 2. Level I contains the submental and submandibular triangles, bounded by the posterior belly of the digastric muscle posteriorly, the midline of the neck anteriorly, the hyoid bone inferiorly, and the body of the mandible superiorly. Level I is subdivided into levels Ia and Ib. The former comprises the fibrofatty lymphatic packet between the midline of the neck medially and the posterior belly of the digastric laterally and the inferior edge of the mandible superiorly and the hyoid bone inferiorly. Level Ib contains the upper jugular lymph nodes between the two bellies of the digastric muscle. Levels II, III, and IV contain the lymphatics in the anterior cervical chain, running along the sternocleidomastoid muscle (SCM). The posterior limit of these three levels is the posterior border of the SCM; their anteromedial border is the vertical line formed by the lateral borders of the strap musculature. Level II contains the jugular lymph nodes and extends from the level of the skull base superiorly to the inferior border of the hyoid bone inferiorly. Level III contains the middle jugular lymph nodes, extending from the inferior border of the hyoid bone superiorly to the inferior border of the cricoid cartilage inferi-

ory. Level IV contains the lower jugular lymph nodes, extending from the inferior border of the cricoid cartilage superiorly to the superior border of the clavicle inferi- orly. As with level I, level II is subdivided into levels IIa and IIb. The superior border of level IIb is the base of the skull. This lymph node packet extends inferiorly to the hori-

tonal plane defined by the inferior border of the hyoid bone; the anterior border is the stylohyoid muscle and the posterolateral border is defined by the spinal accessory nerve. Level IIe extends from the level base to the inferior border of the hyoid bone. The nodes in this level extend anteriorly from the eleventh cranial nerve to the lateral border of the sternocleidomastoid posteriorly.

Level V contains lymph nodes in the poste-

rior triangle, bounded by the anterior border of the trapezius posteriorly, the posterior border of the SCM anteriorly, and the clavicle inferiorly. Level V is subdivided into levels Va and Vb. Both levels are constrained anteriorly and posteriorly by the same limits as level V; level Va extends from the skull base superiorly to the hori-

tonal plane demarcated by the lower border of the cricoid cartilage inferiorly. Level Vb extends from this horizontal plane to the superior border of the clavicles inferiorly. Level VI contains all the lymphatics in the central portion of the neck. This level extends from the inferior border of the hyoid bone superiorly to the suprasternal notch inferiorly. The lateral borders of this level are defined by the common carotid arteries. Although not widely accepted, a designation of level VII has been assigned to lymphatics within the anter-

ior mediastinum.

Metastasis to regional lymph nodes occurs in a predictable, sequential fashion. Regional lymph nodes at highest risk for metastases from primary squamous cell cancer of the oral cavity include those at levels I, II, and III, known collectively as the supraomohyoid triangle. In addition, neoplasms of each anatomic subsite have their own predictable first-echelon lymph nodes; these regional lymphatic metastatic patterns are summarized in Table 1. Nodal metastasis of squamous cell cancer of the lip is uncommon but tends to involve adjacent submental and submandibular nodes initially, followed by ipsilateral jugular nodes. Neoplasms of the buccal mucosa also tend to spread first to submental and submandibular nodes prior to metastasizing to the remainder of the anterior jugular chain. Cancers of the upper and lower alveolar ridges involve buccinator, submandibular, jugular, and occasionally retropharyngeal nodes; metastases, however, are uncommon. Likewise, neoplasms of the hard palate do not commonly metastasize to regional lymph nodes, but when lymphatic metastasis occurs it usually involves the buccinator, submandibular, jugular, and retropharyngeal nodes. Lymphatics from the retromolar trigone drain to the upper jugular nodes as well as to the retropharyngeal and intraparotid lymphatic beds. The first echelon of lymphatic drainage from the floor of the mouth is the submandibular and jugu-

lar lymph node packet. Finally, lymphatics of the tongue involve submental, submandibular, and jugular nodes. Most regional metastases are ipsilateral; however, lesions of the midline of the lip, the floor of mouth, or the tongue, will not uncommonly spread to both sides of the neck.

**Epidemiology**

In the United States, an estimated 30,990 cases of squamous cell cancer of the oral cavity and oropharynx are expected in 2006. This incidence has been slowly declining in both men and women, but the disease still affects men more than twice as often as women. Five thousand deaths due to oral cavity cancer occur per year, representing approximately 1% of the cancer mortality in the United States. As with incidence, death rates have been declining over the last 25 years, with rapid declines seen within the last decade. Worldwide, the incidence of oral cancer and oropharyngeal cancer increases 10-fold, with significant changes in its relative proportional incidence. In parts of India and Southeast Asia, oral cavity and oropharyngeal cancer represent greater than 30% of all cancers, likely related to geographic differences in tobacco and other carcinogen consumption.

**Etiology**

The majority of patients with cancer of the oral cavity have a significant history of tobacco and alcohol consumption. Both tobacco and alcohol contribute independently to the development of cancer of the oral cavity. However, their combined effects are synergistic, rather than simply additive, in the development of oral cancer. This multiplicative effect of smoking and alcohol abuse is shown in Figure 3, which demonstrates a 35-fold increase in the risk of cancer for men who smoke two or more packs of cigarettes and consume more than four alcoholic drinks per day.
As previously mentioned, the geographic differences in carcinogen consumption may explain the higher proportion of cancers arising in the oral cavity worldwide. In Southeast Asia, cultural practices such as “reverse smoking,” in which the lit end of the cigarette is held within the mouth, have been shown to produce dysplastic changes in the hard palate. Similarly, betel, a compound chewed regularly throughout Southeast Asia and the western Pacific basin, has been implicated in oral carcinogenesis. Composed of the nut of the areca palm (Areca catechu), the leaf of the betel pepper (Piper betle), and lime (calcium hydroxide), and occasionally mixed with tobacco, betel is chewed for its mild psychoactive effects. Other common practices in Southeast Asia include bidi smoking (tobacco rolled within a betel leaf) and the consumption of paan, a quid composed of the nut of the areca palm (Areca catechu), the leaf of the betel pepper (Piper betle), and lime (calcium hydroxide), and occasionally mixed with tobacco. This quid is placed in the mouth and sucked or chewed over several hours, thereby remaining in contact with the oral mucosa for a significant amount of time.10

Tobacco need not be smoked to be carcinogenic. For example, chronic sniff dipping, in which smokeless tobacco is placed in the gingivobuccal sulcus and retained, has been associated with a nearly 50-fold increase in cancers of the gum and buccal mucosa. Pipe and cigar smoking have also been linked to cancer of the oral cavity.10–12 The deleterious effects of these initiators and promoters of carcinogenesis may be partially reversible; smoking cessation is associated with a sharply reduced risk of cancer, particularly for those who have quit for periods greater than 10 years.9

The mechanisms through which alcohol induces cancer development are less well characterized. The increased risk of cancer of the oral cavity associated with frequent use of alcohol-containing mouthwashes suggests that the etiology involves topical exposure, although this association is controversial.10,11,13 Because alcohol has never been shown to be carcinogenic in either in vitro or animal studies; the specific mechanism responsible for alcohol-induced carcinogenesis has yet to be identified, but promotion of cellular proliferation has been implicated. Other possible mechanisms proposed include enhancement of the metabolism of other carcinogens or the development of nutritional deficiencies, specifically in vitamins A and B2, which themselves promote neoplastic changes in oral mucosa.10,14

Viral infection has also been correlated with the development of head and neck cancer. Human papillomavirus (HPV) is a well-established cause for benign recurrent oral and laryngeal papillomas. Genetic DNA sequences of HPV type 16 have been detected in squamous cell cancers of the tongue, tonsil, and pharynx, and the presence of HPV in the oral cavity has been associated with an almost fourfold increased risk of cancer, independent of exposure to tobacco and alcohol.15,16 However, other population-based studies have not implicated sexual transmission for oral cavity cancer.15,16

The human immunodeficiency virus does appear to confer an increased risk for neoplasia. Squamous cell carcinoma in patients infected with HIV appears additionally to assume an accelerated course; cancers in HIV-infected patients who concomitantly abuse tobacco and/or alcohol occur at an earlier age and result in a significantly poorer disease-specific survival when compared with non-HIV-infected patients.17

Poor socioeconomic status, neglected oral hygiene, and recurrent trauma from ill-fitting dentures have also been implicated in the development of oral cavity cancer.11,15 Outdoor occupations requiring prolonged exposure to ultraviolet radiation pose a greater risk of carcinoma of the lower lip;15 UV radiation may itself be synergistic with the nitrosamines contained in tobacco in effecting DNA damage.18

PATHOLOGY

Slaughter and colleagues first proposed the theory of “field carcinization,” a concept predicated upon the notion that carcinogen-induced cytologic changes occur throughout the mucosal lining of the upper aerodigestive tract, resulting in the persistent risk for multiple primary cancers, despite the removal of overt neoplasm.19 This theory is supported by the threefold increase in the rate of second primary neoplasms in patients with oral cancer. The risk of second primary neoplasms in patients with squamous cell cancer of the oral cavity is approximately 4% annually. Both tobacco and alcohol consumption contribute independently to the risk of second primary neoplasms, with the effects of smoking more pronounced than those of alcohol, and with beer consumption potentially more detrimental than the consumption of other alcohols.20 The risk of developing subsequent primary neoplasms in patients who cease smoking after control of the first cancer is one-sixth that of those who continue to smoke. These subsequent primary malignancies are described as simultaneous if diagnosed at the same time as the primary neoplasm, synchronous if diagnosed within 6 months of the primary neoplasm, or metachronous if diagnosed later than 6 months after the primary neoplasm.

Molecular Events

The development of malignant neoplasms appears to be the result of multiple, accumulated genetic alterations which must occur in the correct sequence for cancer to develop. This progression of genetic events was first described in colorectal neoplasminogenesis and a similar model has since been established for head and neck cancer.21 Microsatellite-based genetic analysis of chromosomal alterations has demonstrated that recurrent premalignant lesions arise from a common clonal progenitor with subsequent outgrowth of clonally divergent populations.22 Phenotypically benign mucosa in the upper aerodigestive tract, therefore, may harbor foci of clonal, preneoplastic cells that are genetically related to cancers at other sites. This observation may explain the incidence of local recurrence following complete surgical resection of cancers in the oral cavity.

Genetic alterations in the progression to carcinogenesis include activation of proto-oncogenes and the inactivation of neoplasm suppressor genes. Among the latter, p53, p16, MGMT (a DNA-repair protein), and death-associated protein kinase (DAP-K), a putative metastasis suppressor, have all been implicated.23 Activation of proto-oncogenes and inactivation of neoplasm suppressors may occur by altered methylation of their promoter sequences,23 or by loss of heterozygosity at their respective loci.24

p53 is a neoplasm suppressor that plays an important role in either initiating apoptosis or

**Figure 3 Multiplicative effects of smoking and alcohol abuse on the development of oral cancer. (Adapted from reference B.)**
Precancerous Lesions

Akin to the progression of genetic events leading to phenotypic malignancy, various precancerous lesions can affect the oral cavity with the potential for malignant degeneration.27 Leukoplakia describes a white patch in the oral cavity that does not rub off. A proportionately 10% of these lesions will display squamous cell carcinoma (either in situ or invasive) on histology.28 In this light, previous reports have examined pathologic specimens in patients undergoing surgery for squamous cell cancer of the head and neck, providing an important link between these etiologic factors and the molecular progression to carcinogenesis.25 In this study, previous reports have examined pathologic specimens in patients undergoing surgery for squamous cell cancer of the head and neck for neoplasm resection margins and regional lymph nodes initially judged to be negative for cancer, a substantial number contain p53 mutations identical to the mutations found in the primary neoplasm, lending credence to the concept of field cancerization.26 These patients demonstrate an increased risk of local recurrence.

Histopathology

Morphologically, squamous cell carcinoma can be classified according to its growth patterns: exophytic, infiltrative, and ulcerative. The latter type is the most common in the oral cavity and demonstrates a proclivity for rapid invasion.

Histologically, squamous cell cancer may be classified into five types: keratinizing, non-keratinizing, spindle cell, basaloid squamous, and verrucous. Keratinizing types generally arise from ectoderm, tend to be ulcerative or exophytic, have a lower tendency for submucosal spread, and have “pushing” or noninfiltrative, margins. Spindle cell carcinoma is rare, demonstrating spindle-shaped mesenchymal cells resembling highly anaplastic sarcoma admixed with components of epidermoid carcinoma (Figure 5). Basaloid squamous carcinoma is also a rare variant with high-grade features (Figure 6).

Verrucous carcinoma was initially described by Ackerman as a slowly growing exophytic or wart-like neoplasm in the oral cavity28 (Figure 7). It is a well-differentiated variant of squamous cell carcinoma and has the histologic appearance of keratinized epithelium arranged in long, papillomatous folds. Like the nonkeratinizing subtype, verrucous carcinoma has “pushing” margins. It typically affects the buccal mucosa of elderly patients with a history of tobacco exposure or poor oral hygiene. True verrucous carcinoma has an astonishingly low metastatic potential. As a result, wide surgical excision is the recommended treatment, although irradiation may be considered in selected patients.27,31 However, there have been controversial reports of anaplastic transformation of verrucous carcinoma in patients treated with radiation therapy. In addition, recurrence of verrucous carcinoma tends to be in the form of less differentiated cancers,
21F-fluorodeoxyglucose has been shown to be more sensitive than conventional imaging techniques for detecting occult nodal metastases. In patients with head and neck cancer, PET scanning has been shown to be beneficial in the follow-up of patients with stage I or II disease. PET scanning can also be used to detect distant metastases in patients with recurrent or persistent disease. PET scanning has also been shown to be useful in the assessment of treatment response in patients with head and neck cancer.

Regional Spread
Prevalence of metastases to regional lymphatics is dominated by the primary neoplasm, the density of lymphatics in the primary site, and the presence of lymphatic invasion. The metastatic potential of primary squamous cell carcinoma is highest in the oral cavity, followed by the lung, then by the liver, and then by the gastrointestinal tract. The prevalence of metastases to regional lymph nodes is approximately 50% for cancers of the oral cavity, with lymphatic drainage secondary to fibrosis of lymphatic channels. The metastatic potential of primary neoplasms of the lip, alveolar ridge, and hard palate is significantly lower than that of neoplasms arising elsewhere in the oral cavity, due to a paucity of lymphatic drainage at these sites. Over all, the 5-year survival of patients with cervical metastases is approximately 50% of that of those without. In patients with metastases to the neck, extracapsular spread of carcinoma to cervical lymph nodes portends a poorer prognosis, as do an increased number of involved nodes and the spread of neoplasm to lymph nodes more inferiorly located within the neck.

A thorough to 20% of patients who succumb to head and neck cancer develop metastases to distant sites, only 4% of these have distant spread without locoregional failure. Treatment efforts have therefore concentrated on locoregional control of the disease.

Distant Spread
Distant metastases from cancers of the oral cavity generally do not occur until the disease is advanced. Distant metastases typically first involve the lungs, followed by the liver, then by bone. Surveillance computed tomography (CT) of the chest, therefore, is often employed as part of the routine follow-up of a patient treated for squamous cell carcinoma of the oral cavity. PET scanning can also be used to detect distant metastases in patients with recurrent or persistent disease. PET scanning has also been shown to be useful in the assessment of treatment response in patients with head and neck cancer.

CANCER OF THE ORAL CAVITY IN YOUNG ADULTS
Squamous cell carcinoma of the oral cavity tends to affect patients around the sixth decade of life, but there is evidence of an increasing incidence in younger adults, specifically cancers of the oral tongue and palate tonsils. The biologic behavior of cancer in the oral cavity in the younger adult population presents a topic of significant debate. Although molecular differences in tumor biology have not been demonstrated in these younger patients, there is some indication that these neoplasms require more aggressive treatment: patients younger than 40 years of age with squamous cell carcinoma of the tongue demonstrate higher rates of local recurrence. However, these rates have not been shown to translate to poorer survival. It should be noted that studies on either side of this debate tend to be retrospective reviews of relatively small patient groups in light of the infrequent nature of this disease.

OTHER MALIGNANT NEOPLASMS OF THE ORAL CAVITY
Other malignancies affecting the oral cavity besides squamous cell cancer include Kaposi sarcoma, extranodal non-Hodgkin lymphoma, mucosal melanoma, and minor salivary gland cancers. Kaposi sarcoma is a common manifestation of AIDS and clinically presents as a nonpruritic, violaceous macule on the mucosa of the upper aerodigestive tract. These neoplasms grow slowly and are amenable to radiation, laser excision, cryotherapy, or intralesional injections of vincristine.

Extranodal non-Hodgkin lymphoma may present as a painless mass along the palate or gingiva or as an asymptomatic enlargement of one tonsil. Treatment is similar to that of non-Hodgkin lymphoma elsewhere in the body. Mucosal melanoma of the head and neck is rare, representing only 3% of all melanomas. Its mortality, however, is significant when compared with mortality of the nonmucosal type. The palate is the most common site of involvement in the oral cavity, with intralesional lymphatic and vascular invasion frequently seen. Surgical excision is recommended, although the ultimate prognosis is typically poor, owing to frequent distant dissemination.

A dentoid cystic carcinoma is the most common minor salivary gland neoplasm of the oral cavity, although mucopidermoid carcinoma and adenocarcinoma are also present in this region. As with other regions, the incidence of minor salivary cancer in the oral cavity is increased following therapeutic irradiation. Treatment protocols are similar to those for primary salivary cancers.

EVALUATION
History and Physical Examination
The first step in the evaluation of a patient with cancer of the oral cavity is a thorough history and a comprehensive examination of the head and neck. The patient should be questioned about symptoms of dysphagia, odynophagia, dysarthria, globus sensation, difficulty breathing, hemoptysis, otalgia, weight loss, and other constitutional symptoms. An especially important component of the complete history, given the aforementioned risk factors for oral cavity cancer, is an adequate social history; the patient should be asked about the consumption of tobacco and alcohol, about occupational, sexual, and avocational exposures (including sunlight), and about previous exposure to radiation.

During the comprehensive examination of the head and neck, the oral cavity should be thoroughly assessed. Pigmentation changes or ulcers of the oral mucosa, the state of dentition, and an evaluation for trismus should all be undertaken. A thorough examination includes both visual inspection and palpation of all subunits in the oral cavity for mucosal lesions and masses. Bimanual palpation is particularly useful in the evaluation of the buccal surfaces and the floor of the mouth. Tongue mobility should be assessed, and palpation of the base of the tongue should not be neglected. Somatosensory function of the lower two divisions of the trigeminal nerve should be evaluated for symmetry. The patient’s neck should be palpated for masses, with palpable masses assessed for size, location, consistency, mobility, and tenderness. Other factors which also require attention, namely tumor size, bleeding, pain, and interference with speech, breathing, or eating, should not be overlooked.

The necessity for a systematic, comprehensive approach to the head and neck examination cannot be overemphasized. It has been shown that a delay in diagnosis for a primary neoplasm of the oral cavity is greatest when the neoplasm is located in the floor of the mouth and shortest when the neoplasm is on the tongue. In addition, the concept of field cancerization implies that finding one lesion in the oral cavity does not preclude the existence of others.

Imaging and Pathologic Evaluation for Regional Metastases
Clinical assessment of regional nodal metastases is not infallible. It may be difficult to appreciate lymphadenopathy in patients with a short, stout neck, in patients with fibrotic changes secondary to previous radiotherapy, and at sites, such as the parapharyngeal or retropharyngeal spaces, typically inaccessible by routine physical examination. Although there is no substitute for a systematic, comprehensive examination of the neck, imaging techniques provide valuable supplemental information regarding the status of regional lymph nodes. The sensitivity of CT and magnetic resonance imaging (MRI) for nodal metastasis...
is between 80 and 90%, but recent studies have implied that clinical examination may be more efficient than CT at the identification of cervical metastases. Although the actual diagnosis of malignancy cannot be made on imaging, there are certain characteristic changes apparent on CT and MRI that suggest the presence of carcinoma. These include rim enhancement, central necrosis, a nodal size of ≥1 cm, and a round shape suggest carcinoma within a neck node.

PET has a sensitivity of approximately 85% and a specificity of approximately 99% in the evaluation of the node-positive neck, but only a 67% sensitivity and 85% specificity in the evaluation of the clinically negative neck (Figure 8). It cannot be relied on as a sole diagnostic modality. A combined strategy involving clinical examination and imaging is therefore indicated. However, because both physical examination and imaging are techniques prone to false-positive and false-negative errors, pathologic confirmation by fine-needle aspiration (FNA) is commonly employed for any suspicious neck mass. FNA is a highly sensitive procedure with minimal morbidity that allows cytologic examination of a mass in the head and neck. Repeat FNA should be considered following an initial nondiagnostic FNA. Open neck biopsy is a procedure with limited applications and should be considered only when both the surgeon and the patient are prepared to proceed immediately with a neck dissection if indicated.

**Imaging Evaluation of the Mandible**

CT and MRI provide useful adjuvant information regarding soft tissue and bony invasion of advanced oral cavity neoplasms, particularly with extension toward the nasal cavity, maxillary sinus, parapharyngeal space, and larynx. Optimal radiologic evaluation of mandibular involvement by cancer, however, remains controversial.

Patterns of spread within the mandible include direct extension through the cancellous bony trabeculae and along the inferior alveolar nerve. Panoramic radiographs are helpful in the evaluation of gross mandibular invasion but cannot resolve minimal cortical invasion. The utility of CT scans may be limited owing to the presence of irregular dental sockets and artifacts (Figure 9). Dedicated CT reconstructions of the mandible (DentaScans, see Figure 9) may obviate some of this artifact, but their utility is controversial. In addition, clinical evaluation is valuable in determining the extent of bony invasion and therefore the optimal method of mandibular resection.

**Endoscopy**

Endoscopic examination may be performed both in the office and in the operating room. Diagnostic nasopharyngoscopy is a simple in-office procedure, routinely employed for the detection of malignancies throughout the upper aerodigestive tract; it is critical in the follow-up of patients with tumors of the head and neck. However, endoscopic examination under anesthesia provides the most thorough inspection of the primary neoplasm and evaluation for second primary neoplasms, as well as the ability to biopsy suspicious sites. The oropharynx, hypopharynx, and larynx should be examined in a systematic fashion.

**Staging**

Staging systems for cancer provide a standardized measurement for the extent of disease. Staging allows for the estimation of prognosis, provides assistance with treatment planning, provides a framework for the evaluation of treatment effectiveness, and promotes a uniform comparison of results. The staging system of the American Joint Committee on Cancer for cancers of the oral cavity is given in Table 2. This TNM staging categorizes tumors based on the extent of the primary tumor (T), the extent of nodal metastasis (N), and the presence of distant disease (M).

While of utmost importance, patient factors, such as comorbidities, and molecular characteristics of the tumor are not incorporated into the current staging system.

**Sentinel Lymph Node Biopsy**

In an effort to improve accuracy of staging and to guide further treatment, the technique of lymphoscintigraphy and sentinel lymph node biopsy have recently been applied to cancers of the oral cavity. This technique, adopted from the melanoma literature, involves injection of a radiocolloid marker into the primary tumor with subsequent timed scintigraphy of the neck; the first-echelon node specific to the particular tumor is thereby identified. In theory, that particular node could be removed and histologically examined. If tumor is found in that node, a complete neck dissection would then be undertaken; if the node is clear of tumor, no further treatment of the neck would be indicated. Unfortunately, the data regarding this technique are sparse. Although initial reports put the negative predictive value of a sentinel node for carcinoma elsewhere in the neck as high as 100%, more recent studies have reported a false-negative rate up to 33%. Further prospective, randomized studies are required before establishing this technique as useful in the armamentarium of the head and neck surgeon.

**TREATMENT**

In general, early-stage lesions in the oral cavity may be treated by either surgery or radiation with comparable results, and more advanced
cancers are best approached with combined therapy. The proclivity of these tumors for locoregional failure, however, mandates recognition of the specific prognostic factors associated with each case. Tailoring the most appropriate therapy involves consideration of patient characteristics, including motivation and comorbidities; physician resources, including experience and facilities; and tumor presentation, including location, grade, and extent of disease.

Furthermore, the optimization of aesthetic form and preservation of proper functions of speech, respiration, and deglutition must be reconciled with tumor eradication.

Surgery

In light of the comparable results for early-stage lesions treated with either surgery or radiation therapy, factors in favor of surgical resection include the ability to stage local invasion and the avoidance of the sequelae of radiotherapy, namely xerostomia and osteoradionecrosis. The primary limitation of surgery, however, involves functional impairment, particularly when resection involving the mandible or a large portion of the tongue is necessary.

Surgical Approaches. Different approaches to the oral cavity exist, depending on tumor location and extent. Peroral excision is suitable for small lesions of the oral cavity. A cheek flap, however, may be constructed for larger lesions. A V-Y flap may be used for anterior lesions in the oral cavity if one wishes to avoid external facial incisions, but this is done at the expense of bilateral mental nerve sacrifice.

Carcinomas arising at or extending to the posterior portion of the oral cavity may require a mandibulectomy for adequate exposure. A paramedian mandibulectomy with paralingual extensions, that is, a mandibular swing, illustrated in Figure 10, offers more versatility and less morbidity than a mandibulectomy through a lateral approach. Placing the mandibulectomy anterior to the mental foramen preserves the integrity of the inferior alveolar nerve and may exclude the osteotomy from portals typically employed for adjuvant external beam radiation.

The mandible should be spared in the absence of bony invasion. Oncologically, there is no benefit from removal of a portion of the mandible simply to keep the contents of a neck dissection in continuity with the primary resection. Functionally, resection of the anterior arch of the mandible results in significant disability, including drooling and interference with eating, in direct relation to the amount of bone removed. Aesthetically, this may also result in a significant recession of the pogonion, leading to what is known as an “Andy Gump” deformity.

Instances of bony invasion by tumor, however, mandate resection of that portion of the

Adapted from the American Joint Committee on Cancer Staging Manual, 6th edition.
Cancers of the hard palate often require an inferior maxillectomy. The same principles should be followed for the maxilla as are for the mandible: as little bone as needed should be removed to maintain a balance between functional outcome and oncologic result. However, the rehabilitation of hard palate defects with the use of prosthetics, in addition to free tissue transfer, is significantly easier than that of mandibular defects.

**Surgical Margins.** An important concept in the management of cancers of the oral cavity concerns the adequacy of surgical margins. Local recurrence in patients with positive surgical margins following resection may be as high as four times that following resection with negative margins. Furthermore, local recurrence rates and 5-year survival rates of patients with “close” surgical margins (less than 5 mm) are comparable to those with microscopically positive margins. In that light, it is critical to ensure the resection of adequate margins at the time of surgery. It should be remembered, however, that oral cavity margins shrink approximately 30 to 50% from the in situ measurement by the surgeon to the final pathologic evaluation after formalin fixation.

**Radiation Therapy**

An environment high in oxygen provides an ideal setting for therapeutic radiation, leading to the generally favorable radioresponsiveness of most early-stage head and neck cancers; invasion of bone or deep muscle, therefore, portends a poorer response to radiotherapy.

Modalities for primary radiation include wide-field or intensity-modulated external beam radiation therapy, interstitial implantation, that is, brachytherapy, or a combination of modalities. Definitive radiotherapy shares comparable results with surgical treatment for early-stage oral cancers and is therefore preferred for early-stage lesions in patients in whom surgical management is contraindicated. The dosage of radiation depends upon the extent of disease and the tolerance of surrounding normal tissues to radiation injury. In general, definitive radiotherapy may be delivered with doses of 60 to 65 Gy over 6 weeks for smaller tumors, with larger tumors requiring up to 70 Gy delivered over 7 weeks.

Improvement continues in the mode of radiation delivery. Hyperfractionation or accelerated fractionation with boosts is more effective than traditional radiation therapy in unresectable head and neck cancers; this added benefit, however, does not approach the added benefit obtained with concomitant chemotherapy and radiation therapy. Interstitial brachytherapy has also been employed effectively for carcinoma of the oral cavity. Intensity-modulated radiation therapy may increase the amount of radiation delivered to the tumor itself while sparing the surrounding normal tissues, such as the major salivary glands and the mandible, leading to a potential decrease in xerostomia and osteoradionecrosis, respectively.

In addition to the side effects of mucositis and xerostomia, major complications of definitive radiotherapy to the oral cavity include osteoradionecrosis, pathologic mandibular fractures, and mucosal ulcerations. The risk of osteoradionecrosis necessitates comprehensive dental care prior to the initiation of radiotherapy. The adjuvant use of hyperbaric oxygen, either prophylactically or for treatment of mandibular osteoradionecrosis, although commonly practiced, remains controversial.

**Combined Therapy**

A combination of surgery and chemotherapy is recommended for advanced cancers of the oral cavity in light of the high propensity for locoregional failure. Although neoadjuvant, ie, preoperative, radiotherapy has been used in the past, the current standard of care for combined modalities is surgery followed by adjuvant radiotherapy with or without chemotherapy. Indications for adjuvant radiotherapy include multiple positive nodes, extracapsular lymph node extension, and positive margins of resection, as well as Stage III or IV primary disease (Table 3). Adjuvant radiotherapy has been shown to improve locoregional control in the presence of extracapsular spread or positive resection margins, but it should not be construed as a panacea for inadequate operations: it does not appear to decrease the risk of local recurrence in patients with positive margins to a level similar to comparable patients with negative margins not treated with radiotherapy.

The addition of chemotherapy improves overall and disease-free survival, especially when undertaken concomitantly with radiation therapy. It should be noted, however, that these concomitant chemoradiation regimens hold a significant increase in morbidity and up to a 5% mortality rate when compared with adjuvant radiotherapy alone.

The ideal timing of postoperative radiotherapy with or without chemotherapy is 6 weeks following surgery. For Stage III and IV squamous cell cancer of the head and neck, locoregional recurrence is 5.5% when adjuvant radiotherapy is initiated within 6 weeks of surgery, but 31.5% when adjuvant therapy is delayed for more than 6 weeks. This increase in nodal recurrence is observed whether the nodal metastases were initially confined to a single nodal level or whether multiple levels were involved and is not abrogated by higher doses of radiation.

**Figure 12** Marginal mandibulectomy. (Adapted from reference 49.)
Chemotherapy

As with radiation, chemotherapy can be delivered either prior to (neoadjuvant), following (adjuvant), or simultaneous with (concomitant) definitive treatment. Neoadjuvant chemotherapy has not been shown to confer a survival advantage.63 Adjuvant cisplatin and 5-fluorouracil (5-FU) following postoperative radiotherapy decreases the incidence of distant metastases but confers no difference in 4-year locoregional control, overall survival, or disease-free survival.52 As discussed above, however, concomitant chemoradiation has been shown to be effective in improving overall survival and progression-free survival in patients with advanced head and neck squamous cell cancers. The price paid for this improved survival is an increase in mucositis and hematopoetic toxicity. Chemotherapy is also frequently employed in the palliation of advanced head and neck cancer not amenable to other primary methods of treatment.

Chemoprevention

Recent efforts to expand the armamentarium of treatments for cancer of the oral cavity have included the investigation of chemopreventive agents.65 A number of genetic events leading to carcinogenesis are further elucidated. attempts are being made to identify potential agents that can prevent DNA damage or enhance DNA repair. A prospective randomized trial demonstrated effective treatment of oral leukoplasia with a 6-month trial of isotretinoin (13-cis-retinoic acid), with significant reduction in lesion size and reversal of dysplasia. However, withdrawal of treatment led to relapse within 3 months in over half the population. A follow-up study on a 1-year course of isotretinoin after primary treatment for squamous cell cancer of the oral cavity, oropharynx, and larynx demonstrated no significant difference at 32 months in local, regional, or distant recurrences between the treated and untreated groups. Other studies of chemoprevention in oral cavity cancer have involved the use of beta-carotenes, alpha-tocopherol, and ascorbic acid. Similarly, no randomized, prospective trial has demonstrated any long-term benefit with the use of these agents. Initial animal studies in the topical application of cyclooxygenase-2 inhibitors appear promising, but no human trials have proven as optimistic. Because the response to chemopreventive agents may include genetic alterations not readily apparent phenotypically, a number of investigations continue.

Management of the Neck

An issue of ongoing controversy concerns the management of the neck in patients without clinical evidence of regional nodal metastases (the N0 neck). As stated earlier, lymphatic metastases from primary tumors of the oral cavity occur in a predictable fashion through sequential spread. Although previous surgery or irradiation may result in aberrant lymphatic drainage, there are well-established first-echelon lymph nodes for each primary tumor site. In light of the propensity for various sites within the oral cavity to spread to regional lymphatics and the high risk of nodal recurrence, and in light of the fact that pathologic evidence of micrometastases has been observed on gross sections in up to one-third of elective neck dissection specimens, what constitutes the ideal approach to the N0 neck?

Elective Neck Dissection. It has been previously reported that, despite the data quoted above, elective neck dissection offers no survival advantage compared with observation alone.64 However, in patients at risk for neck metastasis, failure tends to be from advanced nodal disease, despite close follow-up; because elective neck dissection has been shown to improve locoregional control, it may therefore impact positively on the quality of patients’ survival. Recognizing that some sites of the oral cavity have a decreased propensity for spread to regional lymphatics, specifically hard palate, alveolar ridge, and midline aspects of the lip, the risk of regional failure with primaries of the oral cavity at most subsites is sufficiently high to warrant elective treatment of the neck.

Elective neck dissection is not without its complications. First described by Crile in 190665 and popularized by M artin and colleagues,66 the radical neck dissection is associated with significant morbidity due to sacrifice of the spinal accessory nerve, the SCM muscle, and the internal jugular vein. Significant compromise of shoulder function results from the loss of the spinal accessory nerve, and cosmetic deformity from the removal of the SCM. Removal of the internal jugular vein risks significant edema of the face and occasional central nervous system deficits, particularly following bilateral neck dissection or when radiotherapy is employed.

In light of this morbidity, there has been a trend toward selective neck dissection, based on the aforementioned predictable pattern of lymph node metastases. A selective lymphadenectomy clearing nodal levels I, II, and III (so-called “supraomohyoid neck dissection,” or SOHND) is traditionally recommended for N2 patients with primary squamous cell cancers of the oral cavity. While some have advocated the use of the SOHND in N3 necks without evidence of extracapsular spread, concerns of skip metastases to inferior cervical nodes at levels III or IV in the absence of demonstrable involvement at levels I and II may limit these recommendations.67 Clearing level IV during a SOHND adds little in terms of operative time and may reduce the approximately 5% incidence of isolated level IV metastases from tumors of the oral cavity. However, dissection of level IV places the patient at a slightly increased risk for postoperative chyle leakage. For primary tumors of the oral cavity, the risk of involvement of level V is minimal, and is therefore not routinely included in the selective lymphadenectomy of N2 necks for oral cavity primaries.

Elective Neck Irradiation. The theoretical advantages of treating the N0 neck with surgical lymphadenectomy include the ability to obtain pathologic staging information, the preparation of donor and recipient vasculature for microvascular reconstruction when indicated, and the avoidance of morbidity associated with radiotherapy. However, no significant differences in regional recurrence have been demonstrated following treatment of the N0 neck with either elective neck irradiation or elective neck dissection.64 The modality chosen to address the clinically negative neck, therefore, may largely be influenced by the philosophy of the treating physician. As a general rule, however, the treatment modality chosen for the primary carcinoma of the oral cavity is employed concurrently to address the risk of occult regional metastases.

Therapeutic Neck Dissection. For the clinically positive neck, the traditional surgical procedure of choice has been the comprehensive neck dissection, with preservation of the spinal accessory nerve, and, increasingly, the internal jugular vein and SCM, in cases without gross involvement of these anatomic structures by tumor. The continuing evolution of a more selective approach to the neck, however, has included the clinically positive neck as well. Comprehensive neck dissections with preservation of all three major structures discussed above may be performed for the N1, N2a, and N2b neck when technically feasible. A more selective neck dissection may be acceptable for N2 disease without extracapsular extension, particularly when the single involved node is in level I. In patients in whom the primary tumor has been treated with radiotherapy, the neck is often included in the radiation portals as well; in these N-positive patients, a postradionec tion neck dissection is often planned as a staged procedure. There is some evidence, however, that the neck may be followed with serial CT, thereby obviating unnecessary neck dissections in patients with a complete response to therapy.63 The role of PET scans in the follow-up of these patients is under investigation.

SPECIFIC SITES IN THE ORAL CAVITY

Lip

Squamous cell carcinoma of the lip, by virtue of its location, tends to present at a relatively early stage. The lower lip is affected more commonly, presumably secondary to sunlight exposure. Origins at the oral commissure occur in fewer than 1% of cases.

Comparable cure rates have been reported for small carcinomas of the lip using either surgery or radiation therapy, but the former is the treatment of choice in most instances owing to its lower morbidity and better cosmetic results. A dvantages of surgery over irradiation include the ability to assess tumor margins and rapid rehabilitation. Lesions of up to one-third of the lip length may be resected with primary closure, and a number of options exist for flap reconstructions of larger defects. Specifically, a lip-switching procedure, that is, the Abbé-ESTlander flap, may be employed for defects between one-third and one-half the
length of the lip. This involves mobilizing a portion of uninvolved opposite lip, rotating it to fill the defect in the involved lip while keeping it attached to its blood supply. In a staged fashion, the attachment to the uninvolved lip is divided. The Krapanzic flap, a bilateral rotation/advancement flap may be used for even larger defects involving greater than half the lip length.

Metastases from carcinoma of the lip are uncommon (7 to 16%) except in advanced lesions, recurrent lesions, or lesions arising at the oral commissure. When lymphatic spread arises from midline lip lesions, bilateral lymph node metastases are common. Depth of invasion is an important prognostic factor for regional lymph node metastases, particularly for lesions greater than 2 mm in thickness. Other prognostic factors include size of tumor, histologic grade, and subsite.

Overall survival rates are approximately 90% when surgery is used for stages I and II, and surgery plus adjuvant chemoradiation is used for stages III and IV. Survival estimations in most studies, however, may be skewed by the exceedingly high proportion of patients who present with stage I disease. Surgical salvage for local recurrence is successful in over 70% of cases. Survival rates for each subsite in the oral cavity are summarized in Table 4. Despite the relatively low incidence of nodal metastasis in tumors at this site, mortality in patients with regional lymphadenopathy is significantly higher than patients with N0 necks, leading some authors to advocate elective lymphadenectomy in all patients with squamous cell carcinoma of the lip.

Buccal Mucosa

Cancers of the buccal mucosa are characteristically locally aggressive, spreading to the adjacent gingiva and involving the retromolar trigone or pterygoid region in up to one-third of cases. The intraoperative photograph in Figure 13 depicts an advanced squamous cell cancer of the right buccal mucosa extending to the skin. Surgical resection is recommended for stage I and II tumors, with combination therapy employing both surgery and chemoradiation for stages III and IV. Using this treatment modality, 5-year survival rates have been reported at 77% for stage I, 65% for stage II, 27% for stage III, and 18% for stage IV. Unfortunately, treatment of tumors of the buccal mucosa is difficult given the significant functional deficit their surgical excision often engenders. Myriad reconstructive methods have been attempted, including skin grafting, microvascular free tissue transfer, local flap advancement, and even healing by secondary intention, each having its attendant morbidities.

Alveolar Ridges

Carcinomas of the alveolar ridge typically present with soreness or pain in the gum, ulceration with intraoral bleeding, loosening of teeth, or ill-fitting dentures. Patients tend to present with symptoms within 3 months of onset. Cancer of the upper alveolar ridge may extend superiorly to involve the floor of the nasal cavity or maxillary sinus. Carcinoma of the alveolar ridge, however, more commonly arises from the lower alveolus, and these cancers may spread along the course of the inferior alveolar nerve toward the skull base. Based on 2-year survival rates, marginal mandibulectomy has been demonstrated to be an oncologically sound procedure for stage I and II disease of the alveolar ridge. Marginal mandibulectomy is contraindicated, however, if the mandible is enveloped by tumor. If there is tumor invasion through the cortical plate, or if there has been recent tooth extraction in proximity to the tumor. The use of adjuvant radiotherapy or chemoradiotherapy is advocated, as with other cancers of the oral cavity, for instances of inadequate surgical margin, perineural invasion, extensive nodal metastases, or extracapsular extension within nodal metastases. It should be noted, however, that regional metastases to cervical lymphatics are uncommon from carcinoma of the alveolar ridge.

Carcinoma of the upper alveolar ridge is treated in a similar manner to that of the lower ridge, with single-modality therapy recommended for stage I and II disease. There is no equivalent of the marginal mandibulectomy in the maxilla, however, and en bloc resection is recommended for all tumors, including resection of involved teeth and hard palate when necessary. Using surgery as primary modality with the addition of postoperative radiotherapy or chemoradiotherapy for advanced lesions, the following 5-year survival rates have been demonstrated: 77% for stage I, 70% for stage II, 42% for stage III, and 24% for stage IV.

Retromolar Trigone

Cancers of the retromolar trigone, like those of the lower gingiva, are often associated with chewing tobacco. Branches of the glossopharyngeal nerve provide sensory innervation to the retromolar trigone, so patients with carcinoma of this region may present with pain referred to the ipsilateral ear. Numbness in the distribution of the inferior alveolar nerve is an ominous sign for invasion of the mandible and perineural extension. Trismus may result from invasion of the pterygoid musculature. Direct extension into the pterygopalatine fossa may also lead to disease at the skull base. The proximity of the structures of the oropharynx to the retromolar trigone also places them at risk for involvement by direct extension. The tight adherence of mucosa to underlying structures often necessitates resection of the ascending portion of the mandible. Using a protocol of surgery with or without chemoradiation therapy, 5-year disease-free survival rates are 83% for stages I to III combined and 61% for stage IV. There has been some discussion of radiation therapy alone for cancers of the retromolar trigone given the difficulty in surgical access to this portion of the oral cavity, but removing surgery from the treatment protocol drastically reduces the survival.

Hard Palate

Although relatively rare in the United States, carcinoma of the hard palate is more prevalent in areas in which the practice of reverse smoking is more common. The heat generated from holding the lit end of the cigarette near the hard palate has been demonstrated to result in malignant transformation. Presenting symptoms of cancer of the hard palate include pain, bleeding, altered speech, or improperly fitting dentures. Biopsy may be necessary to distinguish carcinoma of the hard palate from other mimicking entities such as necrotizing sialometaplasia. There is, unfortunately, often a confounding delay in presentation of patients with cancer of the hard palate: at presentation, over half have had symptoms for at least 12 weeks, and over one-third wait at least 6 months before seeking treatment.

For early-stage lesions, no difference has been demonstrated between radiation therapy or surgery as single-modality treatments, so selection of therapy should be based on the anatomic location...
and extent of the disease, the presence of second primaries, and associated patient comorbidities. Surgery followed by adjuvant radiotherapy is recommended for advanced-stage disease, which may extend into the nasal cavity through the incisive foramen or may approach the skull base via the greater palatine foramina. Because of the paucity of cases, 5-year survival rates have been reported in a limited fashion. Overall survival with optimal treatment is 92% for stage I, 43% for stage II, 37% for stage III, and 17% for stage IV tumors.

Regional lymphatic drainage from the hard palate is sparse; metastases to cervical lymph nodes are relatively uncommon.

**Floor of the Mouth**

By virtue of their location, cancers of the floor of the mouth often remain undetected until they progress to advanced disease. Bulky tumors affect normal speech and deglutition, and patients may also complain of pain referred to the ipsilateral ear from tumor involvement of the lingual nerve. Advanced tumors may also invade the tongue or mandible by direct extension. As a result, an aggressive surgical paradigm for the management of these neoplasms is warranted. Regardless of stage, local recurrence is 13% in patients who undergo complete resection with histologically negative margins.

Second primary neoplasms are particularly common in cancers of the floor of the mouth. In addition, elective treatment of the neck is warranted owing to the significant incidence of occult nodal metastases, even with T1 lesions. Patients with high-stage primary cancers are at increased risk for advanced nodal metastases: approximately one-third of patients with T1 tumors present with N2 disease. The risk of contralateral nodal metastases is significant with these primaries, and multiple levels are often involved.

Primary therapy includes surgery with the addition of postoperative chemoradiation for stage III and IV disease and allows for survival rates of 95% for stage I, 86% for stage II, 82% for stage III, and 52% for stage IV. Of note, postoperative radiation therapy does not seem to affect overall survival significantly: it does, however, decrease the rate of regional but, interestingly, not local recurrence. Figure 14 illustrates the surgical management of a patient with biopsy-proven squamous cell cancer of the floor of the mouth invading the ventral surface of the oral tongue. The patient underwent resection of the lesion at the floor of the mouth, extending to the ventral surface of the tongue, with concomitant marginal mandibulectomy, tracheostomy, and bilateral SOHND. Repair of the surgical defect was accomplished with the use of a radial forearm free tissue transfer.

**Oral Tongue**

The most common presenting symptoms and signs for carcinoma of the oral tongue include localized pain with the presence of an ulcer, frequently on the middle one-third of the tongue, dysarthria or glossodynia with eating. As with cancers of the floor of the mouth, primary neoplasms on the oral tongue may present with referred pain in the ipsilateral ear, owing to involvement of the lingual nerve. Second primary neoplasms are also common in cancers of the tongue, occurring in approximately one-quarter of patients.

There are no reported differences in the rate of locoregional control or survival between surgery and irradiation for T1 and T2 lesions. Surgical resection is typically employed for these early-staged tumors, whereas combined modalities are indicated for higher-staged tumors. Occult metastases in regional lymphatics are common in carcinoma of the oral tongue, particularly when the depth of the primary tumor is greater than 4 mm. Other risk factors for occult metastasis include the presence of perineural or perivascular invasion, infiltrating-type margins, poorly differentiated primary tumors, and T2 stage. The rates of locoregional control and survival are improved with elective neck dissection, even for T1 and T2 tumors. Selective neck dissection is adequate treatment for the N1 neck: no differences in survival or locoregional control have been demonstrated in patients undergoing comprehensive or selective neck dissections.

Improvements in the observed rates of overall 5-year survival have been attributed to a more aggressive approach to the neck in patients with early-stage tumors and the addition of postoperative radiotherapy or chemoradiotherapy in patients with advanced-stage disease. Reported 5-year survival rates with these modalities are 90% for stage I, 72% for stage II, 54% for stage III, and 34% for stage IV. Overall, significant improvement in 5-year disease-free survival is seen with the following parameters: clear margins, clinical T1 or T2 disease, clinical stages I or II disease, lack of nodal metastases (or T1N2 patients), and postoperative radiotherapy for patients with close or positive margins. The increasing use of mandible-sparing procedures and selective, rather than comprehensive, neck dissection may result in improved quality of life in the survivors, as well.

**RECONSTRUCTION OF THE ORAL CAVITY**

Following the resection of cancers of the oral cavity, reconstruction of the defect must be individualized based on the extent of the defect and the availability of reconstructive techniques. Selected small, intraoral defects may be closed primarily or covered with a local flap, a split-thickness skin graft, or acellular dermis. They may also be allowed to heal by secondary intention. Larger defects require more complex flap reconstruction. A number of factors affect the type of reconstruction used. These include tumor extent and location, patient comorbidities, surgeon experience and/or preference, and the anticipated postoperative dysfunction in respiration, deglutition, or speech.

A variety of reconstructive techniques is available for defects in the oral cavity. Two key reconstructive techniques deserve mention: pedicled flaps and microvascular free tissue transfer.

The pectoralis major myocutaneous flap provides well-vascularized soft tissue for the reconstruction of the oral cavity. It is a pedicled flap, receiving its blood supply from the pectoral branch of the thoracodorsal artery and can be used, with or without an attached skin paddle, for the reconstruction of both intraoral and external defects. Its reliable vascularity, proximity to the head and neck, and availability for harvest while the patient is in the supine position has led to its wide acceptance for reconstruction of head and neck defects. The flap, however, has several
disadvantages in intraoral reconstruction: its skin-paddle contains nonglabrous tissue; its soft tissue bulk may be inappropriate for smaller defects; and it has a limited arc of rotation.

Microvascular free tissue transfer has revolutionized head and neck reconstruction, providing flaps and their nutrient vessels from such disparate sites as the fibula, the scapula, the iliac crest, the rectus muscle, and the radial forearm to repair complex defects with uniformly perfused tissue. The fibula, radial forearm, and anterolateral thigh flaps are most frequently used in the reconstruction of intraoral defects, the latter two for predominantly soft-tissue reconstruction and the former for reconstructions requiring bone.

The fibula free flap is an osteomyocutaneous flap based on the peroneal artery and its two attendant peroneal veins. It has the benefit of being able to provide significant bone stock for mandibular defects, even allowing for postoperative dental implantation. Its drawback is its relatively short pedicle and occasionally unreliable skin paddle, the survival of which is often more operator-dependent than that of other flaps. Because the blood supply to the fibula is both endosteal and periosteal, osteotomies are possible, allowing the reconstructive surgeon the ability to contour the bone to the ablative defect.

The radial forearm free flap is an extremely reliable fasciocutaneous flap based on the radial artery and its attendant venae comitantes. It has also been described as an osteomyocutaneous flap, with the inclusion of the radius and/or the palmaris longus (absent in 10 to 15% of patients). The advantages of the radial forearm flap include the fact that the skin in the region is thin, pliable, and relatively hairless. In addition, the flap is relatively easy to harvest and the pedicle is long; this allows for versatility in the use of this reconstructive method. Disadvantages are minor and are usually limited to donor-site morbidity, for example, scarring and often some degree of carpal weakness.

The anterolateral thigh free flap is a fasciocutaneous flap based on the descending branch of the lateral femoral circumflex artery and its vein. Unlike many flaps used in head and neck reconstruction, this can be made sensate with the inclusion of the lateral femoral cutaneous nerve. It has a long pedicle length and provides more bulk than the radial forearm flap, allowing for improved reconstruction of larger defects. Its drawback, however, is that the vascular anatomy to the anterior thigh is more often variable, making this flap more difficult to use.

Mandibular defects may be successfully reconstructed with composite bone flaps, including the free fibula and the iliac crest osteomyocutaneous flaps. Such vascularized composite flaps provide reliable bone stock for optimal aesthetic contour and masticatory function. Figure 15 illustrates the surgical management of a patient with biopsy-proven squamous cell cancer of the floor of the mouth, involving the anterior part of the mandible and the anterior part of the tongue. The treatment included resection of the floor of the mouth, subtotal glossectomy, segmental mandibulectomy, tracheostomy, and bilateral selective neck dissections incorporating nodal levels I through IV. Mandibular reconstruction was accomplished with the use of two flaps: a fibula for bone stock and a radial forearm for the provision of soft tissue coverage.

Reconstruction of the maxilla presents a unique situation. Maxillary defects may be reconstructed with vascularized osteomyocutaneous flaps (fibula, iliac crest, and scapula have all been used), which allow for improved orodental rehabilitation and an overall increase in the quality of life. However, surgeon experience and patient comorbidities may interfere with optimal results for this technique. As a result, reconstruction is often accomplished simply with prosthodontia, without significant decrease in patient benefit.

**SALVAGE SURGERY**

There is a dictum in the treatment of cancers of the head and neck: the first intervention is the best
opportunity for cure. That is, recurrent squamous cell cancer is significantly more difficult to treat than a primary tumor, with the rate of success of salvage therapy hovering around one-third, even in patients with low-stage initial tumors.\textsuperscript{78-83} Overall, anywhere from one-quarter to one-half of patients with squamous cell cancer of the oral cavity suffer a recurrence; local recurrences predominate (58%), followed by locoregional (27%), and distant recurrences (16%), with some patients suffering recurrence at more than one site.

Strategies for the treatment of recurrent oral cavity squamous cell cancer vary. All modalities are employed, including salvage surgery, chemotheraphy, radiation therapy (with or without brachytherapy), and combinations of the above. Often, treatment is dictated by the size and site of the recurrence as well as the type of therapy previously employed.

The success of salvage therapy depends on a number of tumor, patient, and treatment factors. Patients with more advanced primary tumors tend to do worse, as do patients recurring fewer than 6 months after their initial definitive treatment. The site of recurrence also appears to affect postresection prognosis, with locoregional recurrence portending the worst prognosis, followed by nodal recurrence, and then by nodal recurrence alone; there is some evidence, however, that recurrence in the neck portends a worse prognosis overall. Younger patients appear to have a better survival.

Finally, the type of salvage therapy under- takes appears to be significant in overall survival, with patients undergoing salvage surgery enjoying significantly longer survival time than those undergoing other treatment modalities. Despite this finding, the overall cure rate with salvage surgery has not been found to be significantly higher than that seen with other treatment modalities. The numbers in most studies are small, care must be taken in interpreting these statistical trends.

Other poor prognostic indicators include the use of a neck dissection and the employment of radiotherapy in the primary treatment, although these variables may only be markers for biologically more aggressive disease, rather than being true, independent variables. Although counterintuitive, overall survival and success of salvage do not depend on the size of the recurrence; stage of recurrence is important only insofar as it renders a patient not a candidate for salvage surgery and not an independent variable.

Unfortunately, only about one-third of patients who recur are candidates for salvage surgery. Surgical salvage should be limited to the resection of visible, gross tumor. Re-resection of the primary site in the absence of evidence of local recurrence leads to an increase in the morbidity of the salvage therapy without an increase in its benefits.

Median survival after recurrence of squamous cell carcinoma of the oral cavity is 9 months, emphasizing the need for disease control with primary therapy.

**CONCLUSIONS**

Carcinomas of the oral cavity are disparate in presentation and in therapy. As with most carcinomas in the head and neck, tobacco and alcohol abuse are significant risk factors contributing to genetic changes in both normal and malignant tissue that are just beginning to be elucidated. These genetic changes provide an overall "cancerization" to the entire mucosa, predisposing patients to second primary neoplasms. Treatment generally involves single-modality therapy (either radiation or surgery) for early-stage carcinomas and combined therapy (generally surgery followed by concomitant chemoradiation therapy) for larger neoplasms. Neck metastases are common but vary with site and stage of the primary tumor; their presence portends a significant decrease in survival. Rehabilitation may be managed with prosthetic devices or reconstruction of surgical defects, pedicled rotation flaps, or free tissue transfer.

Neoplasms of the Oropharynx and Hypopharynx

Amy Anne D. Lassig, MD; Theodoros N. Teknos, MD; Douglas B. Chepeha, MD, MPH

The upper aerodigestive tract is divided into anatomical sites in which the behavior of the types of neoplasms varies. The oropharynx and hypopharynx represent pharyngeal conduits for respiration and alimentation and are important regions for the origin of malignancy in the head and neck. The oropharynx lies just beyond the oral cavity and connects the oral cavity to the nasopharynx, hypopharynx, and larynx. As such, it is somewhat out of immediate view but can be well visualized on physical examination. The hypopharynx is less accessible to easy visual inspection in the office, requiring indirect mirror examination or flexible nasopharyngoscopy for evaluation, and as such is an anatomical region that is not well known by nonotolaryngologists. The hypopharynx connects the oropharynx to the cervical esophagus below but also shares space with the glottic and supraglottic structures. Malignancies of the oropharynx and hypopharynx are uncommon relatively to all of those arising elsewhere in the body; oropharyngeal cancers make up approximately 1% of new cancers diagnosed each year and hypopharyngeal cancers occur even less commonly. Nevertheless, oropharyngeal neoplasms comprise 10 to 20% of all head and neck cancers and approximately 9,000 new cases are reported each year. Hypopharyngeal neoplasms, on the other hand, represent about 5 to 10% of all new head and neck malignancies registered each year.

Although oropharyngeal and hypopharyngeal neoplasms largely comprise squamous cell carcinoma, the causes and behaviors of these lesions vary by site. The treatment paradigms for neoplasms of the oropharynx and hypopharynx have evolved significantly over the past decades, and a multidisciplinary approach is paramount to these therapies. Multiple modalities including surgery, radiation, and chemotherapy are available for treating these lesions with the balance shifting toward organ preservation programs in more recent years. Basic science and clinical research protocols continue to search for the development of treatment plans which provide the greatest survival and lowest morbidity and mortality. Despite the advances in chemoradiation treatments, surgical therapy continues to be a necessary part of the treatment of these malignancies, and the ability to perform radical resection in these sites is essential to the practice of head and neck surgery. Likewise, the necessity of performing complex reconstructions of the oropharynx and hypopharynx has not diminished. In the end, clinicians in many disciplines must work well together to recognize and treat malignancies of the oropharynx and hypopharynx optimally and to provide these patients with the best achievable quantity and quality of life.

OROPHARYNX
Anatomy and Physiology
The oropharynx lies at the junction of the oral cavity with the remainder of the upper aerodigestive tract, including the nasopharynx, hypopharynx, and supraglottis. Form and function in this region are highly intertwined, resulting in important challenges for the physician treating patients with neoplasms in this area. The oropharynx is made up of several anatomic subsites including the tonsillar complexes, the soft palate, the base of tongue and the pharyngeal wall. These structures lie within fascial and muscular compartments that are important to the understanding of patterns of spread of the neoplasms (Figure 1).
The anterior border of the oropharynx is marked by the edge of the soft palate superiorly and the superior aspect of the hyoid bone inferiorly. The circumvallate papillae define the anterior edge of the base of tongue, and the anterior insertions of the anterior pillars mark the anterior aspect of the tonsillar complex. The posterior border of the oropharynx is delimited by the posterior pharyngeal wall, and likewise the lateral border is bounded by the lateral pharyngeal walls and tonsillar complexes. The soft palate indicates the level of the superior limit of the oropharynx, and the inferior extent is marked by the pharyngoesophageal folds and valleculae, both considered part of the oropharynx.

The tonsillar complexes are a set of bilateral structures abutting the posterior aspect of the oral cavity. They are comprised of an anterior tonsillar pillar and posterior tonsillar pillar with intervening capsule-encased tonsillar lymphoid tissue. The palatoglossus muscle underlies the anterior pillar and the palatopharyngeous underlies the posterior pillar to create a muscular sling for the palate tonsils. These structures are contiguous with the soft palate. The palatine tonsils represent lymphoid tissue of the Waldeyer ring and are a common site of origin for both lymphoid and epithelial malignancy. The vascular supply to the region includes the tonsillar branch of the facial artery, the tonsillar branch of the lingual artery, the ascending pharyngeal artery, and branches of the greater and lesser palatine arteries. Lymphatic drainage from the tonsillar fossae primarily includes retropharyngeal lymph nodes as well as levels II, III, and IV lymph nodes. Contralateral drainage can also occur with malignant neoplasms.

The base of tongue represents the posterior third of the tongue and is demarcated anteriorly by the circumvallate papillae and sulcus terminalis. The base of the tongue is comprised of intrinsic tongue musculature covered by squamous cell mucosa and submucosa. The lingual tonsils, another lymphoid tissue component of the Waldeyer ring, are located within the base of the tongue. Bilateral lingual arteries serve as the vascular supply to the base of the tongue. The cranial nerve (CN) XII, hypoglossal nerve, allows for motor innervation. CN IX, the glossopharyngeal nerve, allows for sensory innervation. Lymphatic vessels from the base of tongue drain primarily to lymph nodes in levels II, III, and IV. Lymphatic structures often cross the midline to result in bilateral lymphatic drainage.

The soft palate extends posteriorly from the hard palate and is comprised of the palatine aponeurosis, an extension of hard palate periosteum, with attached muscles. The tensor veil palatini, innervated by the third division of CN V (trigeminal nerve), forms a sling around the pterygoid hamulus and inserts onto the palatine aponeurosis. The levator veli palatini, innervated by CN X, the vagus nerve, inserts in a vertical fashion into the palatine aponeurosis and elevates the palate. The uvula hangs inferiorly at the posterior aspect of the soft palate and is comprised of uvular muscle covered by mucosa and submucosa. Minor salivary glands are also present within the soft palate mucosa and submucosa and can give rise to benign and malignant neoplasms. The sensory innervation of the soft palate is provided by the glossopharyngeal nerve and the second division of CN V. The vascular supply is primarily from branches of the internal maxillary artery via the descending palatine artery. Lymphatic drainage from the soft palate primarily involves the level II and retropharyngeal lymph nodes, and drainage can be bilateral.

The posterior pharyngeal wall is comprised of mucosa overlying submucosa, musculature, and fascial layers. Immediately deep to the mucosa and submucosa lies the superior and, more inferiorly, the middle constrictor muscles. Deep to these muscles is the buccopharyngeal fascia followed by the arid and then the prevertebral fascia. The prevertebral musculature overlies the vertebral column. Potential spaces lie between these structures. The retropharyngeal space lies between the buccopharyngeal fascia and the alar fascia, and the danger space lies between the alar and prevertebral fascias. These fascial layers are important barriers to spread of malignant processes originating within the oropharynx. Once these barriers have been violated and the prevertebral musculature is involved with tumor, the lesion is no longer considered resectable. Lymphatic drainage of the posterior pharyngeal wall is to retropharyngeal lymph nodes as well as lymph nodes at levels II, III, and IV.

Just as the posterior pharyngeal wall is surrounded by muscular layers, fascial barriers, and potential spaces, the remainder of the oropharyngeal subsites are as well. Deep to mucosa and submucosa, the superior and middle pharyngeal constrictors form a muscular tube surrounding the structures of the oropharynx. Laterally, the parapharyngeal space abuts the oropharynx, a complex region that can be invaded by oropharyngeal malignancies. The parapharyngeal space is an inverted pyramid extending from the skull base superiorly to the greater cornu of the hyoid bone inferiorly. The lateral boundary of the space includes the deep lobe of the parotid gland, a portion of the mandible, and the medial pterygoid muscle. The pterygomandibular raphe marks the anterior aspect of the space and the prevertebral fascia posteriorly. Important structures including the great vessels, CNs IX to XII, the sympathetic chain, and lymphatics are contained within the parapharyngeal space and can be compromised by tumor in the region.

The oropharynx plays many critical physiologic roles. At the most basic level, it serves as a respiratory and alimentary conduit. Also importantly, the structures of the oropharynx play complex roles in speech and swallowing. The basic mechanism of swallow is divided into four phases. The first two, the oral preparatory and oral phases, are under voluntary control, and the last two, the pharyngeal and esophageal phases, are involuntary. The oral preparatory phase makes the food ready for swallowing. The oral phase moves the food from the oral cavity to the oropharynx. During the pharyngeal phase, the food bolus is rapidly propelled through the pharynx to the esophagus. This pharyngeal phase involves glottic protection, velopharyngeal closure, tongue base retraction, constrictor contraction, and cricopharyngeal muscle relaxation. The final phase of swallowing is the esophageal, during which foodstuff travels from the cervical esophagus into the stomach.

The oropharyngeal structures are critical to this process. During the preparatory and oral phases of swallowing, the soft palate is raised and slightly anterior to allow food to remain within the oral cavity and to keep the nasal airway open. The soft palate is also essential to the propagation of the swallowing mechanism during the oral phase, as the tongue elevates to abut the palate and push food particles posteriorly. The soft palate also serves as the anatomic separator of the oral cavity and oropharynx from the nasal cavity and nasopharynx. This separation is essential to the mechanism of swallowing, during which elevation of the palate allows for velopharyngeal competence, preventing the reflux of foodstuff into the nasopharynx. The base of tongue is also essential to swallow: it serves to initiate the pharyngeal phase of swallow by thrusting posteriorly to abut the posterior pharyngeal wall which then contracts to propel the bolus as the process continues.

In addition to swallowing, the oropharyngeal structures are also essential to speech. The oropharyngeal structures create a compliant conduit for airflow and are also important to modifying resonance of phonation. Most important in this role, the soft palate allows air passage in the nasal and oral cavities to be separate and creates a controlled volume of airflow, thus preventing hypernasal speech. This is important as all phonemes in the English language, except for m, n, and ng, are produced via airflow through the oral cavity, requiring concurrent velopharyngeal closure. In addition, the oropharyngeal structures assist in the articulation portion of speech production. The soft palate plays an important role in this function. By contracting to abut the posterior pharyngeal wall during speech, explosive consonants, such as p, b, g, d, and t, can be created, Other structures within the oropharynx contribute to the spincteric velopharyngeal competency and include the palatoglossus and palatopharyngeus as well as the superior constrictor.

**Histopathology**

The oropharyngeal portion of the upper aerodigestive tract is lined primarily by stratified squamous cell epithelium. This is most commonly nonkeratinized but can become keratinized in response to irritation. The region where the soft palate contacts the posterior pharyngeal wall marks the superior limit of the oropharynx and is called the Savant ridge. This is the location of the transition from pseudostratified ciliated columnar or respiratory epithelium of the nasal tissues to stratified squamous cell epithelium. Lymphoepithelial...
The most common malignancy of the oropharyngeal structures is squamous cell carcinoma, comprising greater than 90% of neoplasms. These lesions are more commonly keratinizing, but nonkeratinizing ones are also quite common. Multiple other carcinomas also occur, however, and include adenousquamous, basaloid, and spindle cell squamous cell carcinoma as well as verrucous carcinoma. Adenosquamous and basaloid variants are rare but more aggressive variants of squamous cell carcinoma. Spindle cell variant of squamous cell carcinoma contains spindle cells coexisting with squamous cells within the neoplasm, and is also termed sarcomatoid carcinoma. This lesion generally behaves more aggressively with a higher propensity for local recurrence and distant spread. Verrucous carcinoma is marked by papillomatous fronds of well-differentiated squamous cells. These tumors advance locally but generally do not metastasize. They are not radio-sensitive, and the treatment is wide excision. In addition to variants of squamous cell carcinoma, precursor lesions to squamous cell carcinoma also occur within the oropharynx. Leukoplakia and erythroplakia are less common in the oropharynx than in the oral cavity. These lesions can undergo malignant transformation to become a squamous cell carcinoma, with this occurring more commonly in an erythroplakic lesion. Finally, the concept of field cancerization must be mentioned with regard to squamous cell carcinoma of the upper aerodigestive tract. This idea, put forth by Slaughter in 1953, suggests that for a number of patients, multifocal areas of precancerous change surround diagnosed cancers. Such “field cancerization” significantly affects diagnosis and treatment planning in the region. Recent work by Brahklaus and colleagues suggests that field cancerization and second primary neoplasms occur along a continuum of disease. The mechanism of this process continues to be clarified through the ongoing study of molecular carcinogenesis.

Other types of neoplasms also occur within the oropharynx, originating from the various histological cells and structures that comprise the tissues. Benign processes such as papilloma, pyogenic granuloma, and pseudoeplheliomatous hyperplasia occur in the oropharynx and can imitate malignant neoplasms. Papilloma, of course, can undergo malignant transformation to squamous cell carcinoma, but this occurs in less than 5% of lesions. Minor salivary glands give rise to benign and malignant neoplasms, with the balance tipped toward malignant lesions such as adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and acinic cell carcinoma. The most common minor salivary gland malignancy is adenoid cystic carcinoma. This neoplasm occurs as tubular, cribriform, and solid growth patterns and is characterized by frequent perineural and hematogenous spread. Treatment is wide excision with postoperative radiation. Mucoepidermoid carcinoma is the second most common minor salivary gland malignancy and is histologically graded as low, intermediate, and high. Treatment is wide excision, frequently with added neck dissection for larger lesions with suspicious or positive cervical metastases, followed by postoperative radiation for aggressive features. Lymphoma commonly occurs in the Waldeyer ring structures, and the palatine tonsils are the most frequent site of extra-nodal non-Hodgkin lymphoma within the head and neck. Treatment is with chemotherapy and radiation, and the role of the surgeon is only in tissue diagnosis. Lymphoepithelial carcinoma is a malignant neoplasm of the oropharynx which has both lymphoid and epithelial characteristics. This is a poorly differentiated, nonkeratinized neoplasm histologically identical to World Health Organization (WHO) Type III nasopharyngeal carcinoma. This tumor frequency presents in patients younger than typical patients with squamous cell carcinoma and is known to be quite radiosensitive. True sarcomas can occur within the oropharynx but are quite uncommon.

Etiology and Epidemiology
Squamous cell carcinoma of the oropharynx like other malignancies is thought to result from multiple genetic alterations which result in unregulated cell proliferation and an unchecked cell cycle. These genetic changes can result from multiple environmental exposures as well as inherited defects. Once altered, these cancer cells proliferate and evade the natural process of apoptosis. The result is a tumor which may locally, regionally, or distantly metastasize. The immune system is a critical player in this process and at present great interest lies in understanding this interaction. It is known that patients with immune system deficiencies resulting from inherited defects, medications (transplant or other immunosuppression), or illness (such as HIV) are at a significant disadvantage in the battle against these neoplasms.

As with most subtypes of the upper aerodigestive tract, squamous cell carcinoma of the oropharynx most frequently occurs in relation to tobacco and alcohol exposure. These substances act as carcinogens individually in a dose-dependent manner. When considered separately, tobacco smoke is a greater risk factor. When used together, however, alcohol and tobacco have a synergistic cancer-causing effect and are thought to be causative in 80 to 90% of oropharyngeal cancers. Use of other substances can also be causative or contributory in squamous cell carcinoma of the oropharynx. A combination of betel leaves and the areca nut commonly consumed in India and Southeast Asia, betel quid is a risk factor for oropharynx and upper aerodigestive tract squamous cell carcinoma. In addition, mate products largely consumed in South America have been found to increase independently the risk of squamous cell carcinoma of the oral cavity and oropharynx.

Viral infection has also been shown to be associated with squamous cell carcinoma of the upper aerodigestive tract. Human papilloma virus (HPV), initially implicated in cervical cancer, has been more recently thought to also induce a viral carcinogenesis within the upper aerodigestive tract, most often in the oropharynx at the palatine and lingual tonsillar subsites. At these locations HPV is responsible for a sizeable proportion of cancers. HPV DNA has been found in 45 to 100% of all tonsillar neoplasms and is thought to be causative in greater than 50%. HPV 16 is by far the most common HPV type in oropharyngeal cancer, inducing carcinogenesis via oncogenes E6 and E7. A recent case-control study found that oropharyngeal squamous cell carcinoma is strongly associated with oral HPV infection and HPV seropositivity, completely independent of alcohol and tobacco use. This study concluded that the mechanism of carcinogenesis is likely entirely different than alcohol or tobacco induced tumors, and that HPV tumors are likely sexually acquired. HPV-positive squamous cell carcinoma is more likely to occur in younger patients. These cancers portend an improved prognosis, particularly in patients with high viral load, and single institution work from the University of Michigan indicates that these tumors are more likely to respond to organ preservation therapy. In the future, HPV vaccines may play an important role in the prevention and treatment of oropharyngeal squamous cell carcinoma.

The epidemiology of squamous cell carcinoma of the oropharynx has identified the greatest risk factors, tobacco and alcohol use. There are approximately 5,000 new cases of oropharyngeal neoplasms diagnosed each year in the United States. The incidence of squamous cell carcinoma of the oropharynx is 2 per 100,000 persons in the United States. The United States National Cancer Institute Surveillance Epidemiology and End Results (SEER) database reports an incidence of 10.5 per 100,000 for oral cavity and pharynx neoplasms combined. It continues to be more common in men than in women, and the incidence is higher in African-American men than in Caucasian. The overall incidence of squamous cell carcinoma and the mortality from it have decreased minimally over the last 30 years. Most squamous cell carcinomas of the oropharynx are diagnosed in persons older than 45 and are most common between the ages of 60 and 80. The most common site of malignancy in the oropharynx is the tonsil.

Clinical Manifestations and Mechanisms of Spread
Squamous cell carcinoma of the oropharynx presents with a variety of symptoms depending on the subsite of the primary neoplasm. These neoplasms are often asymptomatic initially and frequently evade examination by the untrained eye. Thus, these neoplasms may be locally advanced at the time of diagnosis. Additionally, 15 to 75% may have evidence of cervical lymph nodal metastases at the time of presentation, and the
presence of such adenopathy decreases survival by approximately 50%. Such regional metastases are typically predictable in nature, occurring in the primary echelon lymph nodes for the oropharynx in levels II and III and the retropharynx. Approximately 5 to 10% have distant metastases on initial evaluation.

Symptoms of oropharyngeal malignancy include sore throat, otalgia, odynophagia, and globus sensation. As the neoplasm progresses and adjacent structures become involved, symptoms such as dysphagia, dysarthria, and trismus may develop. Difficulty in swallowing often leads to weight loss, malnutrition, and weakness. Once symptoms are present, the neoplasms are often at a quite advanced stage.

The tonsillar fossae and tonsils are the most common locations for squamous cell carcinoma in the oropharynx, comprising approximately 75% of oropharyngeal neoplasms. Small, early neoplasms are often asymptomatic and can present with a neck mass in approximately 25% of neoplasms. With growth of the neoplasm, frequently dysphagia and odynophagia as well as otalgia and hemoptysis occur. These neoplasms are often exophytic, originating in the tonsil itself and extending onto the anterior tonsillar pillar. Tonsillar squamous cell carcinomas often extend onto other subsites of the oropharynx, frequently onto the base of tongue and less often the posterior pharyngeal wall. These neoplasms also often advance anteriorly into the oral cavity especially to the retromolar trigone and buccal mucosa. As these tumors continue to enlarge, they can invade deeply to involve the mandible as well as nervous structures such as the CN IX, the lingual nerve, and the inferior alveolar nerve. This invasion can result in jaw pain, loose teeth, dysphagia, and dysesthesias. Further growth of the neoplasm can result in pterygoid muscle invasion, typically medial then lateral. This results in trismus and discomfort. Locoregional cervical metastases also occur as the neoplasm progresses and greater than 65% of patients with tonsillar squamous cell carcinoma present with adenopathy at diagnosis.

Base of tongue neoplasms, like tonsillar cancers, often present at an advanced stage. Early symptoms for these lesions include throat discomfort, however, lesions are often difficult to visualize, especially by the nonotolaryngologist. Base of tongue neoplasms are often submucosal and thus only deep oropharyngeal palpation reveals their location. These lesions tend to be aggressive and are more likely to be less differentiated. These lesions spread to involve the glossotonsillar sulcus, tonsillar fossa and pillars, soft palate, and retromolar trigone. Deeper invasion can occur along the intrinsic muscles of the tongue and advanced neoplasms can involve the mandible and pterygoid muscles or the supraglottic larynx. Cervical metastases can occur early, even in small neoplasms, and more than 60% of patients diagnosed with a base of tongue neoplasm have evidence of adenopathy at presentation. In addition, approximately 20% of patients with base of tongue neoplasms have evidence of bilateral lymphatic spread. The aggressive behavior of base of tongue neoplasms is quite distinct from the behavior of oral tongue lesions, and the resulting poorer outcomes reflect this. Increased difficulty achieving local control in these lesions results in a higher rate of distant metastases.

Squamous cell carcinoma of the lateral and posterior pharyngeal walls is much less common than primary lesions of the tonsils or base of tongue. Like these neoplasms, however, this location can be quite difficult to visualize. As a result, lesions in this area can be quite advanced at diagnosis, and cervical adenopathy is the presenting sign in 20% of patients. Patients also often present with sore throat as well as dysphagia and odynophagia. As these neoplasms enlarge, weight loss, dysphonia, and otalgia are common complaints. These neoplasms often spread to oropharyngeal structures but can extend superiorly into the nasopharynx and inferiorly into the hypopharynx. Once these neoplasms traverse the barriers of muscle and fascia surrounding the pharynx, particularly posteriorly, or have significant superior extension, their resectability comes into question.

Squamous cell carcinoma of the soft palate comprises approximately 15% of oropharyngeal neoplasms. Contrary to other subsites, these lesions are more easily visualized on physical examination and often present with symptoms earlier in their course. Pain and odynophagia are frequent presenting symptoms. As these lesions progress, they can extend along the soft palate to the tonsillar structures and retromolar trigone or anteriorly along the hard palate. These lesions become more worrisome with superior extension into the nasopharynx. Rates of cervical metastases are less common than in other subsites of the oropharynx, but lymphatic drainage can be bilateral and retropharyngeal lymph nodes are included.

Diagnosis and Work-Up

The diagnosis and work-up of oropharyngeal malignancies should be completed in an expeditious manner as with any other malignancy. The first step is to perform a complete history including previous evaluation and treatment of the neoplasm as well as comorbidities which affect suitability for treatment. A thorough physical examination follows the history. A full head and neck evaluation is performed with attention particularly to the oropharynx and adjacent anatomic sites. Direct illuminated inspection should be performed in these areas followed by palpation. The neck should be evaluated for evidence of regional metastases. A tention should also be given to examination findings consistent with advanced disease such as trismus, bony invasion, cutaneous involvement, CN deficits, or signs of unresectable disease. Flexible fiberoptic nasopharyngoscopy should be performed to complete the evaluation of the primary neoplasm as well as to evaluate the remainder of the upper aerodigestive tract.

Radiologic evaluation should next be completed. Computed tomography (CT) scanning of the neck with contrast is extremely helpful in delineating the extent of the primary neoplasm, the presence of regional metastases, and the status of surrounding structures. Magnetic resonance imaging (MRI) scanning is helpful in patients in whom further soft tissue delineation is needed. Findings such as CN or dural enhancement in advanced disease are reliably revealed by MRI, and thus this study can be helpful when resectability is in question. Positron emission tomography (PET) studies have more recently become much more widely used in the evaluation of head and neck malignancy. This is not routinely used in the work-up of a new known primary oropharyngeal malignancy but can be helpful in delineating questionable sites of distant or regional metastases. PET is much more useful in posttreatment surveillance and treatment decisions, and the role of this scan is still being delineated. Panorex can be useful at times for mandibular and dental evaluation, but this is often not necessary as CT scans give adequate bony information.

Evaluation for pulmonary metastases or synchronous primaries must be performed prior to initiation of treatment. Our center routinely orders a chest CT, as multiple studies to date show this to be highly sensitive for this work-up. A chest radiograph, however, is generally acceptable as well, although patients with high-risk disease features should be screened with CT. Although useful, a chest CT is not a perfect screening tool for distant metastases; thus, several centers have evaluated the use of PET as a screening tool for distant metastases, and some suggest its combination with chest CT will likely give the most accurate assessment.

Laboratory and medical work-up should be completed to evaluate the patient’s general health as well as fitness for surgery, anesthesia, or other treatments (chemotherapy and radiation). Routine laboratory tests, such as a basic metabolic panel and complete blood count, should be obtained. Some recommend a screening liver function panel as an indicator of metastatic disease and to indicate hepatic health in a population with frequent alcohol abusers. An EKG should be included in the work-up. Other outstanding medical problems should be evaluated as indicated.

The diagnostic work-up proceeds with staging endoscopy under general anesthesia. Direct laryngoscopy and esophagoscopy are performed to delineate the primary neoplasm and to evaluate for any synchronous second primary neoplasms. Bronchoscopy is often not performed due to the accuracy of thoracic CT but can be helpful in visualizing small endotracheal lesions. The oral cavity, oropharynx, surrounding structures, and cervical region should be palpated to determine the extent of disease. Tattoo of the neoplasm is then performed with India Ink to mark the area for future surveillance. Biopsies of the neoplasm and any surrounding regions of concern should be completed after the visual inspection is complete. This may include tonsillectomy for presumed tonsillar primary. The primary tumor tissue is necessary for a diagnosis even if a previous fine-needle aspiration (FNA) of a cervical lymph
those who have local or regional recurrences. In lymphadenopathy, have high histologic grade and disease, have low neck or multiple levels of neck nodal disease will cause patients to be staged. In general, any evidence of nodal disease will cause patients to be considered at least stage III. T4a neoplasms and more bulky lymphadenopathy will fall into Stage IV, with T4b considered unresectable.

Oropharynx are 57% for Stage I disease and 54% for Stage II disease. Patients with higher stages at diagnosis have a worse prognosis, with 5-year survival rates for Stage III disease of 43% and of Stage IV disease of 30%.

Staging and Prognosis

Oropharyngeal squamous cell carcinoma is staged with the American Joint Committee on Cancer (AJCC) system (Table 1). The tumor itself is categorized to give a T value. This categorization is based on size, involvement with adjacent sites, and finally involvement of areas which indicate advanced disease or poorer prognosis. Cervical lymphadenopathy is likewise categorized to give a N value. In general, any evidence of nodal disease will cause patients to be considered at least stage III. T4a neoplasms and more bulky lymphadenopathy will fall into Stage IV, with T4b considered unresectable.

Distant metastases are thought to occur in approximately 5 to 10% of patients at presentation and impart a poor prognosis. Lung, liver, and bone are the most common sites of distant metastases. Over the course of the disease, distant metastases will occur in 15 to 20% of patients with oropharyngeal squamous cell carcinomas and are more common in patients who present with advanced disease, have low neck or multiple levels of neck lymphadenopathy, have high histologic grade and those who have local or regional recurrences. In general for the oropharynx, approximately 20 to 30% of patients with neoplasms larger than T1 and who are clinically N0 will have evidence of occult regional metastatic disease. The presence of such cervical metastases is thought to decrease survival by approximately 50%. Five-year survival rates for patients with squamous cell carcinoma of the oropharynx are 57% for Stage I disease and 54% for Stage II disease. Patients with higher stages at diagnosis have a worse prognosis, with 5-year survival rates for Stage III disease of 43% and of Stage IV disease of 30%.

Treatment

General Approach. The treatment for squamous cell carcinoma of the oropharynx has evolved significantly over the last quarter century. The concept of organ preservation has changed the treatment paradigm such that surgical therapy is often no longer the first-line treatment. Radiation and chemotherapy have taken the forefront in many centers with surgery left for salvage of treatment failures. The end result is that the technical challenges of surgery in this region are all the greater. With these changes, a multidisciplinary approach to treating head and neck cancer has become paramount. Otolaryngologists, medical oncologists, radiation oncologists, dentists, nurses, speech pathologists, and others must work in concert as a team to care for these patients with complicated problems.

Organ Preservation. The idea of preserving native structures within the upper aerodigestive tract while treating malignancy in the area has been an attractive goal in the recent history of head and neck cancer. This is particularly important in the oropharynx as the defects in speech and swallowing resulting from surgical resection can be significant. Over the last century, radiation has been used in many forms in the treatment of malignancy of the head and neck. During the 1980s, radiation was combined with chemotherapy, and the era of organ preservation began. Prior to this chemotherapy had been an adjunct for palliation; but, with the use and development of platinum-based agents, treatment results changed. The combination of cisplatin with 5-fluorouracil allowed chemoradiotherapy to be used for curative intent. Early studies of such protocols focused on laryngeal cancer, including the landmark US Veterans Administration Laryngeal Cancer Clinical Trial published in 1991 which showed no significant survival difference between patients undergoing induction chemoradiotherapy [5-fluorouracil (5-FU) and cisplatin] and radiation versus surgical resection and radiotherapy. Since that time, multiple studies have emerged evaluating and endorsing organ preservation treatments in the head and neck and in the oropharynx specifically. This treatment continues to evolve and advance. Chemotherapy regimens and agents continue to be developed and studied in the treatment of squamous cell carcinoma of the head and neck. Likewise, radiation therapy protocols continue to be studied and modified for optimum results. Intensity modulated radiation therapy has been recently developed to aid in dosing radiation therapy. This method aims to give maximum dose to neoplasm but a lesser dose to lower risk, functional surrounding structures, such as the parotid glands, and pharyngeal constrictors, to help minimize complications and side effects. Fractionation schemes of radiation therapy including accelerated fractionization and hyperfractionization continue to be studied to determine the most effective regimen with the least morbidity. As the understanding of the molecular mechanisms of carcinogenesis and response to treatment continue to unfold, organ preservation therapy will continue to evolve and improve. For example, recent single institution work from the University of Michigan indicates that good response to organ preservation therapy and improved prognosis are indicated by low EGFR and p16 expression in oropharyngeal tumors. Ongoing scientific study at the basic science and translational levels are essential to forward progress in organ preservation and treatment success, and over time these discoveries make their way from bench top to bedside.
Treatment Plan. Oropharyngeal malignancies can be treated by radiation, chemotherapy, and surgical resection. Treatment decisions must be based on neoplasm site and stage as well as patient desires and comorbidities. In the majority of cases, our group prefers to avoid surgical resection as the primary means of treating oropharyngeal malignancies. Surgical treatment of the primary neoplasm at this site can result in significant morbidity. In addition, as cervical metastases tend to occur early in oropharyngeal squamous cell carcinomas, the neck must be addressed and treated even at an early stage. Treatment of the neck often must include the retropharyngeal nodal basin which is not well addressed with standard neck dissection. Despite these factors, surgical resection can be an appropriate method of treating oropharyngeal neoplasms, particularly when a tumor is unresponsive to induction chemotherapy or after failure of primary chemotherapy and radiation protocols.

Early-stage oropharyngeal neoplasms which are T1 or T2 primaries with little or no nodal disease (N0 or N1) can be treated by definitive radiation therapy. With evidence of nodal disease however, consideration is given to adding chemotherapy to the regimen, although this is not absolutely necessary with only N1 disease. With such organ preservation treatment, residual or recurrent disease is treated by surgical resection. Early-stage neoplasms of the oropharynx can also be treated with wide excision of the primary neoplasm with treatment of the neck including unilateral or bilateral neck dissection. Evidence of nodal disease in the neck dissection specimen requires treatment with postoperative radiation. High-risk features from the surgical resection include extracapsular extension of the nodal disease as well as close or positive margins on the primary resection. These patients should be treated with chemotherapy and radiation therapy postoperatively. Other risk indicators such as perineural or vascular invasion and multiple positive nodes also argue for postoperative treatment with both chemotherapy and radiation therapy, however, the benefit of adding chemotherapy is still being determined. Recently Pradier and colleagues presented the use of CO2 laser in Stage III and IV squamous cell carcinoma of the head and neck with adjuvant radiotherapy. With this treatment, they had equivalent success to surgery followed by radiotherapy with respect to survival and locoregional control, and they reported diminished operative morbidity. Such results will continue to be investigated over time, and the role of laser treatment will continue to be developed. In addition, fiberoptic capabilities for this laser are being developed at present which will continue to increase its ease in use.

Open approaches to the oropharynx are more frequently used for lesions that are moderate to large in size. These approaches are combined with surgical treatment for the neck and require cervical incisions. Typically, neck dissection is performed prior to resection of the primary neoplasm. Operative and incision planning is important for appropriate access, optimum cosmesis, and well-vascularized skin flaps. This is particularly important in the posttreatment neck where vascularity is already compromised, and in such cases it is particularly important to ensure that important structures such as the common carotid artery are not left at risk under repairs with vertical limbs or trifurcations. Frequently a lip split incision is necessary to achieve sufficient access to oropharyngeal structures. This incision is best designed as a midline extension of a unilateral apron incision used for unilateral neck dissection. The midline limb of the incision should contain several Z angulations to break up the incision visually and ensure accurate reapproximation of skin flaps at the completion of the operation. This should continue up to the vermilion border, and this border should be appropriately marked preoperatively. Methylene blue is also used to mark the midline at the superior and inferior extent of the exposed surgical field and used to mark planned incisions. If bilateral neck dissections are planned, the apron incision can also be extended up the midline to perform a lip split. Alternatively, a visor flap can be raised and folded over the mandible for access. The lateral pharyngotomy approach is a means of resecting neoplasms of the inferolateral oropharynx. An incision in the pharynx is planned which spans from the hypoglossal nerve superiority to the superior laryngeal nerve inferiorly. A vertical pharyngotomy is made, and the thyroid cartilage ala is retracted. This allows visualization and resection of neoplasms at the postero-lateral base of tongue as well as the lateral pharyngeal wall. A Connett-type mucosal inverting stitch is used for closure of the pharyngotomy site.

A second open approach to neoplasms of the oropharynx is a pharyngotomy via the transhyoid route (Figure 2). This allows exposure and resection of midline base of tongue, posterior pharyngeal wall, and some neoplasms of the inferior aspect of the lateral pharyngeal wall. Planning for this approach, with immediately preeresection direct laryngoscopy, is especially important as the site of the pharyngotomy should be carefully chosen to avoid violating the neoplasm.
The primary neoplasm is resected once neck dissection is completed. Suprathyroid musculature is divided from the hyoid as in a laryngectomy. The vallecula is entered at an oncologically sound site away from the neoplasm. The pharyngotomy is extended to visualize the lesion and bring it into the operative site. Dissection proceeds around the neoplasm. Release of the digastric and stylohyoid muscles allows greater exposure if necessary and rarely this approach is combined with a lateral pharyngotomy for even wider exposure. Care must be taken to preserve the hypoglossal nerve if uninvolved in neoplasm as well as the ipsilateral lingual artery. If the ipsilateral lingual artery must be ligated during the resection, the contralateral lingual artery must be preserved to preserve arterial inflow to the tongue. Generally, the transhyoid pharyngotomy approach can be closed primarily. The advantages of this approach include avoidance of a lip split or mandibulotomy, but disadvantages include difficult exposure of the neoplasm which extends superiorly or anteriorly.

The approach which allows greatest exposure of oropharyngeal malignancies is the mandibulotomy with mandibular swing and lip split. In preparation for mandibulotomy, the midline lip-splitting soft tissue cuts are made. The midline lip-splitting cut is extended through the musculature and mucosa into the oral cavity. The incision then makes a 90° turn to extend horizontally along the mandibular alveolus. Care is taken to preserve an adequate cuff of alveolar mucosa to allow for closure. Once the soft tissue cuts are made, the bony mandibular split is planned in a parasymphaseal location. A reconstruction plate that is 2.0 or larger is bent to the location and tooth roots, bone marrow, or the inferior alveolar canal are not involved, a rim mandibulotomy is used to allow for greatest bony stability. Tooth extraction may be necessary along the site of osteotomy.

Once the mandibulotomy is complete, the mandible is opened and reflected laterally (Figure 3). Soft tissue dissection then proceeds posteriorly to expose the neoplasm. The neoplasm is widely excised. Reconstruction of the area is planned based on the resulting defect. As this approach allows the greatest exposure of the area, the resulting defect can be quite sizeable and generally requires a pedicled or free flap for reconstruction. The mandibular bone is then plated as planned previously.

Because oropharyngeal malignancies can invade bone also, mandibulotomy can be necessary for the resection of the neoplasm. Physical examination findings such as loose teeth, neoplasm fixation to bone, and diminished sensation in the CN V3 distribution can indicate mandibular involvement with the neoplasm. CT scanning, particularly with bony windows, and panorex imaging can confirm this and indicate the need for bony resection. If bony invasion is minimal and tooth roots, bone marrow, or the inferior alveolar canal are not involved, a rim mandibulotomy will be adequate. Otherwise, a segmental mandibulectomy and composite resection will be necessary (Figure 4). Just as in mandibulotomy for neoplasm access, the mandible should be plated with a 2.0 or larger reconstruction plate. Once bony resection is complete, frozen section margins can be sent of the marrow, periosteum, and inferior alveolar nerves. Reconstruction must then be completed as will be described below.

**Reconstruction.** Reconstruction of oropharyngeal defects often is not simple because of the complex integration of form and function in this region. Reconstruction varies by the site of the defect and extent of surrounding tissue involved as well as by the size of the tissue loss. Each defect is considered individually to obtain the best end result. In addition to defect considerations, patient characteristics must be considered when choosing reconstruction. This includes functional needs, available donor sites, comorbidities, and tolerance of anesthetic. As with other reparative tasks, the reconstructive ladder is a useful tool in thinking about methods of repair. The tool allows one to consider the closure and repair of surgical defects from the most simple to the most complex.

The reconstructive ladder begins with a region of open tissue after neoplasm resection, and the most basic means of reconstruction along the ladder are suitable for small, simple defects. The first means of reconstruction begins with healing by granulation or secondary intention, which of course requires no further surgical intervention. This method can be used in the oropharynx for simple tissue defects. Healing by secondary intention allows granulation tissue to fill a small defect with sensate tissue that is generally not tethered. This would be appropriate for a small defect at the soft palate, tongue base, or pharyngeal wall but should not be used in areas in continuity with the neck, adjacent to important structures.

**Figure 2** Transhyoid resection of oropharyngeal tumor. This transhyoid pharyngotomy approach is particularly useful for resection of base of tongue tumors.

**Figure 3** Mandibulotomy for access to oropharyngeal tumor and subsequent resection.

![Magnetic resonance imaging (MRI) showing bone marrow involvement with squamous cell carcinoma necessitating a composite resection. (A) Axial T1-weighted, gadolinium enhanced and with fat saturation image demonstrates an enhancing squamous cell carcinoma involving the left base of tongue with extension across the midline, (B) axial T1-weighted precontrast image shows early bone marrow involvement of the left mandible which will require a composite resection for tumor extirpation.](image-url)
or overlying bone. Healthy tissue is required for adequate granulation and thus, patients with poor vasculature or tissue health will achieve a less optimum result from this method. Similarly, primary closure can be used on small defects within the oropharynx which have sufficient tissue laxity for reapproximation. Benefits of this method also include sensation tissue but tethering of structures can occur which may result in functional defects. Healthy tissue is also a requisite for primary closure.

The next step along the ladder’s progression is the skin graft. For oropharyngeal defects, a split-thickness graft is generally used. A split-thickness skin graft is appropriate for some small- and intermediate-sized defects and is often harvested from the lateral aspect of the thigh using a dermatome. Skin grafts are most useful in regions that are not highly mobile or subject to tensile forces, as the graft must remain adherent for inosculation and graft take. Areas that can be skin grafted include the soft palate and pharyngeal wall. Typically split-thickness skin grafts will not heal well to exposed bony surfaces. The graft is traditionally secured with a bolster, but Dermabond (octyl-2-cyanocrylate) and overlying sutures are also a successful means of immobilization.

The reconstructive ladder proceeds to local flaps for reconstruction of moderate-sized defects. Tissue health including things such as history of past radiation, nutritional status and vascularity are also important for this type of tissue rearrangement. Common types of local flaps used to reconstruct oropharyngeal defects include a posterior tongue flap. This portion of tongue can be divided and pedicled posteriorly and rotated into a tonsillar or palatal defect. The vascularity is dependable; however, the patient may have significant speech and swallowing functional defects resulting from fixation of the tongue. The palatal island flap is useful in the oropharynx. This local flap is based on the greater palatine artery and is a rotation flap comprised of the mucosa, submucosa, and periostium overlying the hard palate. This tissue is rotated into a small- or medium-sized tonsillar pillar or soft palate defect with good results. Another local flap used to reconstruct oropharyngeal defects is the buccal mucosal flap. This flap is an advancement flap of buccal mucosa which can cover small defects of the retromolar trigone, tonsillar pillar, and soft palate.

Regional flaps are the next means of reconstructing oropharyngeal defects. These flaps historically were the workhorse means of reconstructing larger oropharyngeal defects prior to the era of free tissue transfer. Such pedicled regional flaps are still used today for reconstruction of the oropharynx and include the pectoralis major flap, deltopectoral flap, and latissimus dorsi flap. The pectoralis major flap is a myocutaneous pedicled flap based on the pectoral branch of the thoracoacromial artery. The pectoralis major flap can be used to reconstruct the tonsillar region, base of tongue, and soft palate but generally reaches no further superiorly than the top of the oropharynx. These flaps are reliable and allow for a large myocutaneous paddle to be rotated into place in a single stage. The donor-site morbidity is relatively mild from a functional standpoint but can be less than ideal from a cosmetic standpoint, particularly for a woman. These flaps are insensate and can be less than optimum for three-dimensional filling of a large defect due to their tether to the chest. As a result functional outcomes for speech and swallowing can be less than ideal.

The latissimus dorsi pedicled regional flap can be used to reconstruct oropharyngeal defects. This flap is based on the thoracodorsal artery off of the circumflex scapular system. This flap is a reliable, myocutaneous flap that can be used in a single stage. Intraoperative positioning may add operative time to the procedure, but the donor-site morbidity is mild. Difficulties with the flap are due to inadequate reach to oropharyngeal defects and lack of ability to create an optimum three-dimensional reconstruction due to the long rotational pedicle. The latissimus dorsi muscle can also be used as a free tissue transfer as will be later discussed with the subscapular system free tissue transfer.

The deltopectoral flap is another pedicled regional flap used to reconstruct oropharyngeal defects. This flap is based on perforators from the intercostal arteries, particularly the first two, off of the internal mammary artery. This flap was popularized in the 1960s for head and neck reconstruction. It has been used for reconstructing mucosal pharyngeal defects. This flap can be raised in a single stage but delaying it allows for greater pedicle length. The donor-site morbidity is minimal. The reconstructive result from this flap in the oropharynx is marginal and thus this flap is typically not a first choice for such reconstruction.

Free tissue transfer represents the last rung on the reconstructive ladder and for many patients is the gold standard today for reconstruction of moderate and large defects of the oropharynx. As with smaller defects in the oropharynx, the choice of free flap depends on the details of the defect. Defects may require soft tissue only or bony reconstruction. Bulk may be necessary to help restore function. In addition, availability of donor sites must be considered when choosing a means of free tissue transfer reconstruction. Soft tissue flaps of the subscapular system will be discussed during the segment on free tissue bony reconstruction.

For defects that require only soft tissue reconstruction and require little bulk, the radial forearm fasciocutaneous free tissue transfer is an ideal choice. This flap is based on the radial artery, venae comitantes, and cephalic vein and is a reliable method of free tissue reconstruction (Figures 5 and 6). Vascularity of the hand and distal forearm is tested preoperatively with the Allen test to ensure that the ulnar artery will be adequate via the superficial palmar arch. The donor morbidity is typically minor, but a skin graft is typically required for closure. The forearm flap is especially useful in palatal and pharyngeal wall reconstruction due to its pliability and flexibility. It can also be used for smaller defects of the tonsillar fossa and base of tongue that do not require significant bulk.
When more bulk is required, the lateral arm fasciocutaneous flap is a good choice. This flap is based on the posterior radial collateral artery and is a paired venous system. Harvest of the posterior radial collateral artery with this flap can be completed without concern for the residual arterial inflow to the arm. The donor site can frequently be closed with a linear approximation of the wound margins without use of a skin graft. This flap works well for moderate to large defects of the base of tongue and tonsillar region. It can be used for large palatal and pharyngeal defects as well. The flap allows for adequate bulk in regions where the volume of the reconstruction is important to the functional result.

The anterolateral thigh free tissue transfer is another fasciocutaneous flap which allows for bulk in oropharyngeal reconstruction. The anterolateral thigh is based on the descending branch of the lateral femoral circumflex artery which is found surrounded by the vastus lateralis, rectus femoris, and tensor fascia latae. This flap allows for nice bulk of reconstruction in the oropharynx especially for large defects of the base of tongue and tonsil, and the donor-site morbidity is relatively minor. This flap can, however, be technically difficult to harvest, and at times perforators adequate for cutaneous paddle arterial inflow can be difficult to find.

In a situation where significant bulk is necessary for adequate soft tissue reconstruction, the rectus abdominus free flap is a good choice. This muscleocutaneous flap is based on the deep inferior epigastric artery and vein; however the superior epigastric vessels can be used as well. There is no opportunity for sensory nerve transfer. The rectus abdominus is quite reliable, and harvest is not technically demanding. Significant bulk can be provided by this flap which is useful in large defects including those of the tongue. The donor-site morbidity is typically mild but can include an ileus in the immediate postoperative period or a ventral hernia during the recovery. A variant of this flap is the rectus abdominis myocutaneous fl ap, from the angular branch, allowing the skin paddle of this flap which is best centered at the mid- to lower-third of the fibula. Although this flap is typically used to reconstruct the mandible with the bony portion of the flap. This bony reconstruction is reliable and can allow the placement of osseointegrated implants to the bone at a later date. Donor-site morbidity can include weakness of dorsiflexion of the great toe and edema. Ambulation is possible within the first postoperative week.

The iliac crest free tissue transfer represents another alternative for bony reconstruction of the mandible in oropharyngeal defects. This flap is based on the deep circumflex artery and its venae comitantes and can reconstruct composite defects resulting from oropharyngeal malignancies. Up to 16 cm of bone can be harvested from the crest, which can be both osteocutaneous and osteomuscutaneous if the internal oblique is included. This flap can nicely reconstruct a mandibular segment and works well for later dental implants. It is technically easier to maneuver if the internal oblique is included. Donor-site morbidity can include ventral hernias which can be prevented by careful postharvest closure as well as postoperative ileus.

A third option for vascularized bone in reconstruction of the oropharynx is the iliac crest free flap. This versatile flap is based on the subscapular system which can supply multiple variations of free tissue reconstruction. The resulting free tissue transfer can be fasciocutaneous, osteocutaneous, and muscleocutaneous as well as combinations of these to result in the scapular, para- scapular, latissimus, and serratus free flaps. The subscapular system begins with the subscapular artery, a branch of the axillary artery. This divides into the circumflex scapular artery and the thoracodorsal artery. The circumflex scapular artery supplies the periosteum of the lateral border of the scapula as well as the scapular and parascapular soft tissue. The thoracodorsal artery sends branches to the latissimus dorsi, serratus anterior, and scapular tip in the form of the angular artery, as well as supplying the surrounding soft tissue.

A further option for vascularized bone in reconstruction of the oropharynx is the iliac crest free flap. This versatile flap is based on the subscapular system which can supply multiple variations of free tissue reconstruction. The resulting free tissue transfer can be fasciocutaneous, osteocutaneous, and muscleocutaneous as well as combinations of these to result in the scapular, para- scapular, latissimus, and serratus free flaps. The subscapular system begins with the subscapular artery, a branch of the axillary artery. This divides into the circumflex scapular artery and the thoracodorsal artery. The circumflex scapular artery supplies the periosteum of the lateral border of the scapula as well as the scapular and parascapular soft tissue. The thoracodorsal artery sends branches to the latissimus dorsi, serratus anterior, and scapular tip in the form of the angular artery, as well as supplying the surrounding soft tissue.

A variety of devastating defects can be reconstructed with a scapular osteocutaneous flap or with a scapular tip osteocutaneous flap, from the angular branch, allowing for longer pedicle length. These flaps supply both good quality bone for the mandible and bulky soft tissue for large tissue deficits. Finally, complex composite defects of intraoral and oropharyngeal soft tissue, bone, and cutaneous soft tissue can be reconstructed by utilizing the entire subscapular system by using a bony scapular segment with two soft tissue paddles or one large folded paddle. The benefits of the scapular region free tissue transfers are versatility and ability to reconstruct a large complex defect with one pedicle. The downside includes a lateral decubitus or semidecubitus position for harvest which prevents two-team surgery. Patient morbidity can include shoulder pain and mild dysfunction.

Rehabilitation

The treatment for oropharyngeal squamous cell carcinoma is not an innocuous or easy endeavor. After chemotherapy and radiation therapy treatment, dysphagia and xerostomia are the most frequent complaints. This can result in gastric tube dependence, reliance on a soft or liquid diet, and aspiration. Patients also complain of sore throat and dysgeusia. These symptoms typically evolve and improve over the first year posttreatment, but attention must be given to rehabilitation, especially through work with a speech pathologist. Likewise, surgical treatment in the area frequently results in dysphagia and dysarthria, depending on the location and size of the primary neoplasm, resection, and type of reconstruction. A patient is essentially assistant to assisting the patient and training the patient to use functional methods to cope with these difficulties. Behavior modification is also important to treatment response and recovery. Because tobacco use has been shown to diminish the effectiveness of treatment, patients must be strongly instructed and assisted in smoking cessation.20 Nutritional status is similarly important in tolerating treatment and recovery, and support in this regard is also essential.21 Finally, patients with oropharyngeal malignancies must be followed closely for recurrence and metastases once treatment is complete. Physical examination, although often difficult due to edema and posttreatment change, is the primary means to do this and should address the primary site as well as the neck. Typically a schedule of return visits of every 6 to 8 weeks year one, every 2 to 3 months year two, every 3 to 4 months year three, every 4 to 6 months year four, and yearly starting in year five. Once patients have reached the 2-year mark posttreatment, the likelihood.
HYPOPHARYNX

Anatomy and Physiology

The hypopharynx is a continuation of the upper aerodigestive tract from the oropharynx. It is comprised of three subsites which are the lateral and posterior pharyngeal wall, postcricoid region, and paired pyriform sinuses (Figure 7). The hypopharynx begins superiorly with the posterior pharyngeal wall at the level of the hyoid bone. Here it abuts the inferior-most point of the oropharynx. The posterior pharyngeal wall continues inferiorly to the level of the lowest point of the postcricoid region. This is marked by the inferior-most aspect of the cricoid cartilage, and it is here that the pharynx becomes the cervical esophagus. The lateral border of the hypopharynx is the mucosa covering the thyroid cartilage. The anterior border of the hypopharynx comprises several structures which are not themselves part of the hypopharynx: the epiglottis, the laryngeal aditus, the aryepiglottic folds, the arytenoids, and cricoarytenoid joints. Sitting just posterior to the cricoarytenoid joints and cricoid cartilage with their attached muscles, is the postcricoid region. This comprises mucosa and submucosa overlying the cartilaginous ring of the cricoid and the posterior muscles of the larynx. At the inferior-most point of the postcricoid region and inferior pharyngeal constrictor, lays the cricopharyngeus muscle or upper esophageal sphincter. This lies just deep to the submucosa at the lowest point of the hypopharynx, inserting onto the cricoid cartilage. The pyriform sinuses are outpouchings of mucosa just lateral to the glottis proper, and they open posteriorly into the pharynx. They are funnel-shaped with the inferiorly oriented apex lying approximately at the level of the base of the cricoarytenoid joint. The superior border is marked by the pharyngoepiglottic fold. The medial wall of the pyriform sinus is adjacent to the aryepiglottic fold, false vocal fold, true vocal fold, arytenoids, and cricoid cartilage. The lateral wall of the pyriform sinus is contiguous with the lateral pharyngeal wall and is bounded by the thyroid cartilage and thyrohyoid membrane.

As in the oropharynx, the pharyngeal wall, pyriform sinus walls, and postcricoid tissue are comprised of mucosa and submucosa. Minor salivary glands are also present, scattered throughout the region. Deep to the posterior pharyngeal wall and lateral walls of the pyriform sinuses, lays the inferior constrictor muscle, and then the pharyngobasilar fascia. In the region immediately posterior to the hypopharynx, the same relationships regarding the alar fascia and prevertebral fascia are present as in the oropharynx. This results in a retropharyngeal space, danger space, and pre-vertebral space that are in continuity with those above. A butting the hypopharynx laterally are the great vessels as well as lymphatic and neural structures just external to the visceral space. The thyroid gland typically is located just inferior to the lowest point of the hypopharynx.

The hypopharynx has a varied neurovascular supply. The arterial inflow stems from the external carotid system in the form of the ascending pharyngeal and the superior thyroid arteries as well as from the inferior thyroid artery off the thyrocervical trunk from the subclavian system. The venous drainage pattern parallels this in the form of the pharyngeal venousplexus. The sensory supply to the hypopharynx is provided by the CN IX as well as the internal branch of the superior laryngeal nerve, from the vagus nerve. Motor innervation of the muscles of the hypopharynx, the inferior pharyngeal constrictor, and the cricopharyngeus, is provided by the pharyngeal plexus, comprised of CNs IX and X. Extensive submucosal lymph channels are evident in the hypopharynx, making regional metastases a prominent feature of carcinomas in this site. The lymphatic drainage of the hypopharynx has been mapped to lymph nodes in levels II, III, and IV, as well as retropharyngeal lymph nodes. Metastases to level I and level V lymph nodes are uncommon, however, level V is more likely to be involved if level IV nodes are positive. More inferior nodal basins can also be involved including the paratracheal, paraesophageal, and level VI lymph nodes. Bilateral drainage can occur especially with primary neoplasms at the medial pyriform aspect of the sinus.

The hypopharynx, like the oropharynx, serves as a respiratory and alimentary conduit. The hypopharyngeal structures are important players in the process of swallowing. The hypopharynx is primarily involved in the pharyngeal phase of swallowing, during which a food bolus travels from the oropharynx, through the hypopharynx, and into the cervical esophagus. During this phase, laryngeal elevation and glottic protection occur as do velopharyngeal closure and base of tongue propagation of the food bolus. As the food transits, the pharyngeal walls of the hypopharynx contract to clear food deposits from the pharynx and pyriform sinuses. At the completion of the pharyngeal phase of swallowing, the pharyngeal pressure continues to increase from the contraction of the pharyngeal constrictors and the tonic contraction of the cricopharyngeus is released. The food bolus then passes through the upper esophageal sphincter into the cervical esophagus.

Histopathology

Mucosa in the hypopharynx comprises stratified squamous cell epithelium. Similar to the oropharynx, this is typically nonkeratinized but can become keratinized in response to irritation. As a result, squamous cell carcinoma is by far the most common neoplasm found in the hypopharynx and is most frequently keratinizing. All variants of this malignancy have been found within the
hypopharynx including verrucous, baseloid, adenosquamous, and spindle cell.

In addition, lymphoepithelial neoplasms have been found in the hypopharynx as have lymphomas. Adenocarcinomas originating from glandular structures native to the hypopharynx or from ectopic gastric tissue have also been found in the hypopharynx. Papilloma, secondary to HPV, and other benign lesions can be present in the hypopharynx. Precursor lesions to squamous cell carcinoma such as leukoplakia and erythroplakia can also occur in the hypopharynx, but are uncommonly seen especially since these lesions are frequently asymptomatic. Minor salivary gland neoplasms of a benign and malignant nature can also occur in this location. Sarcomas can also arise in the hypopharynx.

**Etiology and Epidemiology**

Malignancy of the hypopharynx is not a common illness, and this cancer comprises less than 1% of all malignancies. The incidence of squamous cell carcinoma of the hypopharynx is 0.7 per 100,000 persons in the United States as recorded in the SEER database. At present, this malignancy is more common in men in all subtypes; however, historically it was more common in women in the postcricoid region. The most common site of hypopharyngeal malignancy in the United States is the pyriform sinus; however, in other parts of the world including the Middle East, the postcricoid region is more common. This is thought to be secondary to differences in diet.

Squamous cell carcinoma of the hypopharynx is associated with tobacco and alcohol exposure. Similar to the oropharynx, tobacco is more strongly causative, yet these two substances act synergistically when consumed together. Although HPV has been found in hypopharyngeal squamous cell carcinomas and it may play a part in carcinogenesis in this site, there is no evidence that the viral carcinogenesis that is so prominent in the oropharynx occurs in a similar manner in the hypopharynx. Laryngopharyngeal reflux is thought to play a carcinogenic role, particularly in postcricoid carcinoma. Patients with the Plummer-Vinson syndrome have a high risk of developing hypopharyngeal carcinoma. This syndrome occurs primarily in women and is comprised of a constellation of webbing of the esophagus and hypopharynx, iron-deficiency anemia, dysphagia, and weight loss. Also known as Paterson-Kelly syndrome, it is thought to result in squamous cell carcinoma just proximal to a web because of chronic irritation in this region. Plummer-Vinson syndrome is now more widely recognized and treated than in prior generations, resulting in a decreased incidence of hypopharyngeal carcinoma in this group.

**Pathophysiology and Mechanisms of Spread**

Squamous cell carcinoma of the hypopharynx most commonly occurs in the pyriform sinus. Particularly when the medial wall of the sinus is involved, these neoplasms may invade deeply into glottic and supraglottic structures. The false vocal fold, arytenoid, and aryepiglottic fold may be involved. The criocarytenoid joint or true vocal cord may be involved and result in vocal fold paresis or paralysis. With further extension, these cancers can involve the preepiglottic and paraglottic spaces as well. Lesions originating at the lateral wall of the pyriform sinus often spread to the posterior pharyngeal wall but can involve the thyroid cartilage or the thyroid gland.

Malignancy arising from the posterior pharyngeal wall is likely to spread longitudinally along the pharyngeal wall, superiorly to the oropharynx and inferiorly to the cervical esophagus. These lesions can also invade deeply into the retropharyngeal space or prevertebral muscles. Squamous cell carcinoma of the postcricoid region frequently invades into the cricoid cartilage and posterior glottic musculature, including the posterior cricoarytenoid muscles. All lesions of the hypopharynx may have significant submucosal spread, even with normal appearing mucosa, and this must be considered if primary surgical treatment is being performed. Skip lesions can result from this spread pattern necessitating wider margins (2 to 3 cm) during surgical resection as well as frozen section margins at that time.

Because regional lymphatic channels are so rich in the tissues surrounding the hypopharynx, lymph node metastases are common in hypopharyngeal squamous cell carcinoma. T1 to T2 lesions have evidence of lymphadenopathy at presentation in approximately one-half of patients, but greater than three-quarters of patients with primary neoplasms larger than T2 have evidence of lymphadenopathy at presentation. Approximately 40% of patients have evidence of occult micrometastases in the clinically N0 neck after neck dissection.22 Regional metastases are evident in the contralateral neck at presentation in greater than 15%, and occult positive nodes are present at a greater rate than this, nearly 50% in some studies.23 Five-year survival rates for all-comers with hypopharyngeal cancer are 25 to 40%.

**Clinical Manifestations**

Patients with squamous cell carcinoma of the hypopharynx often present with advanced disease, and this unfortunately affects prognosis. The hypopharynx is not amenable to examination by endoscopes and nasopharyngoscopic examination. In addition, early symptoms of hypopharyngeal malignancy can be vague, and their significance can be missed. Patients often present with dysphagia, voice change, sore throat, or globus sensation. A neck mass is not infrequently the first sign of a hypopharyngeal cancer, with approximately 25% of patients with this malignancy presenting this complaint. As the disease progresses, otalgia often becomes a prominent feature and weight loss is evident. Regional lymphatic spread continues and more than two-thirds of patients have evidence of palpable neck metastases at presentation to the otolaryngologist. Likewise, distant metastatic disease and second primary malignancies are more common in hypopharyngeal malignancies than in most other sites in the upper aerodigestive tract. As a result, signs and symptoms such as hemoptysis, dyspnea, hematuria, and jaundice should alert the physician to the possibility of more widespread disease.

**Diagnosis and Work-Up**

The process of diagnosis and work-up of a hypopharyngeal malignancy is largely similar to that of oropharyngeal malignancies. A thorough history must be obtained including risk factors such as alcohol and tobacco use or Plummer-Vinson syndrome. Other medical comorbidities and all previous treatments must be ascertained. A physical examination is completed which includes an indirect mirror examination as well as flexible fiberoptic nasopharyngoscopy. Large exophytic lesion are easily visualized with these examinations, and many invasive carcinomas can show evidence of vocal fold weakness. Smaller lesions may be less obvious on in-office examination, but have evidence of secretions pooling in the postcricoid region or pyriform sinuses as well as edema and erythema of laryngeal and hypopharyngeal structures. The neck is thoroughly examined for any adenopathy. After the examination, the neoplasm should be staged as well as possible.

The work-up should proceed with diagnostic imaging as well as panendoscopy with biopsy in the operating room. A CT scan of the neck is extremely helpful in evaluating and staging these lesions, particularly with regard to extent of primary neoplasm and evidence of regional lymphatic spread. If cartilaginous invasion is in question or further soft tissue delineation is necessary, MRI scanning can be helpful. The chest must also be evaluated for metastatic disease, and a CT scan of the thorax is the study of choice for this. A chest radiograph is also acceptable but provides less information. The patient then undergoes opening room endoscopy. Direct laryngoscopy, esophagoscopy, and biopsy are completed under general anesthesia, and formal staging is completed in this setting. During this evaluation close attention must be given to detecting a second primary malignancy in the upper aerodigestive tract; the oral cavity is a common site for this to occur with a hypopharyngeal squamous cell carcinoma. Some continue to recommend bronchoscopy as part of the operative endoscopy for the diagnosis of a second primary, however, CT scanning of the thorax is more sensitive for detecting a primary pulmonary malignancy. Once operative evaluation, radiographic imaging, and staging have been completed, the patient optimally should be presented to a multidisciplinary neoplasm board for treatment planning.

**Staging and Prognosis**

Squamous cell carcinoma of the hypopharynx is staged with the AJCC system (Table 4). This begins with evaluation of the primary neoplasm,
to which a T value is assigned. This categorization is based on size, involvement with adjacent sites, and finally involvement of areas which indicate advanced disease or poorer prognosis. Regional lymphatic spread is likewise staged to give a nodal or N category. This is also determined by size and location of nodal disease. Lastly, depending on the presence or absence of metastasis, an M category, is given. These three assessments are put together to create a TNM label for each patient as well as a stage of disease (see Tables 2 and 3). In general, any evidence of nodal disease will cause patients to be considered at least stage III. T4 neoplasms and more bulky lymphadenopathy will fall into Stage IV, with T4b considered unresectable. Positive nodal disease in level V portends a poor prognosis, and contralateral nodal disease is likewise an adverse risk factor. Due to the high frequency of advanced primary neoplasm, extensive regional metastases, and relatively increased incidence of distant metastases and concurrent second primary neoplasms, outcomes in hypopharyngeal squamous cell carcinoma are some of the worst of all head and neck malignancies. Unfortunately, these outcomes have improved by only small degrees over recent decades. The most recent AJCC survival statistics show 5-year survival for squamous cell carcinoma of the hypopharynx to be 41% in Stage I disease and 36% in Stage II disease. More frequently patients present with Stage III and IV disease, which have 5-year survival rates of 36% and 10%, respectively.

**Therapy**

**General Approach.** The general approach to treating squamous cell carcinoma of the hypopharynx has changed significantly over the last several decades. Previously a malignancy treated primarily by surgical extirpation, hypopharyngeal squamous cell cancer is now often treated with organ preservation protocols. As most of this patient population present with advanced disease, few of these neoplasms meet criteria for conservation surgical procedures. Thus, typically the primary attempts at organ preservation are achieved through chemotherapy and radiotherapy as the initial treatment. If the end result of organ preservation therapy is residual or recurrent disease, then radical surgery is performed and frequently requires free tissue transfer reconstruction. Of course, resectability and the absence of distant metastatic disease must be ensured prior to such extensive surgical procedures.

**Organ Preservation.** The idea of organ preservation in treatment of squamous cell carcinoma of the hypopharynx has evolved to prominence over the last 20 years. Radiation therapy for such lesions is not a novel idea, however, this treatment alone is only successful in small primary neoplasms. In the late 1980s and early 1990s interest in preserving the laryngeal and pharyngeal structures grew. Trials specific to hypopharyngeal malignancies built on previous and ongoing studies of organ preservation in the head and neck, such as those mentioned in the oropharynx section. A trial conducted by the (European Organization for Research and Treatment of Cancer) EORTC in the early 1990s showed favorable results comparing induction chemotherapy followed by radiation to surgical treatment followed by radiation in treatment of hypopharyngeal squamous cell carcinoma. A subsequent randomized clinical trial of patients with resectable hypopharyngeal neoplasms compared treatment with induction chemotherapy followed by surgery then postoperative radiation with induction chemotherapy followed by radiation alone (surgery was used for salvage). In this study, patients who underwent all three modalities (chemotherapy, surgery, and radiation) had improved survival over chemotherapy and radiation but of course did not have organ preservation. A further study assessed hyperfractionated radiation therapy and its use in combination with concurrent chemotherapy for advanced head and neck tumors. In this study the combined chemotherapy and radiation therapy regimen produced improved survival. The Radiation Therapy Oncology Group (RTOG) 91-11 (year and number of study initiated in that year) trial evaluated induction chemotherapy with radiation therapy, concurrent chemotherapy and radiation therapy, and radiation therapy alone for advanced laryngeal cancer. Results indicated better locoregional control, laryngeal preservation, and rate of distant metastases with concurrent chemotherapy and radiation therapy but similar overall survival in induction and concurrent regimens. Similar studies are ongoing in a continued search to determine the most effective and least morbid treatment for squamous cell carcinoma of the hypopharynx and other upper aerodigestive tract sites.

**Treatment Plan.** Just as in oropharyngeal malignancy, treatment recommendations for hypopharyngeal malignancy vary based on T classification and nodal burden. Small lesions in the hypopharynx are less frequently diagnosed than advanced but can be treated with less aggressive regimens. T1 T-category lesions (T1a–T1c) without evidence of nodal disease are preferably treated with primary radiation therapy. Conservation laryngopharyngeal surgery is also considered standard of care for these lesions and should include bilateral selective neck dissection. In T1 lesions with N1 nodal disease, radiation therapy can still be considered the definitive therapy. If nodal disease persists posttreatment, a neck dissection should be performed. For T3N1 lesions being treated with primary surgical therapy, consideration should be given to performing a modified neck dissection instead of a selective. Poor prognostic features in the specimen (close margins, extracapsular spread from lymph nodes) should prompt postsurgical chemotherapy and radiation therapy, however, features such as multiple positive nodes, perineural invasion, or vascular invasion should typically be treated with postoperative radiation therapy alone.

For more advanced lesions of the hypopharynx, more aggressive treatment regimens are necessary in an attempt at cure. For stage III or IV squamous cell carcinoma of the hypopharynx, several treatment plans are considered standard of care. At our center, organ preservation protocols prevail, and this occurs by two primary mechanisms. The first occurs with induction chemotherapy, off-protocol or on-protocol as part of a clinical trial (in which case the exact procedure and agents may vary somewhat). Patients receive induction chemotherapy for two cycles and then undergo operative endoscopy to evaluate neoplasm response. Neoplasm tattoo and pretreatment documented staging assist in this evaluation. Evidence of complete response or partial response at the primary site allows patients to continue in the organ preservation protocol with a third cycle of chemotherapy followed by definitive radiation therapy or concomitant chemoradiation. For patients with nodal disease larger than 3 cm pretreatment, a planned posttreatment neck dissection is performed after therapy. For patients who achieve less than partial response at the primary site after induction chemotherapy, surgical salvage is then performed. This includes extirpation of the primary neoplasm, bilateral neck dissection, and necessary reconstruction, typically with free tissue transfer. Patient survival and laryngeal preservation rates are excellent with protocols using single-cycle induction for chemoradiation therapy for selection while utilizing early salvage surgery. With regards to laryngeal preservation rates alone, however, there is no proven difference between induction and concurrent chemoradiation regimens.

Similar to induction chemotheraphy regimens, patients can also be treated with concurrent chemotherapy and radiation therapy. The same principles apply to lack of response or recurrent disease as with induction chemotherapy in that patients are then treated with salvage surgery which is often quite technically challenging. Likewise, the same regimen applies for planned neck dissection posttreatment. As described in the oropharynx section, the criteria for proceeding with planned posttreatment neck dissection continue to change, and the role of PET in this regard continues to be evaluated.

Surgical therapy is also considered the standard of care for Stage III and IV hypopharyngeal cancer. At many centers this may be the first choice in treatment of these patients. This typically includes total laryngectomy with partial or total pharyngectomy and bilateral neck dissections followed by reconstruction. At our center, patients with T4a carcinomas of the hypopharynx have been treated via organ preservation protocols with success rates comparable to surgical therapy. This has not been universal at other centers, however, and as a result, many head and neck specialists recommend surgical therapy for T4a disease. This issue will no doubt continue to be studied via protocols in coming years so that the question of the viability of this approach is answered definitively.

**Surgical Resection.** Surgical treatment of hypopharyngeal malignancies can be used to treat small as well as advanced or recurrent primary disease. For small T1 or T2 neoplasms, consideration can be given to primary conservation surgery as described above. Unfortunately, however, these small primary neoplasms are few and far between. Patients with such small neoplasms must be evaluated as to their suitability to undergo conservation surgery. Factors such as comorbidities and performance status, particularly with regard to pulmonary disease, are important in patient selection for these procedures. Laryngeal subsite involvement and overall extent of disease are also important. Small lesions solely involving the lateral or posterior pharyngeal wall are amenable to primary resection, often via an endoscopic approach. A CO\textsubscript{2} laser is frequently used for this type of approach, and several groups have reported treatment success with this approach.

Suprahyoid and lateral pharyngotomy approaches can be used for open resection of small lesions of the pharyngeal wall. Lesions of the pyriform sinus and postcricoid region can also be evaluated for conservation surgery. Small lesions of the pyriform sinus may be resectable by partial laryngopharyngectomy if the apex is not involved, the interarytenoid region is free, vocal fold motion is preserved, and there is no evidence of cartilaginous invasion. Primary neoplasms of the postcricoid region are nearly impossible to resect with conservation of structures because of the close proximity of this subsite to many laryngeal structures. Larger primary neoplasms of the hypopharynx typically require total laryngectomy with partial or total pharyngectomy (Figure 8). Neoplasms of the larynx are discussed in Chapter 99, “Neoplasms of the Larynx.”

Regardless of the evidence of nodal disease and the C category of the primary neoplasm, patients undergoing primary surgical treatment for hypopharyngeal squamous cell carcinoma should undergo neck dissection at the time of surgical extirpation due to the extensive regional lymphatics in the region. At least unilateral neck dissection should be performed including attention to retropharyngeal lymph nodes; but depending on the location and size of the primary neoplasm, bilateral neck dissection may be necessary. The type of neck dissection performed, selective versus modified radical or radical, is determined by the disease status at presentation. Levels I to V should be addressed in all cases.

**Reconstruction.** As in reconstruction after resection of oropharyngeal malignancies, in selecting a means of rebuilding it is useful to consider the options in a stepwise fashion from simplest to most complex, that is, to reconstruct defects that range from partial to subtotal to total pharyngectomy. Previous treatment effects on tissue vascularity and healing must be considered, as the rate of hypopharyngocutaneous fistulas with free flap closure of hypopharyngeal defects created by surgical salvage of previously chemoradiated tissue is around 20%.25

For small defects of the pharyngeal wall, healing by secondary intention, primary closure, or a skin graft may be acceptable. For larger defects that are subtotal, a pedicled flap such as the pectoralis major or latissimus dorsi can be used for reconstruction (see Figure 9). Similarly, vascularized free tissue can be used in such situations. The radial forearm free flap is an excellent choice in this location. Depending on the extent of the subtotal defect, the anterior lateral thigh free flaps and the temporoparietal fascial flaps could also be considered. For a total laryngectomy with partial or subtotal pharyngectomy defect, the radial forearm is again an ideal choice for a partially tubed reconstruction in this area.

When resection of the primary neoplasm requires total laryngopharyngectomy, a tubed reconstruction is necessary to build a neopharynx. This could be done with a pedicled flap, but a better result is obtained using free vascularized tissue. Such a free flap must have available vessels for vascular anastomoses, should be thin and pliable enough to reconstruct the pharynx, and should cover vital structures such as the carotid artery that are at high risk of exposure. Our first choice for this reconstruction is a tubed radial forearm free flap, an extremely reliable flap, which is pliable enough to nicely recreate a pharynx. If increased bulk is needed, particularly if cutaneous tissue must be reconstructed, the anterior lateral thigh free tissue transfer works well in this reconstruction (Figure 10). Such free fasciocutaneous flaps have been found to decrease fistula rates to 20% for hypopharyngeal reconstruction and also work well if the defect extends into the oropharynx.

Free jejunal grafts can also be used to create a tubed neopharynx. This free visceral transfer is supplied by a single mesenteric artery and vein, often from the second arcade. This flap requires the assistance of a general surgeon for harvest and bears the added risk of major abdominal surgery. The flap is susceptible to ischemia. Strictures occur in about 10% of patients causing dysphagia, which can also result from peristalsis. The voice produced can be “wet” which is improved with postoperative radiation. In cases where the extirpated tissue is inferior to the cricopharyngeus muscle, gastric interposition is necessary to keep the resection oncologically sound while making reconstruction technically possible. This flap is pedicled on the gastroepiploic vessels and is frequently complicated by leak, fistula, or reflux disease. The gastro-omental free tissue transfer is one other option for reconstructing a neopharynx. This involves the harvest of the greater curvature of the stomach with the right gastroepiploic artery. This provides nice great vessel coverage and a lower fistula rate but again involves the complications of abdominal surgery.
are scheduled approximately every 6 to 8 weeks as patients get farther from therapy. Return visits are closely spaced out frequently. Significant alteration in the form of edema and erythema is head and neck region, with particular attention through a thorough physical examination of the complete. The primary means to evaluate patients is through a thorough physical examination of the head and neck, modification of unhealthful alterations for nutrition. This can result in gastric tube dependence, reliance on a soft or liquid diet, and aspiration. Surgical therapy at times preserves swallowing function but limits voice production. This occurs if results are not optimal with partial procedures or if total laryngectomy is performed and the patient has difficulty with tracheoesophageal speech or use of an electrolarynx. Work with a speech pathologist is critical, particularly during the first year posttreatment when the body and mechanisms of adaptation are heavily evolving. The speech pathologist plays an essential role in assisting the patient and training the patient to use functional methods to cope with these alterations in speech and swallowing. Similar to other squamous cell carcinomas of the head and neck, modification of unhealthful behaviors is also important to treatment response and recovery. Strong nutritional supplementation and abstinence from tobacco and alcohol predict a better prognosis for long-term survival.

Finally, just as with oropharyngeal malignancies, patients with squamous cell carcinoma of the hypopharynx must be followed closely for recurrence and metastases once treatment is complete. The primary means to evaluate patients is through a thorough physical examination of the head and neck region, with particular attention to the primary site and the neck. This can be difficult to accomplish because posttreatment tissue alteration in the form of edema and erythema is frequently significant. Patients should be monitored closely on a schedule which is spaced out as patients get farther from therapy. Return visits are scheduled approximately every 6 to 8 weeks during the first year, every 2 to 3 months during the second year, every 3 to 4 months during the third year, every 4 to 6 months during the fourth year, and once a year starting in the fifth year. A significant landmark for patients is that of reaching 2 years posttreatment without recurrence. Once this is achieved, the incidence of local or regional recurrence diminishes significantly, and distant metastases are of more concern. A chest X-ray is typically ordered 6 months and then 1 year after the completion of treatment, and then once a year subsequently. Thyroid function should be assessed on the same schedule to assess for hypothyroidism after surgical or chemoradiation in the area.

**CONCLUSIONS**

Neoplasms of the oropharynx and hypopharynx are challenging lesions for the treating physician and the patient. Although largely squamous cell carcinomas, the management of these lesions in not one-sided and requires a complex understanding of the anatomy, physiology, and disease processes in the area. Management involves complex organ preservation therapies, radical operations, and intricate reconstructions. Multidisciplinary teams of otolaryngologists, radiation and medical oncologists, dentists, speech pathologists, nurses, and other specialists must be assembled to treat patients with these malignancies appropriately. In addition, strong partnerships must be created between treating physicians and basic scientists to continue to understand these diseases better at a molecular level. The acquisition of this knowledge brings better treatment regimens, more advanced protocols, and improvements in morbidity and mortality. Most importantly, research on squamous cell carcinoma of the oropharynx and hypopharynx allows the clinician to meet the challenge of the twenty-first century: to bridge not only the gaps in survival but also to improve on the equally important outcomes which are essential to the quality of a patient's life.

Neoplasms of the Larynx

Marshall Strome, MD
C. Arturo Solares, MD

Laryngeal carcinomas are prevalent in heavy smokers, tend to have a relatively early presentation, and with the exception of supraglottic malignancies, are less likely to metastasize early to the adjacent lymph nodes. Importantly, because of the shortened time from symptom evolution to diagnosis, tumors confined to the laryngeal framework have a substantially better prognosis. Early detection relates to the effectiveness of the American Cancer Society’s campaign regarding early warning signs for malignancy which include persistent hoarseness and the ease of in-office endoscopic examination.

In the last decade, significant changes have occurred in the management of patients with advanced laryngeal malignancies. Prospective randomized studies have shown that a more conservative approach, that is, laryngeal preservation with chemoradiation therapy, as the initial treatment is feasible. Partial or total laryngectomy is reserved for cases of recurrent or persistent disease. Unfortunately, salvage surgery, following chemoradiation, results in increased surgical morbidity, including decreased voice quality following restorative measures and dysphagia. These issues need continued thought. Nevertheless, quality-of-life studies suggest that preservation of the larynx is a worthwhile goal and objective.

This chapter reviews the current knowledge in the diagnosis and treatment of laryngeal cancer and future directions in the management of this disease.

Etiology

Tobacco is the most acknowledged and preventable risk factor for the development of laryngeal cancer, being a documented covariable in 90 to 95% of these malignancies. The risk of malignancy rises as the use of tobacco increases. Other factors increasing the carcinogenic potential of tobacco include hand-rolling cigarettes and use of dark tobacco. The risk of developing laryngeal cancer decreases with time after smoking cessation. Thus, tobacco acts as a promoter and an initiator in carcinogenesis. A French study showed that people who smoked more than one packet of cigarettes a day have a risk that is 13 times higher than that of nonsmokers, and those who drink more than 1.5 L of wine per day have a risk that is 34 times higher of developing head and neck cancer. A additional smoking risk is attributed to early age of onset and duration. Alcohol is an independent risk factor and a significant covariable for laryngeal carcinoma. The combination of alcohol and smoking results in more than an additive risk.

Mate, a Latin American tea that contains high levels of phenols, has been shown to increase the relative risk for laryngeal cancer in people who consume more than 1.5 L/d. Other factors that have been linked to laryngeal cancer are occupational exposure to asbestos, nickel compounds, and certain mineral oils. Glass wool has been associated with an increased mortality in a study from Italy. Laryngopharyngeal reflux has also been linked to laryngeal cancer in some series.

The genetics of head and neck cancer is an area of ongoing research. Aneuploidy accompanies the progression from dysplasia to malignancy. Some of the chromosomal alterations associated with laryngeal carcinogenesis include 9p21 early in the process, 17p13.1, 3p25, and 3p14.2 in the intermediate events, and 8p21.3-p22 in the later stages of the process. Alterations in the p16 gene that acts in cell-cycle regulation have also been linked to laryngeal cancer. Overexpression of p53 is noted in some laryngeal squamous cell carcinomas, and it likely plays an important role in an early stage of malignant transformation. The activation of a proto-oncogene in 11q13 amplifies the oncogene cyclin D1, which activates cell wall progression and is associated with tumor invasion. These are just some of the most relevant genetic alterations linked with laryngeal cancer.

The human papilloma virus (HPV) has been detected in head and neck squamous cell carcinoma, but the specific role of HPV in laryngeal cancer is not clear. Almadori and colleagues reported that one-third of laryngeal tumors had evidence of HPV DNA. The presence of HPV DNA may not represent causality and perhaps only a small subset of laryngeal cancer is directly related to HPV. Moreover, there are conflicting opinions relative to the prognostic implications of HPV. While some studies suggest that detectable HPV may represent a biologically distinct subset of tumors with poor prognosis, others report that patients with detectable HPV have improved survival rates.

Smoking cessation and reduced alcohol consumption are the most effective means of preventing the development and recurrence of laryngeal cancer. A toxin-free work environment is also important. Genetics and susceptibility to cancer are difficult to separate from lifestyle and the environment and thus more difficult to influence in a preventive fashion. Patient education is paramount in cancer prevention.

Epidemiology

It was estimated that 9,510 people in the United States would learn that they have cancer of the larynx in 2006, according to the National Cancer Institute. Although this figure has not changed significantly in the last four decades, the male/female incidence of laryngeal cancer has dropped from 15:1 to less than 5:1 in 2004. This statistical change in the United States has been hypothesized to be a result of women obtaining an equal place in the toxic work environment and participating in what had become an acceptable act: public cigarette smoking. The time between these behavioral changes, that is, since World War II, and the recent gender statistics on cancer of the larynx may represent the duration of exposure needed for malignancy to evolve.

Diagnosis

Early recognition of malignancies of the larynx is crucial. Any patient with hoarseness lasting longer than 4 weeks should be evaluated by an otolaryngologist. Other symptoms of laryngeal carcinoma are hemoptysis, halitosis, and the so-called hot potato voice. A thorough laryngeal examination is essential. While mirror examination suffices in some patients, in others evaluation with a telescope or flexible laryngoscope is required. Patients with a strong gag reflex, or patients whose local anatomy prohibits complete examination of the entire intrinsic larynx, in particular, the anterior commissure, require supplemental examination. The pyriform sinuses should be free of secretions when the examination is performed so that the mucosa is clearly visualized. Vocal cord mobility is assessed and recorded, because it has major implications in staging and management.
Cancers of the supraglottic larynx generally present later due to a paucity of early symptoms. Dysphagia, otalgia, and odynophagia should raise suspicion. Often, these symptoms are managed medically before referral for endoscopy. Airway obstruction with no apparent voice change may represent the presenting sign of a large supraglottic or subglottic lesion. The latter can present as refractory asthma without voice change, and referral may be indicated by a flow volume loop showing upper airway obstruction patterns in a patient with known asthma.

An office video endoscopic laryngeal assessment is outpatient state of the art. Replaying the video will often reveal subtleties not initially seen. With good topical anesthesia, outpatient endoscopic biopsies are easily obtained. With transnasal esophagoscopy (TNE) becoming increasingly available and outpatient flexible bronchoscopy established, is there still the need for an inpatient assessment of disease extent? For limited pathology, there is a shift toward outpatient (office) settings. Advanced stage tumors, we believe, still warrant a traditional exploratory evaluation. In the operating room, fixation of the vocal cord is differentiated from arytenoid cartilage fixation by palpation and can help stage the disease. The laryngeal probe permits assessment of extension into the ventricle. Telescopes can be used to assess the subglottic extent and visualize better the anterior commissure. The operating microscope also affords enhanced visualization. It is important to obtain appropriate biopsy specimens from varied sites to help in management planning.

Imaging studies are of paramount importance in the management of laryngeal malignancies as they may aid in the selection of the most appropriate therapeutic modality. Critical factors in the evaluation of laryngeal images include tumor volume, cartilaginous invasion, spread across supraglottic-glottic-subglottic boundaries, infiltration of preepiglottic, paraglottic, and pharyngeal planes, and nodal disease. Magnetic resonance imaging (MRI) offers greater sensitivity to cartilaginous invasion than computed tomography (CT) but has a higher false-positive rate. Thin-section CT with multplanar capability is competitive with direct coronal MRI and benefits from high specificity. CT and MRI modalities are complementary and should be used judiciously in the preoperative planning. Ideally, these studies should be completed prior to operative endoscopy and before biopsy. Lastly, radiologic evaluation of the chest helps to rule out metastasis or second primary malignancies. Chest CT scan is widely believed to be superior to simple chest X-rays for this purpose, but the available literature does not support this notion. M
core recently, positron emission tomography (PET) has emerged as a part of the imaging armamentarium in laryngeal cancer, but further experience will be required before widespread use of this technology can be recommended.

The need for a biopsy to confirm the diagnosis cannot be overemphasized. The gross appearance of several benign conditions, for example, fungal laryngitis, sarcoidosis, tuberculosis, or Wegener granulomatosis may mimic malignancy. Biopsies should be judicious but must include sufficient tissue volume to ensure the correct diagnosis. Small suspicious lesions should be completely excised with a limited border of healthy laryngeal submucosa to afford depth of invasion evaluation. Frozen sections are usually taken to prevent the need for a repeat endoscopy due to inadequate sampling. Educating the patient is paramount prior to proceeding with definitive management.

Staging is important, enabling standardization of patient populations and permitting comparisons between institutional series. TNM staging is necessary for patient discussion, tumor board consideration, and ultimately therapeutic delivery. It is required by institutions managing cancer patients and maintaining a tumor registry (Joint Commission on Accreditation of Healthcare Organizations [JCAHO] requirement). Table 1 outlines the staging of laryngeal cancer.

### APPRAISAL TO LARYNGEAL CANCER

The main goal of therapy is the eradication of cancer. Quality of life research shows that cancer cure is the main determinant of quality of life outcomes. Patients usually adapt well to lifestyle modifications resulting from treatment sequelae. Secondary objectives include voice quality and adequate swallowing. Tumor considerations, patient issues, and institutional factors all play a role in the decision-making process.

### Tumor

Over 90% of laryngeal cancer is of the squamous cell type. Important tumor parameters include mobility of the vocal cords, anterior commissure involvement, depth of cord invasion, T classification, tumor location, that is, glottic versus supraglottic, and proximity of a supraglottic lesion to the anterior commissure. Exophytic tumors tend to respond better to radiation than endophytic tumors and have a more favorable prognosis. The degree of differentiation has been correlated with metastatic potential, poorly differentiated tumors being more aggressive.

### Patient

Occupational demands, mental and health status, and patient tolerances are germane in formulating a

*Subsites include the following: ventricular bands (false cords); arytenoids; suprahypopharyngeal, infraglottic epiglottis; aryepiglottic folds (laryngeal aspect).
tailored therapeutic regimen. The medical status is critical, with pulmonary function being of particular importance. Voice quality is becoming less of an issue when considering radiation therapy versus judicious laser ablation, yet it merits in-depth discussion with professional voice users. For many, the time disparity between these treatment modalities as well as differences in morbidity are leading more to consider surgical alternatives for early-stage laryngeal malignancy.

Institution

A multidisciplinary approach with input from all parties is state-of-the-art management for laryngeal cancer. This requires well-trained head and neck surgeons, medical oncologists, and radiotherapists who meet regularly at a multidisciplinary conference. This approach avoids the potential bias of a given discipline recommending a specific regimen to the relative exclusions of others. Supporting services should include speech and swallowing therapists, restorative dentistry, psychology/psychiatry, and physical and occupational therapists.

Surgical Treatment

The choice of a surgical approach depends on the tumor size and location. For early laryngeal cancer, there are the traditional partial procedures. However, today, endoscopic surgery is playing an ever-increasing role. In the majority of patients with advanced disease, if surgery is chosen, the treatment remains total laryngectomy, with partial laryngeal surgery reserved for selected patients. In advanced lesions, extirpation of the primary tumor must be accompanied by management of the neck, with an appropriate lymphadenectomy as a primary modality of therapy. A brief description of the traditional surgical procedures follows acknowledging the trend toward newer approaches.

Vertical Partial Laryngectomy. This technique involves removal of the majority of the ipsilateral thyroid cartilage, the true and false vocal cords, and limited subglottic mucosa (Figure 1). It is indicated for tumors that arise on the true vocal cord with limited involvement of the anterior commissure. The defect can be allowed to heal spontaneously or it can be reconstructed with the epiglottis. Another alternative is the rotation of a pedicled muscle flap beneath retained peri-chondrium. A temporary tracheostomy is most often performed but is not universally felt to be requisite. A posterior commissure involvement dictates a frontolateral or extended vertical partial laryngectomy. Contraindications to this procedure include posterior commissure involvement, subglottic extension of more than 10 mm, and potential pulmonary reserve issues. Voice quality is not as good as that achieved with radiation or an endoscopic resection. Endoscopic CO₂ laser techniques have, for the most part, replaced this procedure in our institution as a primary modality; rather, it is performed in selected patients after radiation failure.

Supraglottic Laryngectomy. This technique involves the removal of the epiglottis, thyrohyoid membrane, preepiglottic space, upper half of the thyroid cartilage, and the false vocal folds (Figure 2). We preserve the hyoid bone when

![Figure 1 Diagrammatic representation of a vertical partial laryngectomy. (A) External view showing the resection of the thyroid ala. feasible from an oncologic perspective. This technique is suitable for T1 and T2 tumors of the laryngeal surface of the epiglottis and false vocal cords. The inferior margin only needs to be 2 to 3 mm above the vocal folds. Closure is achieved by approximating the thyroid cartilage remnant to the hyoid bone with three sutures placed 1 cm apart. Patients require a temporary tracheostomy. For infrathyroid tumors, ipsilateral or bilateral neck dissections are performed. Contraindications related to the tumor include involvement of the interarytenoid space, pyriform sinus apex, anterior commissure, and significant invasion of the preepiglottic space. Also, FEV1 greater than 50% is a requirement in some institutions. In our institution, this procedure, like the vertical partial laryngectomy, has taken a secondary role to endoscopic laryngeal surgery.

Supracricoid Partial Laryngectomy with Cricohyoidopexy or Cricohyoidoepiglottopexy. In the supracricoid partial laryngectomy with cricohyoidopexy or cricothyroidoepiglottopexy operation, the whole thyroid cartilage and the paraglottic spaces are resected (Figures 3 and 4). The cricoid cartilage, the hyoid bone, variable the epiglottis and, at least, one arytenoid cartilage are preserved. The preservation of one mobile arytenoid unit results in physiologic speech and swallowing. Maintenance of the cricoid cartilage affords decannulation. For closure, three submucosal 0-Vicryl sutures circumscribe the cricoid cartilage and hyoid bone with or without the epiglottis (cricohyoidoepiglottopexy vs cricothyroidoepiglottopexy). These procedures are indicated for bilateral T1 glottic carcinomas with or without anterior commissure involvement, unilateral T1 glottic carcinomas with anterior commissure involvement, T1 glottic carcinomas with multiple areas of dysplasia, and unilateral or bilateral T2 glottic tumors with or without impaired vocal cord mobility. In addition, selected T3 glottic carcinomas may be amenable to this approach if the ipsilateral arytenoid is mobile and the preepiglottic space is not involved. This procedure can be performed successfully after radiation failure. Contraindications include poor pulmonary reserve, posterior commissure involvement, and subglottic extension below 10 mm.

Endoscopic Resection. Endoscopic surgery for vocal fold malignancies is accomplished with CO2 laser linked to the operating microscope. A new hollow core fiber that allows for the transmission of CO2 laser energy (OmniGuide Corporation) is currently being evaluated at our institution. The use of CO2 laser for the management of laryngeal malignancies was first described by Strong. Vaughan and colleagues, in 1978, reported on the use of CO2 laser for the management of early glottic cancer. Since then, there have been several reports supporting its role in the management of early glottic cancer in selected patients. The reported voice quality is good. Our practice is to perform cryoablation of the residual tissue after the resection (Figure 5). In our experience, this serves two purposes, first it theoretically allows for a better tumor control, but it also decreases collagen deposition and increases hyaluronan, leading to increased pliability and improved vocal function.

Selected supraglottic tumors can also be approached endoscopically. Vaughan and colleagues first described the use of CO2 laser for debulking of supraglottic tumor, but it was Davis and colleagues who first described a technique for transoral CO2 laser resection of the supraglottis. Since 1979, Steiner has been using a transoral CO2 laser technique to resect supraglottic tumors successfully. Initially early-stage tumors were resected, but more recently, there have been reports of advanced supraglottic tumors being resected endoscopically. The advantages of the endoscopic technique include a more rapid recovery of swallowing and speech, a limited need for tracheostomy, and a decreased hospital stay. The procedure is performed using a bivalved laryngoscope specially designed for the operation. The resection is accomplished by midline splitting and resection of the suparyoid epiglottis, followed by a split of the infrathyroid epiglottis with evaluation of the extent of invasion of the tumor at this point. The specimen is removed and subjected to frozen section control. The preepiglottic space is included in the specimen and is often infiltrated. The resection may require removal of all tissue to the inner perichondrium of the thyroid cartilage and thyrohyoid membrane. False cords are also resected when indicated. We currently favor this approach.

Total Laryngectomy. The total laryngectomy procedure involves the removal of the entire larynx, as well as the hyoid bone and cricoid cartilage. An appropriate neck dissection is usually performed. This procedure is usually indicated for selected Stage III and IV disease. In the current
era of conservation therapy, this procedure is usually performed for chemoradiation failures, or when conservation therapy is contraindicated as in the case of extensive cartilage involvement. In our practice, total laryngectomy is rarely performed as a primary treatment modality.

Elective Neck Dissection. The nodal groups at risk for occult spread in laryngeal cancer are levels II, III, and IV. Levels I and V are rarely involved. Therefore, when the neck is treated electively, a lateral neck dissection is all that is required. Paratracheal nodes (level VI) should be dissected in cases of advanced glottic and subglottic cancer.

Nonsurgical Treatment

There have been significant advances in the nonsurgical management of head and neck cancer in recent years. The primary nonsurgical modality for early-stage laryngeal cancer (stages I and II) is radiation therapy. Chemoradiation therapy may have a role in bulky T2 tumors which would require a total laryngectomy but is otherwise not a consideration for early disease. Chemoradiation therapy is generally used in laryngeal preservation for advanced tumors. The concept of laryngeal preservation for advanced laryngeal cancer had its basis in the Veterans Affairs Laryngeal Cancer Study Group (VA study). In this study, 332 patients with stage III to IV laryngeal carcinoma were randomized to either induction chemotherapy with cisplatin and fluorouracil followed by radiation therapy in those with more than 50% decrease in tumor size, or total laryngectomy followed by radiation therapy. Patients in the chemotherapy group underwent total laryngectomy if their tumor did not decrease by more than 50% or if they had persistent disease following radiation therapy. The laryngeal preservation rate was 66% at 5 years with no difference in survival between the chemoradiation and surgery groups. At 12 years, 61% of patients in the chemoradiation group still had their larynx, and their survival rates were similar to those of the surgical arm.

In addition to survival, speech, swallowing, pain, and cosmetic deformity are important to consider when evaluating the efficacy of organ preservation therapy. At 2-year follow-up in the VA study cohort, the chemoradiation group had better objective speech, with only 2 patients (1%) requiring tracheostomy. However, at 10 years, there were no differences between the chemoradiation group and the surgical group in their speech and swallowing abilities as reported by the patients. Interestingly, the chemoradiation patients had better quality of life scores than the laryngectomy patients, and this was related to freedom from pain; better emotional well-being scores, and lower levels of depression, and not to laryngeal preservation. Although this study did not report significant swallowing dysfunction, it has been detailed in other publications.

The National Cancer Institute Cooperative Trials Head and Neck Intergroup (R 91-11) conducted a randomized, three-arm trial to determine whether radiation therapy alone with surgical salvage was superior to either induction chemotherapy followed by radiation therapy or concurrent chemoradiation therapy. Five hundred and forty-seven patients were enrolled, of which 497 patients were ultimately included in the final analysis. The median follow-up was 36 months. At the 2-year mark, no survival benefit was noted in either group. Interestingly, laryngectomy-free survival was greater in the concurrent chemoradiation group (66%) than in the induction chemotherapy (59%) or radiation-alone (53%) groups. Laryngeal preservation was achieved in 88% of patients in the chemoradiation group which was significantly better than the other two groups. The rate of distant control was similar in both chemotherapy groups. It is important to mention that in this study, treatment-related mortality rates ranged between 3 and 5% among all groups which is higher than the expected surgical mortality rates with laryngectomy.
had a diet limited to soft foods.43 Unfortunately, At 2 years, 15% of patients in all three groups 1 year, and 3% had no ability to swallow at all. Particularly affected in the chemoradiation therapy laryngeal surgery. Lastly, swallowing was par- tion and therefore were amenable to conservation surgery. The role of chemoradiation was that it enabled surgeons to establish the pathologic extent of disease, true status of cervical nodes, and status of the surgical margins. Studies showed a significant improvement in lymph node control with postoperative versus preoperative radiotherapy.26 The perceived disadvantages were the need for a larger radiation port and possible delay in the radiotherapy if wound healing was not adequate. Vikram noted the need to deliver postoperative radiotherapy within 7 weeks of the operative procedure. In 7 of 10 patients to receiving postoperative radiotherapy within 7 weeks of surgery, no signs of recurrence developed. In 11 patients in whom the initiation of postoperative radiotherapy was delayed, 3 had regional or local tumor recurrence.23 A more recent retrospective study on 420 patients with oropharyngeal and hypopharyngeal malignancies failed to support Vikram’s findings. This study could not demonstrate that radiotherapy started more than 6 weeks postoperatively affected survival and showed that the status of the margins and stage were the predictors of locoregional recurrence.25 Two prospective randomized studies were designed to determine whether preoperative or postoperative radiotherapy was more advantageous. The largest study was performed between 1973 and 1975 under the direction of the RTOG.53 Patients with carcinoma of the supraglottic larynx and hypopharynx were randomly assigned to receive preoperative radiation of 50 Gy or postoperative radiation of 60 Gy. Patients with oral cavity or oropharynx lesions were randomly assigned to preoperative radiation, postoperative radiation, or definitive radiation therapy (65 to 70 Gy). Surgery was reserved for salvage if residual disease was present 6 weeks after the completion of irradiation. Three hundred and twenty patients were accessed in follow-up, and the median follow-up was 60 months. Based on results in 277 patients across all four regions combined, locoregional control was significantly better for the patients assigned to receive postoperative radiation therapy (65%) than those assigned to receive preoperative radiation therapy (48%, p = .04). This was due to a higher rate of both persistent and recurrent local and regional disease in the preoperative RADIATION OR CHEMORADIATION THERAPY AND SURGERY

Combined radiation therapy and surgery began in the early 1960s. Initial studies compared patients who received preoperative radiation followed by planned surgical resection with historical controls.47–49 Increased survival rates were demonstrated in these early studies. The primary advantage of preoperative radiotherapy was theorized to be that well-oxygenated unoperated tissue had a better vascular supply, making delivery more effective than radiotherapy to an operated field. In addition, the field and extent of radiotherapy would be more limited because this modality could be directly applied to the tumor site.

Postoperative radiotherapy gained general acceptance in the late 1970s. The advantage of postoperative radiotherapy was that it enabled surgeons to establish the pathologic extent of disease, true status of cervical nodes, and status of the surgical margins. Studies showed a significant improvement in lymph node control with postoperative versus preoperative radiotherapy.26 The perceived disadvantages were the need for a larger radiation port and possible delay in the radiotherapy if wound healing was not adequate. Vikram noted the need to deliver postoperative radiotherapy within 7 weeks of the operative procedure. In 7 of 10 patients to receiving postoperative radiotherapy within 7 weeks of surgery, no signs of recurrence developed. In 11 patients in whom the initiation of postoperative radiotherapy was delayed, 3 had regional or local tumor recurrence.23 A more recent retrospective study on 420 patients with oropharyngeal and hypopharyngeal malignancies failed to support Vikram’s findings. This study could not demonstrate that radiotherapy started more than 6 weeks postoperatively affected survival and showed that the status of the margins and stage were the predictors of locoregional recurrence.25 Two prospective randomized studies were designed to determine whether preoperative or postoperative radiotherapy was more advantageous. The largest study was performed between 1973 and 1975 under the direction of the RTOG.53 Patients with carcinoma of the supraglottic larynx and hypopharynx were randomly assigned to receive preoperative radiation of 50 Gy or postoperative radiation of 60 Gy. Patients with oral cavity or oropharynx lesions were randomly assigned to preoperative radiation, postoperative radiation, or definitive radiation therapy (65 to 70 Gy). Surgery was reserved for salvage if residual disease was present 6 weeks after the completion of irradiation. Three hundred and twenty patients were accessed in follow-up, and the median follow-up was 60 months. Based on results in 277 patients across all four regions combined, locoregional control was significantly better for the patients assigned to receive postoperative radiation therapy (65%) than those assigned to receive preoperative radiation therapy (48%, p = .04). This was due to a higher rate of both persistent and recurrent local and regional disease in the preoperative

Weber and colleagues analyzed the survival, locoregional control, and complications after salvage total laryngectomy in the Radiation Therapy Oncology Group (RTOG) 91-11 study. The need for total laryngectomy was less common in the chemoradiation therapy group. In addition, patients who required salvage surgery had a poorer survival than those who did not. The incidence of complications after salvage surgery was no different among all three groups. However, one-third of the patients who required salvage surgery after chemoradiation therapy developed pharyngocutaneous fistulas.44

There are no prospective, randomized trials on the use of chemotherapy as a single modality for the management of laryngeal cancer. Laccour reye and colleagues retrospectively analyzed the local recurrence rates in 35 patients with glottic cancer treated with cisplatin and fluoracil alone. Of 231 patients, 77 achieved complete clinical response with this induction chemotherapy regimen, and 35 of these 77 were treated with chemotherapy alone for cure. Five-year actuarial survival and local control rates in this group were 88.6% and 64.8%, respectively. Salvage treatment for local recurrence in this group yielded a 100% local control and larynx preservation rate. Patients with tumors originating from sites other than the glottis had worse survival and failure rates than those patients with glottic cancer. Although local recurrences were found in about one-third of patients with T1 to T3 disease, there were no disease-related deaths and no patient required a total laryngectomy.46 The role of chemotherapy alone will need to be determined in the years to come. At present, chemotherapy is given concurrently with radiation.
group. Survival was also better in the postoperative group (38%) compared with the preoperative group (33%), but the difference was not statistically significant (p = .10). A 10-year follow-up study showed that locoregional control was significantly better for 141 postoperative radiation therapy patients than for 136 preoperative radiation therapy patients (p = .04), but absolute survival was not affected (p = .15). When the analysis was restricted to supraglottic larynx primaries (60 postoperative radiation therapy patients vs. 58 preoperative radiation therapy patients), the difference for locoregional control was highly significant (p = .007), but survival was comparable in both groups (p = .18). When looking at only the supraglottic larynx, 78% of locoregional failures occurred in the first 2 years. Thirty-one percent (18 of 58) of preoperative patients experienced local failures within 2 years versus 18% (11 of 60) of postoperative patients. After 2 years, distant metastases and second primaries became the predominant failure pattern, especially in postoperative radiation therapy patients. This shift in the failure pattern along with the increased number of unrelated deaths negated any advantage in absolute survival for postoperative radiation therapy patients. The rates of severe surgical and radiation therapy complications were similar between the two arms. This study concluded that given an increased incidence of late distant metastases and secondary primaries, additional therapeutic intervention would be required beyond surgery and postoperative irradiation to impact significantly upon survival.

Recently, reports on the successful use of postoperative chemoradiation therapy in head and neck tumors with high-risk features have been published. Cooper and colleagues reported the results of a phase III trial on postoperative chemoradiation versus radiation alone. This study was supported by the RTOG, Eastern Cooperative Oncology Group (ECOG), and the Southwest Oncology Group (SWOG). Four hundred and fifty-nine patients with head and neck cancer who were noted to have high-risk features, that is, two or more positive lymph nodes, extracapsular spread, and/or positive margins, were randomized to either postoperative radiation or radiation plus cisplatin. Roughly, 20% of patients in either group had laryngeal malignancies. The conclusion was that concurrent postoperative chemoradiation therapy improved the rates of local and regional control and disease-free survival. Importantly, the combined treatment increased adverse effects. In a similar study conducted by the European Organization for Research and Treatment of Cancer (EORTC), the benefit of postoperative chemoradiation therapy in advanced head and neck cancer was demonstrated.

TREATMENT OUTCOMES

Premalignant Lesions and Carcinoma In Situ

The laryngeal pathology of squamous cell epithelium progresses through five categories: hyperkeratosis, hyperkeratosis with atypia, carcinoma in situ (CIS), superficially (micro) invasive carcinoma, and invasive carcinoma. Lesions that show atypia and CIS can be managed with local excision with clear margins. We follow these lesions monthly for 6 months with video stroboscopy and then at 2-month intervals for the first year. Lesions in this category are superficial to the basement membrane. Differentiation between severe hyperkeratosis with atypia and CIS is often difficult. The significance of this differentiation is more academic than clinical as these lesions are managed in a similar manner. Voice quality following surgical excision is dependent on the amount of tissue removed and the location of the tumor. Anterior commissure involvement and resection results in a decreased voice quality. Generally, voice outcomes are good with both surgery and radiation therapy.

Precancerous lesions and CIS should be managed surgically because radiation therapy will fail in 1 out of 10 patients. Successful surgical results are obtained when the entire lesion is resected with clear margins. This is best achieved with CO2 laser surgery. The need for rebiopsy and close surveillance for many years is discussed with the patient. We believe that radiation therapy should be reserved for those patients with a high anesthesia risk or those who do not wish to have repeated surgical procedures. Smoking cessation and antireflux therapy are of paramount importance for a successful outcome.

LARYNGEAL CANCER

Glottic Cancer

Squamous cell carcinoma of the glottis is usually well to moderately differentiated and presents at an early stage (T1 to T2). It is rarely associated with locoregional metastasis. This differs from supraglottic or laryngopharyngeal disease and is thought to be due to sparse submucosal lymphatics in the glottis. Symptoms usually appear early as most carcinomas originate on or near the phonatory surface of the vocal folds. Early-stage disease can be managed with radiotherapy or conservation surgery without the need for elective neck management. The surgical cure rates for T1 to 2 lesions reported in the literature range between 92 and 100%. Reexcision is required in 10 to 50% of patients, with an average of two procedures per patient. Surgical salvage can be done by reexcision, partial or total laryngectomy. Glottal function can be preserved in 92 to 100% of patients. V. voice quality following laser resection is comparable to radiation therapy results in selected cases. In our experience, the addition of corythoectomy significantly improves the voice quality, even when a cordectomy is performed. Local control rates for T1 to T2 lesions with radiation therapy are between 77 and 89% and as low as 70% for T3 lesions. Local cure by radiotherapy for glottic tumors, which almost always matches tumor-free survival, has not changed since 1974. Surgical salvage includes partial laryngectomy and total laryngectomy with voice preservation rates around 75%.

No clear advantage between surgery and radiotherapy has been noted in the literature for early glottic malignancy. Therefore, patients must be thoroughly counseled and involved in decision-making. Surgery is more successful for lesions with subglottic extension and impaired cordal mobility. Postirradiation edema lasting for longer than 3 months has a 43% association with persistent or recurrent disease and requires follow-up by endoscopy and imaging.

Tumor site is of importance in considering the varied therapeutic options. Middle third of vocal fold lesions are easiest to cure and respond well to radiotherapy, endoscopic laser resection, or open cordectomy. Surgical cure rates approach 100% for such lesions excised with good margins, while radiation therapy cure rates approach 95%. Radiation failures may be caused by unrecognized deep invasion. Endoscopically removed lesions are carefully observed via video laryngoscopy, with reexcision or radiotherapy used for recurrence. Radiation is a viable alternative to surgery, but recurrent disease or second primaries may not be amenable to conservation surgery. The anterior commissure is always of concern regarding radiotherapy.

Hypomobility of the vocal fold is associated with reduced cure rates after radiation therapy. Harwood and De Boer noted that impaired cord mobility resulted in lower control rates in T2 lesions, and they suggested the classification be divided into T2a and T2b on the basis of mobility. In this analysis, a 77% local control rate was noted for the former category versus 51% in the latter. In 1996, M. McLaughlin and colleagues reported an 11% recurrence rate for T2a lesions and a 26% recurrence rate for T2b lesions. Surgery salvaged six of nine T2b radiation failures.

T2 and early T3 lesions of the glottis have more recently been managed by supracricoid laryngectomy with criothyroidoepiglottopexy. This operation was championed in Europe in the late 1970s. Reports of this surgery performed in the United States began to enter the American literature in the early 1990s. The operation requires resection of the entire thyroid cartilage and paraglottic space. The criocoid cartilage, the hyoid bone, much of the epiglottis, and at least one arytenoid cartilage are preserved. A study of 36 patients reported satisfactory deglutition, phonation, and 100% decannulation with a 5% local recurrence rate. Sixty-one percent of the patients had been pretreated with chemotherapy. In a current series of 17 patients, 9 (53%) were able to resume eating a normal diet and 6 additional patients had moderate dysphagia. Voice quality was limited in range and intensity but was not equal to that of supraglottic laryngectomy. A total laryngectomy with tracheoesophageal puncture with or without postoperative radiotherapy is another option for T3 glottic cancer and may be the best alternative in some patients, that is, poor pulmonary reserve, poor chemoradiation...
candidates. The locoregional control rates with this approach range from 65 to 77% in some studies.\(^7\)

With the advent of chemoradiation therapy protocols, primary surgery for advanced laryngeal cancer is less common. Although there is no survival benefit demonstrated in recent studies, functional laryngeal preservation has been demonstrated.

**Supraglottic Cancer.** In managing supraglottic cancer, consideration of the neck is requisite. Early supraglottic (epiglottic) tumors, which are suprahypoid, can be grossly excised endoscopically with the CO\(_2\) laser. Suprahypoid lesions rarely involve the preepiglottic space, whereas the infrathyoid squamous cell carcinoma. CT and physical examination are not uniformly helpful in detection. The relationship between preepiglottic space invasion and metastasis to the lateral part of the neck is unclear but metastasis has a reported incidence of up to 50%, even for early tumors.\(^8\) Malignancies to either side of the neck can occur because the preepiglottic space has bilateral lymphatic drainage. It is acknowledged that invasion of the preepiglottic space is associated with a poorer prognosis.

Limited supraglottic tumors, defined as T1 to T3 (because the preepiglottic space invasion upstages the lesion), can be managed with an open supraglottic laryngectomy if the vocal cords are mobile. Limited arytenoid involvement and lateral extension to the medial aspect of the pyramid sinus are not contraindications to partial surgery. With the advent of transoral laser surgery, we believe this approach will fall out of favor. Extended supraglottic laryngectomies are associated with increased difficulty in deglutition. Also, these more aggressive tumors often require postoperative radiation. Extended resections that allow preservation of voice and airway can include removal of the vallecula and base of the tongue up to the level of the circumvallate papilla. Despite reconstruction, this surgical magnitude affects swallowing; and, when combined with radiotherapy, rehabilitation can be challenging.

The acknowledged risks for open excision of supraglottic malignancies, aspiration and altered deglution, make patient selection critical. You, motivated patients with good pulmonary reserve fare best. Minimal aspiration always occurs but, for the most part, is readily tolerated. However, those with chronic pulmonary disease and reduced ciliary clearance are at greater risk for pneumonia. Most still believe the ability to walk a flight of stairs is important in clearing patients for surgery.

Those failing therapeutic full course radiation for supraglottic lesions are at increased risk because of the inability to detect submucosal extent of the persistent carcinoma. Occasionally, when the original tumor configuration is completely understood and evaluation of the recurrent lesion is favorable, partial laryngeal surgery may be warranted. The morbidity for salvage surgery is increased due to wound healing issues, persistent edema, and pharyngeal dysfunction from radiation fibrosis.

**Subglottic Cancer.** Subglottic cancer is unusual. Shah and Shah reported that only 1% of 2,180 laryngeal cancers were located 1 cm below the vocal folds.\(^9\) The clinical presentation is usually airway obstruction. Not infrequently, the carcinomas are initially misdiagnosed as lower airway in origin. True subglottic lesions arise below the conus elasticus (1 cm below the free edge of the true vocal cord) and spread locally to invade the cricoid cartilage and thyroid gland with lymphatic spread to lower deep jugular lymph nodes, the Delphian node (prelaryngeal), and the paratracheal nodes.\(^8\) Management requires total laryngectomy because invasion of the laryngeal framework is common.\(^9\) Ipsilateral thyroidectomy and paratracheal node dissection are essential. Positive paratracheal nodes and extensive invasion requires postoperative radiotherapy to include the superior mediastinum to prevent sternal recurrence.

**FUTURE DIRECTIONS**

There is continued evolution in the surgical management of laryngeal cancer.

**Robotic Laryngeal Surgery**

Hockstein and colleagues, from the University of Pennsylvania, reported that it was feasible to use the da Vinci robot system for laryngopharyngeal surgery following studies with a human mannequin and a cadaver model.\(^90\) Later, this group reported the first transoral robotic supraglottic laryngectomy in a canine model.\(^92\) This work demonstrated that bleeding could be readily controlled with this technology. Monopolar cautery was used to perform the surgery, a technique thought to produce greater thermal injury than with an appropriately used CO\(_2\) laser. Recently, OmniGuide (Boston, MA) developed a hollow core fiber that allows transmission of CO\(_2\) laser energy through flexible instruments.\(^93\) We coupled this technology to the da Vinci Surgical Robot system to determine if the combined modalities would prove to be efficacious in the management of supraglottic laryngeal lesions. We conducted cadaveric dissections and animal studies demonstrating the utility of this technology.
Subsequently, a 74-year-old woman presenting with a large supraglottic malignancy had an endoscopic tumor excision, successfully, with this technology. The patient was able to swallow without difficulty on postoperative day 5. Follow-up endoscopic examination at 1 month showed no evidence of residual laryngeal tumor. Robotic CO₂ laser supraglottic laryngectomy was attempted in 2 additional patients; but adequate exposure could not be attained, and traditional approaches were utilized. Clearly, the daVinci Surgical Robot coupled with CO₂ laser technology can be used in selected instances for extirpation of supraglottic neoplasms. However, further development of this technology is needed for a greater applicability in the future.94

**Adjuvant Cryotherapy after Laser Resection of Early Glottic Cancer**

Based on our data inferring that adjunctive cryoablative therapy improved postoperative vocal outcomes in patients with early stage glottic carcinoma treated with laser resection, a prospective study was implemented to evaluate the vocal outcomes of patients managed with the combined modalities.31 Twenty patients with early stage glottic carcinoma were evaluated. The mean follow-up was 32.6 months. The primary outcome measures were disease free survival as well as subjective and objective measures of posttreatment vocal quality. Serial videolaryngoscopy was performed in all instances. The extent of the resection was graded, and three professional observers reviewed the videos in a blinded manner. The extent of the resection was graded according to the criteria of the European Laryngological Society Working Committee (ELSWC). Five patients had a Type I cordectomy, 8 had a Type II, 5 had a Type III, and 2 had a Type IV. One patient failed locally which gave an overall mean disease-free follow-up of 32.6 months (range, 3 to 93 months). CO₂ laser resection and cryoablative therapy were associated with a significant improvement in subjective voice quality (p < .0005). Long-term dysphonia was uniformly improved vis-à-vis the pretreatment condition, even among patients with the most advanced disease undergoing the widest resections. Post-treatment web formation was not noted among four patients with anterior commissure involvement. Based on this initial study we concluded that endoscopic laser laryngeal surgery performed in conjunction with cryotherapy for early-stage glottic carcinoma yielded excellent primary site control while improving subjective and objective measures of voice quality. Combined laser surgery and cryotherapy is a possible alternative to radiation therapy for selected patients with early-stage glottic carcinoma who desire curative therapy while optimizing vocal outcomes.

**LARYNGEAL TRANSPLANTATION**

The first successful composite human laryngeal transplantation was performed in our department on January 4, 1999.95 The recipient, a 40-year-old male, had sustained a crush injury to his larynx 20 years earlier, rendering him aphonic. Multiple prior attempted reconstructive efforts had failed. The donor was a 40-year-old male who had succumbed to a ruptured cerebral aneurysm. The primary consideration for laryngeal extirpation in the United States is cancer. Laryngeal transplantation in patients treated for malignancy would carry an unacceptable high risk of recurrent or second malignancy if conventional treatment with corticosteroids and calcineurin inhibitors were needed for immunosuppression.

Transplantation after tumor ablative surgery will only be possible when immunosuppression does not increase the risk of tumor recurrence. Everolimus is an immunosuppressive agent that has shown early evidence of potent antitumor activity. Our recent data lead us to conclude that everolimus can inhibit the in vivo growth of squamous cell carcinoma. Its antiproliferative and immunosuppressive capabilities make it attractive as a stand alone therapeutic modality or a partner in a dual treatment protocol.96,97

Diseases of the Salivary Glands

Rodney J. Taylor, MD
Jeffrey S. Wolf, MD

There are three paired major salivary glands in the human: parotid, submandibular, and sublingual. These glands drain via ducts into the oral cavity. Saliva from the parotid gland enters the oral cavity adjacent to the second maxillary molar tooth via Stensen duct. The submandibular gland duct, known as Wharton duct, opens into the anterior part of the floor of the mouth. Multiple sublingual ducts enter Wharton duct or may drain separately into the floor of the mouth. The minor salivary glands individually drain through the mucosa of the oral cavity and pharynx.

Histologically, salivary glands are composed of acinar and ductal cells. The organization of the glands is 80% acinar, 15% ducts, with the remaining percentage comprised of nerves, connective tissues, and blood vessels. The composition of saliva differs depending on the gland: the sublingual glands secrete mucous saliva, the parotid glands secrete serous saliva, and submandibular glands secrete both mucous and serous saliva. Saliva is 99% water and contains electrolytes, urea, lipids, amino acids, and proteins including digestive and other enzymes and immunoglobulins.

The primary secretion of saliva occurs in the acinar region of the glands where protein production and water secretion occurs. The initial saliva secreted in the acinus is hypotonic and as saliva travels down the branching ducts, the saliva secreted in the acinar region is modified by both protein secretion and salt reabsorption by ductal cells. The final saliva product that enters the oral cavity is isotonic.

The neural control of saliva production is a complex interaction of the sympathetic and parasympathetic nervous systems. Secretion of saliva occurs in response to both alpha- and beta-adrenergic stimulation as well as parasympathetic stimulation. There is a basal or resting flow of saliva as well as an inducible flow in response to stimulation which may increase 10 to 20 times over basal flow. Over a 24-hour period, 1 to 1.5 L of saliva are secreted.

ANATOMY

The parotid gland is located on the face between the ramus of the mandible and the mastoid process. The medial surface of the gland is surrounded by the musculature that originates on the styloid process. The gland has two “lobes” that are artificially divided by the facial nerve, the lateral lobe being significantly larger than the deep lobe. The parotid duct traverses the surface of the masseter muscle and crosses anterior to the ramus of the mandible one-finger’s breadth below the zygomatic arch. It turns medially to penetrate the buccinator muscle at the level of the second maxillary molar tooth.

The parotid is innervated by the glossopharyngeal nerve. The fibers begin in the inferior salivatory nucleus and travel with cranial nerve (CN) IX through the jugular foramen. Jacobson nerve travels back into the skull via the inferior tympanic canalculus into the middle ear. The nerve penetrates the roof of the tympanic cavity into the middle cranial fossa. It forms in part the lesser petrosal nerve which exits the skull at the foramen ovale where it synapses in the otic ganglion. The parasympathetic fibers join with the auriculotemporal nerve (V3) and enter the parotid gland with this nerve. The sympathetic fibers travel with the branches of the external carotid artery from the sympathetic ganglia to gland.

The submandibular gland occupies the majority of the submandibular triangle in the neck. It is located superior to the digastric tendon and against the mylohyoid and hyoglossus muscles. Like the parotid, it is composed of two lobes: a superficial lobe that is superficial to the mylohyoid and a deep lobe that extends behind the posterior part of the mylohyoid. In nonobese patients, the gland can usually be easily palpated in the neck. Wharton duct arises in the deep lobe of the submandibular gland and courses between the hyoglossus and the mylohyoid. It extends to the papilla on the floor of mouth lateral to the lingual frenulum. The duct passes underneath (medial) to the lingual nerve.

The submandibular gland is innervated by secretomotor fibers of the facial nerve which originate in the superior salivatory nucleus. They exit as the nervus intermedius and travel with CN VII until the descending portion of the nerve. The fibers then exit as the chorda tympani through the middle ear deep to the malleus and superficial to the incus and exit via the petrotympanic fissure. The chorda tympani joins the lingual branch of V3, and travels along the floor of mouth where parasympathetic fibers descend and synapse in the submandibular ganglion and enter the gland. The sympathetic fibers accompany the arterial blood supply.

The sublingual duct is closely associated with the distal half of Wharton duct and is located between the mylohyoid and hyoglossus muscles. The sublingual glands are innervated by parasympathetic fibers from the submandibular ganglion and the sympathetic fibers accompany its arterial supply.

SALIVA FUNCTIONS

There are many functions of saliva. The alpha amylase in saliva initiates digestion of starches into maltose. Saliva assists with taste perception as food dissolves in it and is carried to the pore of the taste bud. Perhaps most importantly, the wetness of saliva allows for lubrication of food into a slick bolus that is easily transported to the oropharynx. The flow of saliva can whisk away food debris that remains in the oral cavity, which is important for oral hygiene and the protection of the teeth. Lysozyme in saliva prevents overgrowth of oral microbes. Immunoglobulins in the saliva play an important immune role. In some nonhuman animals, evaporation of saliva during panting acts as a cooling mechanism.

INFLAMMATORY DISEASES OF THE SALIVARY GLANDS

Viral Infections

The best-known viral infection of the salivary glands is mumps. Mumps is a paramyxovirus infection and is transmitted by respiratory droplets. Inflammation of the parotid glands (parotitis) occurs in 40% of patients with the mumps. After a prodrome of nonspecific viral symptoms, patients may develop parotitis or infection at other sites: the testes, pancreas, eyes, ovaries, central nervous system, joints, or kidneys. The swollen parotid glands may be tender but are not typically erythematous or warm. Chewing and eating often exacerbates the pain associated with viral parotitis. Less commonly, submandibular and sublingual glands may also be involved.

Although it is typically a clinical diagnosis, mumps virus can be isolated from nasopharyngeal swabs, urine, blood, and fluid from buccal cavity typically from 7 days before up until 9 days after the onset of parotitis. Serious complications are uncommon but can include sensorineural hearing...
loss often unilateral, meningocencephalitis (1.5% mortality), pancreatitis, and orchitis.

Clinical mumps has become uncommon in communities where universal immunization with the measles, mumps, and rubella vaccine is practiced.

There are other acute viral parotid infections. Viruses such as parainfluenza, influenza, coxsackie, ECHO, and choriomeningitis virus may also cause parotitis. In patients with human immunodeficiency virus (HIV), adeno virus and cytomegalovirus can cause parotitis. The management of most cases of viral parotitis is supportive therapy.

HIV infection is associated with benign lymphoepithelial cysts of the parotid and possible glandular malfunction (Figure 1). It is unknown whether the HIV-associated parotid disease is caused by the virus itself or related to progressive lymphadenopathy associated with HIV. HIV-associated salivary disease may occur early in HIV disease when CD4 levels are within the normal range and this may be the initial presenting sign of HIV infection. Up to 20% of children with HIV will have salivary gland involvement.

Histologically, these glands are composed of multiple adjacent cysts. They contain lymphocytes and macrophages in a serous yellow fluid with cholesterol centers. There may be many features of HIV-related salivary gland disease including dry eyes, xerostomia, and arthralgia.

The lymphoid infiltration that occurs in some patients is known as “diffuse infiltrative lymphocytosis syndrome.” It shares clinical features with Sjögren syndrome; however, it differs in that the predominant infiltrating cells are CD8 positive T cells as compared to CD4 in Sjögren syndrome.

Diffuse infiltrative lymphocytosis syndrome may be favorable prog nostic marker in HIV disease.

Most HIV-infected patients with parotid gland benign lymphoepithelial cysts can be treated with observation and antiretroviral medication. For others, who are symptomatic or more concerned about their cosmetic appearance, sclerotherapy or repeated needle aspiration may offer a reasonable option. Radiation therapy and surgery should be reserved for select cases. There is concern for underlying Kaposi sarcoma and lymphoma in these cysts, which have been reported in up to 10% of patients.

Bacterial

A acute bacterial infections of the salivary glands accounts for 80% mortality rate in the nineteenth century. Among prominent persons to die of this disease was the twentieth president of the United States, James Garfield. In the antibiotic era, the mortality of bacterial parotitis and parotid abscesses has decreased dramatically.

There are many potential causes of bacterial sialadenitis. It is hypothesized that retrograde contamination from oral bacteria as well as stasis of salivary flow has import in the pathogenesis of acute suppurative lymphadenitis. Most commonly dehydration or obstruction from calculi leads to static salivary flow. Diseases, conditions, and medications that cause dehydration or decreased salivary flow are thus potential causative agents of sialadenitis. Traditionally, abdominal surgery, in which patients are on nothing by mouth (NPO) or third-spacing fluid postoperatively, may facilitate salivary gland infections. Chronic debilitating diseases such as liver or renal failure, malnutrition, and HIV infection are associated with higher incidence of sialadenitis. Bulimia and cystic fibrosis are also associated with acute bacterial salivary gland infections. Any conditions that lead to xerostomia, including Sjögren syndrome, and prior radiation as well as medications that cause xerostomia predispose patients to acute salivary gland infections. Certain occupations such as glass blowing and trumpet playing increase the risk of sialadenitis by both mechanical trauma to the ducts as well as retrograde contamination.

The populations most at risk of sialadenitis are people at the extremes of the age range, with the elderly population at the greatest risk. In addition to the decreased salivary quantity in the elderly, chronic debilitating illness can further contribute to dehydration and poor nutritional states. Patients with psychiatric conditions such as depression, anorexia nervosa, and bulimia are at increased risk of bacterial sialadenitis.

Although an acute infection can occur in any salivary gland, the major glands are more likely to become infected, especially the parotid. The parotid gland is at increased risk because it produces serous saliva which does not contain the quantity of mucins, glycoproteins, or antibodies that the more mucous secreting glands, that is, submandibular and sublingual glands do.

The pathogenic microorganism most commonly responsible for acute supplicative parotitis is Staphylococcus aureus. This is followed in frequency by Streptococcus pyogenes (Group A beta hemolytic Streptococcus), S. pneumoniae, and Hemophilus influenzae. Other microorganisms, such as gram-negative and anaerobic bacteria, can be found in salivary gland infections, but this is relatively uncommon. Immunosuppressed patients may have unusual microorganisms such as Salmonella species.

The clinical presentation of patients with acute sialadenitis includes pain and edema over the involved gland. It is unilateral 90% of the time. Stensen or Wharton ducts may be edematous or erythematous, and purulent material may be expressed by massaging the affected gland.

Patients may present with bacterial sepsis which is more common with parotid sialadenitis. Patients with acute parotitis may appear toxic and can progress to develop multiorgan system failure. The diagnosis of acute bacterial sialadenitis is predominantly clinical. With the exception of patients with abscesses, diagnostic imaging is not typically needed in acute sialadenitis (Figure 2). Laboratory testing may reveal a leukocytosis with predominance of neutrophils.

The differential diagnosis of acute sialadenitis includes other infections such as actinomycosis, cat scratch disease (CSD), and dental infections. Also included in the differential are autoimmune and inflammatory diseases such as Sjögren syndrome and Wegener granulomatosis, and neoplasms such as lymphomas.

The treatment of acute bacterial sialadenitis is hydration, warm compresses, and improved oral hygiene. Sialagogues function to increase salivary flow and along with salivary gland massage may improve clearance of the bacterial infection. Antibiotic therapy is needed and geared toward the treatment of gram positives and anaerobic bacteria. A augmented penicillins such as amoxicillin with clavulanic acid, ampicillin with sulbactam, and beta-lactams with anti-staphylococcal coverage are the primary treatment.

Neonatal Sialadenitis

Neonatal suppurative sialadenitis usually occurs in the parotid glands with a higher incidence in preterm and male neonates. Like bacterial parotitis in adults, it is usually caused by S. aureus; however, Escherichia coli and Pseudomonas species have also been reported. Data suggest that risk factors may include cytomegalovirus infection and maternal methyldopa use. This usually presents as fever, anorexia, and failure to gain weight. The glands may be unilaterally or bilaterally edematous, and the overlying skin may

Figure 1 Lymphoepithelial cysts in the parotid gland of patients with HIV. The left side of the figure contains a T2-weighted image of a cyst in the left parotid (arrow). Note the intensity of the cyst on T2. The right side of the figure is a T1-weighted image of bilateral parotid cysts (arrows).
become erythematous. Diagnosis is clinical with fine-needle aspiration (FNA) to collect purulent material for culture. Open drainage procedures are reserved for patients in whom clinical improvement does not occur or a frank abscess forms.24

Recurrent Parotitis of Childhood
Recurrent parotitis (RP) of childhood is of unknown etiology and is thought to be probably immune mediated.26 Although it is rare, it is second to mumps as the most common inflammatory salivary gland disorder in children. It has a biphasic age distribution with peaks at 3 and 10 years. Children suspected of this disease should be screened for Sjögren and immune deficiency syndromes.27 Signs and symptoms at presentation include recurrent episodes of glandular swelling, pain after a meal, fever, and malaise. The diagnosis is mostly clinical, and ultrasound can confirm this diagnosis. Treatment is supportive with hydration, gland massage, and sialogogues. Antibiotics are not beneficial in the treatment of this disease.26

Chronic Sialadenitis
Chronic sialadenitis is a localized condition of the salivary glands that is characterized by repeated episodes of painful inflammation that results in parenchymal degeneration and replacement of the gland by fibrous tissue. The average age of onset is the sixth decade, and patients with this disease have a history of acute sialadenitis. The repeated episodes of sialadenitis are thought to be caused by chronic obstruction of the ducts, ductal dilation, or decreased salivary flow. Over time, irreversible changes in the glandular architecture result in ectasia of the ducts and inflammatory and fibrous infiltration. Historically, treatment has been difficult and has included duct ligation, removal of the gland, and tympanic neurectomy. More recent treatment options include partial gland removal with duct preservation and intraductal infusion of penicillin or saline.28,29

Sialolithiasis
Salivary calculi may present as isolated events or in the setting of chronic sialadenitis. It is typically a disease of the sixth through ninth decades of life and may be largely responsible for the development of chronic sialadenitis.

Salivary calculi are usually composed of hydroxyapatite $[\text{Ca}_5(\text{PO}_4)_3(\text{OH})]$ combined with cations such as magnesium, ammonia, and zinc. Frequently organic material, such as protein and mucopolysaccharides, is also found in stones, and some stones are composed entirely of organic material.30

The etiology of stone formation has yet to be elucidated but may include a variety of factors such as salivary stasis, ductal narrowing, the presence of a nidus from trauma, or inflammation, and the absence of natural crystallization inhibitors such as myoinositol hexaphosphate.30 Eighty percent of salivary duct stones occur in the submandibular duct (Figure 3), 19% occur in Stensen duct (Figure 4), and 1% occurs in the sublingual ducts.12,32 This differential among glands is thought to be due to the viscosity of mucous saliva.12,33

The presentation of sialolithiasis consists of postprandial pain and edema. It may be a colicky type of pain with a classic crescendo pattern. The stone may be palpable along a duct. This is accomplished with a bimanual examination of the floor of mouth in patients with submandibular stones. Parotid stones present more of a challenge because the stones may be small, the buccal fat pad may make palpation more difficult, and 80% of parotid stones are radiolucent.34 Contrast studies can be helpful for identification of radiolucent stones associated with proximal duct dilation. Trauma to the duct from pressure may lead to fistula formation between the duct and the gland parenchyma. Ultrasound, magnetic resonance sialography (MRS) and digital subtraction sialography have been used with some success in diagnosing radiolucent stones.35–38 Recently sialoendoscopy has been utilized to diagnose and treat submandibular and parotid stones.39

Initial management of calculi is conservative and supportive. Nonsteroidal antiinflammatory medications, warm compresses, and sialogogues may be useful especially in the face of a non-obstructing stone. Stones near the ductal orifice can be “milked” out of the orifice, but most
require sialolithotomy. Occasionally, sialodochoplasty will be required to remove a stone. More "state-of-the-art" ways to remove stones include sialoendoscopy with basket retrieval and lithotripsy.35,39

GRANULOMATOUS SALIVARY GLAND DISEASES

Nontuberculous mycobacterial infections are most common in children 2 to 3 years of age. They usually present with an enlarging neck mass. These infections most frequently involve lymph nodes that are within or adjacent to the parotid and submandibular glands and will commonly have sinus tracts to the skin. The overlying skin may be discolored. The diagnosis is largely clinical and may require excluding other diseases. Tissue histopathology is usually nonspecific, and mycobacterial cultures usually take up to 6 weeks for the results. FNA biopsy can be used to make the diagnosis and is preferred over incisional biopsy. Imaging is nonspecific and reveals asymmetric adenopathy with contiguous low-density ring-enhancing masses.40 The treatment of choice is usually excision, which usually results in the most rapid resolution of the disease.41

Tuberculosis involves the salivary glands less commonly than cervical lymph nodes. These patients will have painless indolent enlargement of the parotid or submandibular glands. These infections are usually in lymph nodes within the glands rather than actual parenchymal disease. Other than the enlarged glands, the patient may be asymptomatic without constitutional signs or facial nerve involvement. A throat skin testing may lead to suspicion of tuberculosis. Diagnosis of glandular involvement is usually made by excisional biopsy of the gland. More recently, polymerase chain reaction (PCR) techniques have been described as a diagnostic modality for this disease.42 A nontuberculous chemotherapy is needed to treat systemic disease.

Actinomycosis of the salivary glands is rare and has been most commonly described in the parotid gland.43–45 Most cases are odontogenic and are thought to spread retrograde along salivary ducts. Actinomycosis occurs predominantly in immunocompetent individuals, and patients present with painless enlargement of the involved gland. Causative microorganisms are bacteria of low pathogenicity and cause disease only in the setting of antecedent tissue injury, such as dental work. The disease process is characterized by the formation of induration of tissues and draining sinuses that discharge "sulfur granules." Diagnosis is usually made through culture of Actinomyces species (Actinomyces israelii, A. bovis, A. naelsundii) from clinical specimens, or microscopic visualization of gram-positive, non-acid-fast, thin, branching filaments in cytologic specimens. Penicillin is the drug of choice and is usually administered for 2 to 12 months. Surgical therapy is often indicated for curettage of bone, resection of necrotic tissue, excision of sinus tracts, and drainage of soft tissue abscesses. The prognosis for treated infection is excellent.

CSD is a type of granulomatous lymphadenitis that may involve the salivary glands. Greater than 90% of patients have a history of exposure to cats. Approximately 70 to 90% of CSD cases occur in the fall and early winter months. This seasonality is presumed to be due to a mid-summer rise in kittens acquired by increased flea infestation. In most children and adolescents, swollen lymph nodes are the main symptom of the disease, and the illness often is mild. A bout one-third of patients with CSD have generalized symptoms. These include fever, headache, odynophagia, fatigue, loss of appetite, headache, rash, and malaise. In the United States, about 22,000 cases are diagnosed annually, most of them in people under the age of 21. With salivary involvement, the patients will present with edematous glands or masses within the salivary gland. The skin over these swollen lymph nodes may become warm and red, and occasionally the lymph nodes drain purulent material. The causative agent is Bartonella henselae, and the serologic test for CSD is positive in 90% of the patients.46 PCR techniques expedite the diagnosis. Elevated serum titers can be found 1 to 3 weeks after the onset of the illness. The titers continue to rise for the first 8 weeks and then gradually decrease over the next several months.47 The disease is usually self-limited, but for persistent cases as well as immunocompromised patients, antibiotics may be needed. Typical first-line treatment for CSD is azithromycin or rifampin.

Tularemia is an insect-borne disease that may involve the parotid gland. The most common hosts in the United States are ticks and the cottontail rabbit. After an incubation of 3 to 4 days, a papule forms at the site of cutaneous transmission. Involved lymph nodes may enlarge and drain, and the infected patients may develop fever, myalgias, malaise, or headache. The causative microorganism Francisella tularensis is difficult to isolate from the blood, and the diagnosis is most commonly made with serologic tests. The treatment is with aminoglycosides and fluoroquinolones.

Toxoplasmosis is caused by Toxoplasma gondii and is usually contracted by exposure to domestic cats. Humans can become infected with T. gondii by ingesting either material contaminated with infectious oocytes or tissue cysts contained in raw or undercooked meat from another intermediate host. The parotid gland may be involved through intraparotid lymph nodes. Most cases of toxoplasmosis in the immunocompetent host are subclinical or benign. The most severe symptoms occur in the congenitally acquired form and in immunocompromised hosts. In the severe and disseminated cases, patients will also develop myalgia, anorexia, necrotizing encephalitis, pneumonitis, hepatosplenomegaly, and myocarditis. The diagnosis of toxoplasmosis is usually made by immunoglobulin M (IgM) immunofluorescent antibody (IFA) test. A naught IgM -IFA titer of 1:160 or greater or an IgM enzyme-linked immunosorbent assay (ELISA) titer of 1:256 or greater is considered diagnostic of recently acquired T. gondii infection. The treatment consists of a combination of pyrimethamine and a sulfonamide (or clindamycin) in immunocompetent adults.48

SALIVARY NEOPLASMS

Benign and malignant salivary neoplasms encompass as broad and diverse a histologic spectrum as found in any organ system (Table 1). Although they are relative rare, their range of clinical behavior is wide.

Pathogenesis of Benign Salivary Gland Neoplasms

The salivary gland unit and its component cell types provide the basis for understanding the development of the array of neoplasms of the salivary glands. The multicellular theory postulates that the multiplicity of cell types in normal salivary glands have the potential to give rise to any of the numerous neoplasms occurring within the salivary glands. Evidence for this is based on
70% of all tumors being benign.\textsuperscript{51} Nagler and similar anatomic distribution, with approximately a decade later than benign neoplasms. Spiro reviewed the largest series, which approximately 45% had adverse effects on the long arm of chromosome 8.\textsuperscript{52} Others have shown that overexpression of pleomorphic adenoma gene 1 (\textit{PLAG1}) proto-oncogene in vivo and in transgenic mice produces the growth of both pleomorphic and malignant salivary neoplasms following reciprocal chromosomal translocations involving 8q12.\textsuperscript{54-56} The association of p53 in the tumorigenesis of malignant salivary gland neoplasms appears to be modest with less than 15% of malignant neoplasms having alterations in p53 tumor suppressor gene.\textsuperscript{57-59}

Environmental Factors

Prior exposure to ionizing radiation is associated with a higher risk of developing both benign and malignant salivary gland neoplasms. A population-based study of atomic bomb survivors who were followed by the Radiation Effects Research Foundation (RERF) in Hiroshima and Nagasaki, Japan, demonstrated that individuals who were exposed as a result of the atomic bomb had a higher rate of benign and malignant neoplasms, particularly mucoepidermoid carcinoma (MEC).\textsuperscript{60} Additionally, those having received radiation to the head and neck demonstrated a 2.6-fold increase in benign salivary neoplasms and a 4.5-fold increase in malignant salivary neoplasms involving the parapharyngeal space and those suspicious for malignancy, imaging is recommended to assess the extent of involvement of adjacent vital structures. A high-resolution computed tomography (CT) with contrast or magnetic resonance imaging (MRI) with gadolinium provides excellent characterization of neoplasms in the context of the local anatomy. The strength of CT is its ability to delineate fat planes and vascular structures, as well as demonstrate bone involvement. Its disadvantage is that it gives exposure to ionizing radiation and may be compromised by dental artifact; furthermore, it distinguishes inflammation from neoplastic processes less well. Prefavoride tumors of the parapharyngeal space can be easily identified by CT with location of the carotid artery and medial displacement of the parapharyngeal fat pad.\textsuperscript{69} A also, studies have shown that low-grade and benign neoplasms appear as well-demarcated, homogeneous lesions on CT in

DNA studies which have demonstrated that basal duct cells, luminal cells at all levels of the duct system, myoepithelial cells, and acinar cells are all capable of aberrant proliferation.\textsuperscript{69} In contrast, the semipluripotential bicellular theory proposes that stem cells in the intercalated duct and excretory duct give rise to the variety of neoplasms that are observed.\textsuperscript{60}

### Incidence

Salivary gland neoplasms comprise approximately 3 to 4% of head and neck neoplasms. They most commonly present in the fifth to sixth decades with malignant tumors presenting approximately a decade later than benign neoplasms. Spiro reviewed the largest series, which included 2,807 salivary gland neoplasms over a 35-year period. The parotid gland represents the most common site (70%), followed by the minor salivary glands (22%), and the submandibular gland (8%). Other large series show a similar anatomic distribution, with approximately 70% of all tumors being benign.\textsuperscript{51} Nagler and Laufer reviewed 245 patients with salivary gland neoplasms and found that 73.5% were benign and 68% occurred in the parotid gland with pleomorphic adenoma representing the most frequent histopathologic type (76%).\textsuperscript{52}

### Genetic Alterations

Although the precise genetic sequences leading to tumors are not known, increasingly genetic alterations are being discovered that are associated with several neoplasms. The range of alterations include loss of heterozygosity, chromosomal rearrangements, point mutations, and monosomy or polysomy. El-Nagar and colleagues reported that 4 of 11 pleomorphic adenomas (36.4%) had allele loss on the long arm of chromosome 8.\textsuperscript{52} Others have shown that overexpression of pleomorphic adenoma gene 1 (\textit{PLAG1}) proto-oncogene in vivo and in transgenic mice produces the growth of both pleomorphic and malignant salivary neoplasms following reciprocal chromosomal translocations involving 8q12.\textsuperscript{54-56} The association of p53 in the tumorigenesis of malignant salivary gland neoplasms appears to be modest with less than 15% of malignant neoplasms having alterations in p53 tumor suppressor gene.\textsuperscript{57-59}

### Radiographic Evaluation

Routine imaging is not essential for small neoplasms involving the superficial part of the parotid gland. However, for large neoplasms, submandibular and minor salivary neoplasms, neoplasms involving the parapharyngeal space and those suspicious for malignancy, imaging is recommended to assess the extent of involvement of adjacent vital structures. A high-resolution computed tomography (CT) with contrast or magnetic resonance imaging (MRI) with gadolinium provides excellent characterization of neoplasms in the context of the local anatomy. The strength of CT is its ability to delineate fat planes and vascular structures, as well as demonstrate bone involvement. Its disadvantage is that it gives exposure to ionizing radiation and may be compromised by dental artifact; furthermore, it distinguishes inflammation from neoplastic processes less well. Prefavoride tumors of the parapharyngeal space can be easily identified by CT with location of the carotid artery and medial displacement of the parapharyngeal fat pad.\textsuperscript{69} Also, studies have shown that low-grade and benign neoplasms appear as well-demarcated, homogeneous lesions on CT in

### Clinical Evaluation

Typically, patients with salivary gland neoplasms will present with a painless, unilateral mass. Benign neoplasms are slow growing and tend to have longer duration of symptoms. Rapid change in size may be the result of obstruction of Stensen duct causing sudden enlargement or may arise from cystic degeneration. A accelerated growth in a longstanding neoplasm is a warning of possible malignancy arising from a pleomorphic neoplasm. Malignant neoplasms occurring in the parotid gland are frequently painless but may be associated with pain and facial weakness. Benign neoplasms of the submandibular gland are generally painless. Malignant submandibular neoplasms may invade the lingual and hypoglossal nerves, mandible, floor of mouth and tongue, and such involvements are hallmark of advance disease. Symptoms arising from neoplasms of minor salivary glands depend on their location; intraorally, the first signs may be poorly fitting of dentures, loose teeth, and malocclusion.

A comprehensive head and neck examination should be performed to assess the extent of the neoplasm. Intraoral examination may reveal bulging of the pharyngeal wall arising from deep lobe involvement of the parotid gland or from a minor salivary neoplasm in the parapharyngeal space. Cranial neuropathies may indicate neural involvement from adenoid cystic carcinoma (ACC). Careful examination of the neck may reveal cervical lymph node metastasis of a high-grade malignant neoplasm. Dermatological examination of the scalp and face is crucial and may confirm a cutaneous malignancy. Other sites of involvement from minor salivary gland neoplasms include the palate, lacrimal gland, sinonasal tract, and larynx.

contrast to high-grade lesions which appear as infiltrative and ill-defined.70

M RI provides superior soft tissue detail without ionizing radiation; however, its high expense, sensitivity to motion, poor osseous detail, and contraindication for patients with implants are limiting factors. Fat, muscle, nerves, and other soft tissue structures have more clearly differing enhancement characteristics, which provides a mechanism for better soft-tissue detail. M RI is superior in its ability to delineate involvement of the pterygoid musculature, dural involvement of extensive skull-base lesions, and perineural involvement.71,72 Both imaging modalities can effectively identify nodal metastasis. Indeed, for extensive neoplasms with suspected bony involvement, M RI and CT may complement each other in the diagnostic work-up. Presently, positron emission tomography (PET) has not proven sufficiently accurate for routine utilization.73

**Cytologic Evaluation**

FNA has emerged as a safe, accurate tool in the work-up of patients with salivary gland neo-

plasms. Certainly, the experience of the cytopathologist has an impact on the accuracy for the various histologic subtypes which may be challenging even for the expert cytopathologist. There is some debate regarding the indications for FNA. Many believe it is not warranted when the result will not change the management. Supporters feel that when a malignancy is diagnosed, it permits better preoperative planning and counseling for the patient. In some instances, it may preclude surgical intervention by detecting non-neoplastic processes or secondary involvement from metastatic spread. Baccoto and colleagues reviewed 841 FNA’s collected over a 16-year period to assess their overall accuracy.73 The overall accuracy was 97%; the sensitivity to the presence of a neoplasm 98%, and the specificity for absence of a neoplasm 98%. Heller and colleagues reviewed 169 consecutive patients presenting at a tertiary academic medical center who had FNA performed for salivary gland masses who also went on to surgical resection.74 Eleven percent of the samples were not adequate for evaluation; the FNA diagnosis of malignant or suspicious lesion had positive and negative predictive values of 84% and 77%, respectively. Half of the 10 patients with false-negative FNA results were found to have low-grade lymphoma on the final histologic evaluation. FNA diagnosis of a benign neoplasm had positive and negative predictive values of 83% and 88%, respectively. A cytopathologic diagnosis of a nonneoplastic lesion was predictive in only 47% of cases. Others have reported accurate diagnosis of malignant tumors whereas the diagnosis of nonparotid neoplasms may be less accurate and the overall accuracy may be less in nontertiary less experienced centers, ranging from 44 to 88%.75,76

**Histologic Types of Benign Neoplasms**

**Pleomorphic Adenoma.** Pleomorphic adenoma (benign mixed tumor) is by far the most common histologic subtype of all of the salivary glands neoplasms, and represents approximately 70% of parotid neoplasms, and three-quarters of all benign neoplasms.71 Pleomorphic adenoma was believed to derive from a pluripotential reserve cell of the intercalated duct that gives rise to both epithelial cells and stromal producing myoepi-

thelial cells. The stromal component may vary and can be myxoid, chondroid, or osteoid. Generally, there is a thin capsule with pseudopod extension of the neoplasm through the capsule. For this reason, enucleation leads to unacceptable recurrence rates and risk of neoplasm spillage. Most neo-

plasms (nearly 90%) occur in the superficial lobe, and a wide cuff of normal parotid tissue or super-

ficial parotidectomy is the recommended treat-

ment. Neoplasms that extend to or originate in the deep lobe require a total parotidectomy. For those that arise in the submandibular gland, complete excision of the gland is also recommended. Observation of pleomorphic adenomas is not recommended in young or healthy individuals because of the risk of malignant transformation. Although the risk is small early on, it increases to 10% for neoplasms present for greater than 15 years.74

**Warthin Tumor.** Warthin tumor is the second most common benign salivary gland neoplasm and occurs almost exclusively in the parotid gland. It is also referred to as papillary cystade-

nomatous lymphomatous. Warthin tumors represent 10% of parotid tumors and are bilateral 10% of the time; there is a strong male predominance and an association with tobacco exposure.68,81 Most commonly, these neoplasms are located near the angle of the mandible, occurring in the tail of the parotid. Microscopically, these neoplasms are characterized by papillary epithelium with a lymphoid stroma projecting into cystic spaces with a double layer of oncocytic cuboidal cells. It is believed that these tumors arise from ectopic ductal epithelium in intraparotid lymph nodes.78 Superficial parotidectomy is the recommended treat-

ment for complete excision and avoidance of recurrence.

**Basal Cell Adenoma.** Basal cell adenoma is the most commonly occurring monomorphic ade-

noma and occurs most commonly in the upper lip. These are usually well-capsulated, slow-

growing lesions that may also occur in the parotid gland. Microscopically, several growth patterns may be observed, and confusion with the solid growth pattern of adenoid cystic carcinoma may arise. Generally, basal cell adenomas will have a more visible capsule, lack invasion and perineur-

al spread, and has rows of peripheral palisading cells with a thick basement membrane. Complete excision with a margin of normal tissue is the recommendation for treatment.

**Myoepithelioma.** Myoepitheliomas are derived from the myoepithelial contractile cells that line the duc
tal unit. As with most benign salivary neo-

plasms, they are well demarcated and have a thin capsule histologically. The cells are homogenous and oval to polygonal shape but sometimes may have a spindle appearance.82 Scibba and Brannon reviewed 23 cases in which 70% demonstrated a spindle cell type, 17% a plasmacytoid cell type, and the remainder mixed. Twelve of 23 were in the parotid, while 22% each were found in both the submandibular gland and minor salivary glands. There was no observed difference in clinical behavior based upon cell type. These neoplasms tend to have an innocuous clinical course with complete excision being the treatment of choice.

**Canalicular Adenoma.** Canalicular adenoma is an uncommon, clinically nonaggressive tumor that classically occurs in the elderly and involves the minor salivary glands of the oral cavity, the upper lip being the most prevalent site.83 They may have the cystic appearance of a mucocele and at times are multifocal.84 Histologically, these neoplasms are well circumscribed and lack any destructive features; occasionally they may be unencapsulated. The cells are aligned in parallel rows in a canalicular-fashion. Complete excision is the treatment of choice.

**Oncocytoma.** Oncocytomas are benign neo-

plasms that occur in all of the major as well as minor salivary glands with the parotid being most common site. A painless, slow-growing mass in a middle-aged adult is the typical presentation. The cell of origin is the mitochondrial-rich oncocyte. These tumors are encapsulated and granular in appearance microscopically, owing to the abun-
dant mitochondrial content. The lack of lymphoid component readily distinguishes it from a War-

thin tumor. These tumors may cause diagnostic challenges with other neoplasms comprised of clear cells, such as MEC, acinic cell carcinoma, “clear cell” oncocytoma, epithelial-myoepithelial carcinoma, clear cell adenocarcinoma, and met-

astatic renal cell carcinoma.85 When they are found in minor salivary glands, they may assume a clinically more aggressive behavior and infiltrate local structures. Although rare, malignant oncocytic carcinoma does exist and should be distinguished from its benign counterpart. Surge-

cal excision is the recommended treatment for benign oncocytomas.86

**Oncocytic Papillary Cystadenoma.** Oncocytic papillary cystadenoma is a rare lesion and has been described most frequently in the larynx but has been seen in the nasopharynx and oral cavity. It usually occurs in the supraglottis in the elderly and may present with hoarseness or upper airway obstruction.87 The pathogenesis of the lesion is debatable, and some question if it is a true neo-

plasm or a process of metaplasia-hyperplasia from the duc
tal epithelium. They are painless, solitary masses that present with hoarseness when involving laryngeal structures and may be confused for other cystic laryngeal structures.88 These tumors histologically are similar to War-

thin tumors, but they lack a lymphoid matrix. Treatment is surgical excision.

**Sebaceous Adenoma.** Sebaceous adenomas are uncommon and usually asymptomatic. Sebaceous glands are commonly present in parotid and sub-
mandibular glands. The neoplasms are classified as sebaceous lymphadenoma or sebaceous ade-

noma. Histopathologic observations strongly sug-

gest that sebaceous lymphadenomas arise from
Histology, with a biphasic growth pattern of exo-

Sialadenoma papilliferum had a more complex
to arise from the excretory ducts at a deeper level.

Microscopy, inverted ductal papillomas appeared
the upper lip, and the buccal mucosa. With light

tively. The sites for the three intraductal papillo-

ance. The sialadenoma papilliferums presented
as papillary lesions clinically. The inverted ductal
papillomas and intraductal papillomas appeared as
submucosal nodules. The lip and the palate were
the most common locations for inverted ductal
papilloma and sialadenoma papilliferum, respect-
ively. The sites for the three intraductal papillo-
mas were the parotid papilla of the Stensen duct,
the upper lip, and the buccal mucosa. With light
microscopy, inverted ductal papillomas appeared
to arise from the excretory ducts near the mucosal
surface, whereas intraductal papillomas appeared
to arise from the excretory ducts at a deeper level.
Sialadenoma papilliferum had a more complex
histology, with a biphasic growth pattern of exo-

phytic papillary and endophytic components.92
Sialadenoma papilliferum has a recurrence rate of
10 to 15% and seems to assert a more significant
biological behavior than inverted ductal papili-
oma and intraductal papilloma. Surgical excision
is recommended.

Histologic Types of Malignant Neoplasms

Just as is the case with their benign counter-
parts, there is a wide variety of histologic types
of malignant neoplasms. The broad categories
include carcinomas, adenocarcinomas, malignant
mixed neoplasms, lymphomas, and metastatic.
Malignant neoplasms account for less than 15% of
all salivary neoplasms; hence they are even
more rare than benign salivary neoplasms. Sev-
eral malignant histologic types are more frequent
and emphasis will be placed on them. The loca-
tion in the salivary subunit in which the neoplasm
originates is believed to correlate with its clinical
aggressiveness with those of the excretory duct
behaving more aggressively than neoplasms from
the intercalated duct region.93 Advanced-stage
neoplasms generally are associated with a worse
survival. Tables 2 and 3 describe American Joint
Committee on Cancer TNM categorization and
TNM staging, respectively.

Mucocoeplidermoid Carcinoma. Mucocoepli-
dermoid carcinoma (MEC) is the most common
malignancy of the salivary glands; the parotid

gland represents the most common site account-
ing for 70% of these neoplasms. It is the second
most common malignancy of the submandibu-
lar glands following ACC. MEC is the most
common salivary malignancy of childhood. For

minor salivary neoplasms, the palate and buccal
mucosa are the most frequent sites. Patients may
present with a range of symptoms, including a
painless, slow-growing mass to a rapidly enlarg-

ing mass and cervical metastasis, with or without
facial nerve paralysis. The biological behavior is
related to histologic grade of the neoplasm. Well-
differentiated (low grade) neoplasms have a low
propensity for local invasion and metastasis, while
poorly differentiated (high grade) neoplasms may
be locally aggressive with regional and distant
metastases (DM). Moderately differentiated
(intermediate grade) neoplasms have a tendency
for local recurrence but metastasize uncommonly.
Histologically low-grade neoplasms have more
mucinous cells (>50%) while high-grade neo-

plasms may a paucity of mucinous cells that may
only be detected by immunohistochemical mark-

ers. A US Armed Forces Institute of Pathology
(AFIP) review of 234 MECs demonstrated that
75% of patients were neoplasm free at 5 years,
but clinical features associated with metastasis
or death were advanced age, neoplasm size, and
preoperative symptoms. Histopathologic features
that are associated with poor outcome were cystic
component less than 20%, four or more mitotic
figures per 10 high-power fields, neural involve-
ment, necrosis, and anaplasia.94

Adenoid Cystic Carcinoma. Billroth is cred-
ited for first describing this intriguing neoplasm
with unique features, but the term “adenoid cy-
tic carcinoma,” which describes its histologic
appearance was not coined until 1953. ACC is the
second most common salivary malignancy with
most series reporting the majority occurring in
the submandibular gland and minor salivary
glands.95,96 Some of the hallmarks of ACC are its
slow growth with lengthy presentation and its
propensity for perineural spread. A painless
growth is the most common presentation with
neural deficits depending on the site of involve-
ment, including unilateral tongue weakness, face-
nal paralysis, and trigeminal nerve distribution
symptoms.

Three main histologic subtypes based upon
neoplasm architecture are recognized, which cor-
relate with prognosis and clinical behavior: cri-
biform, tubular, and solid. The cribriform pattern
has a glandular architecture with the classic fea-
tures of a “Swiss cheese” appearance where cells
are arranged in clusters and are separated by oval
spaces. The tubular pattern demonstrates elon-
gated tubular structures that have a central lumen
and also show a glandular architecture. The solid
pattern is characterized by high cellularity with
sheets of cells with little evidence of glandular
architecture. Any given neoplasm may have ele-
ments of all of the patterns, which leaves the
pathologist with the challenge of deciding which
pattern predominates. Patients with neoplasms
with the solid pattern predominating have the
worst prognosis while those with the cribriform
pattern have the best. Those with tubular pattern
have an intermediate prognosis.97

ACC is renowned for its tendency for both
local and distant recurrence that may occur follow-

ing definitive treatment. ACC has a strong
proclivity for neurotropism and perineural
spread, with a tendency for tracking along major
neural structures. Skip lesions are common and
are seen in most of these neoplasms, although it
is believed that perineural spread occurs along
the path of least resistance and is microscopically
contiguous with the primary neoplasm. Garden
and colleagues reported on the 30-year experience
at MD Anderson Cancer Center with 198 sali-
vary and lacrimal ACCs; 62% occurred in minor
salivary glands, 21% in the submandibular gland,
and the remaining among parotid and lacrimal
glands.98 Among these patients, perineural spread
was found in 69%, with named nerves involved
28% of the time. DM was the most common site
of failure (37%), but skull base and neck recur-
rences were also frequently observed. Micro-
scopical disease and involvement of named nerves
lead to worse prognosis, but with postoperative
radiation, locoregional control was improved.

Cervical metastases are uncommon for ACC
while distant failure occurs frequently, often
years after treatment. Patients may survive for

</table>
protracted periods even in the presence of local and DM. Most recurrences occur in the first 5 years but recurrences occur commonly 20 years later and more. Common sites of hematogenous distant spread include lung (70%), bone, and liver. Because of frequent late failure, actual survival rates have been difficult to assess. Initial extent of disease was the dominant prognostic factor with advanced age and duration of symptoms also associated with poor outcome. Patients with advanced disease at presentation and those with neoplasms located in the submandibular region and sinonasal tract had worse outcomes.

Fordice and colleagues reviewed 160 patients at MD Anderson Cancer Center with ACC during the 20 years between 1977 and 1996, with 140 treated with surgery and postoperative radiation therapy. The average age was 49.5 years. Combined treatment yielded an 85% locoregional freedom from relapse, and disease-specific survival at 5, 10, and 15 years was 89, 67.4, and 39.6%, respectively. Thirty-five patients (21.9%) had DM as the only site of failure. Perineural invasion of major nerves, positive margins at surgery, and solid histological features were associated with increased treatment failures. Four or more symptoms present at diagnosis, positive lymph nodes, solid histology, and perineural invasion of major nerves were associated with increased mortality from the neoplasm.

Spiro and colleagues reviewed 196 previously untreated, patients with ACC treated at Memorial Sloan-Kettering Cancer Institute with minimum 10-year follow-up to evaluate the factors contributing to DM. Variables assessed for their impact on DM included age, gender, site, size, node status, stage, grade, and locoregional treatment failure. Treatment failure occurred in a total of 122 of 196 determine patients (62%), 74 (38%) of whom had DM, which was usually associated with locoregional recurrence (51 patients), but DM was the only indication of failure in 23 whose primary neoplasm was controlled. Of the 74 patients with known DM, the length of disease was recorded as the only involved site in 50 patients, but was involved in addition to other sites in 17, bone metastases alone occurred in 5, and the remaining 2 developed disseminated disease. Disease-free intervals varied from 1 month to 19 years (median 36 months) and exceeded 10 years in 9 of 113 patients (8%) with adequate information about treatment failure. Survival with DM was less than 3 years in 54%, but more than 10 years in 10% (maximum 16 years). The only significant factors influencing survival were the size of the primary neoplasm (p < .0001), local or nodal recurrence (p = .0006), and the presence of nodal involvement (p = .02).

Acinic Cell Carcinoma. Acinic cell carcinoma accounts for approximately 6% to 8% of salivary gland malignancies, with 81 to 97% occurring in the parotid gland and it is the second most common pediatric salivary gland malignancy. It commonly presents as a painless parotid mass, with facial weakness being rare. It has a 3% chance of occurring bilaterally, second only to Warthin neoplasm in that regard. It tends to have a benign biological course and has the best overall outcome of all salivary gland malignancies. Rarely, a more aggressive form occurs.

There are several histologic subtypes that do not generally correlate with survival. They include: solid, microcystic, papillary cystic, and follicular with the majority of cancers displaying multiple cell types. The intercalated duct or reserve cells of the terminal duct are believed to be sites of origin. Acinic cell carcinoma may have morphologic features similar to other clear cell carcinomas, such as MEC, epithelial-myoid epithelial carcinoma, oncocytoma, and renal cell carcinoma. Rarely, there is a form of acinic cell carcinoma that is differentiated with a more aggressive biological activity and worse prognosis; it usually has a higher rate of mitotic activity, nuclear atypia, and solid growth pattern. Spiro and colleagues reviewed 67 patients treated over a 30-year period, and patients with small neoplasms without local invasion did extremely well. However, larger, more extensive neoplasms had a much worse survival. Cure rates for the entire series were 76, 63, and 55% at 5, 10, and 15 years, respectively. Cervical lymph node metastases occurred in 16% of the patients, and DM in 12%. Hoffman and colleagues evaluated 1,353 cases registered in the National Cancer Data Base for the years 1985 to 1995. Five-year disease-specific survival was 91.4%. Worse survival was associated with high grade (p < .0001), age greater or equal to 30 years (p = .0055), and the presence of metastatic disease (p < .0001). Although acinic cell carcinoma usually has a favorable course, rarely an aggressive form occurs.

Adenocarcinoma. It is important to clarify that because malignancies arising in the salivary ductal unit are technically termed adenocarcinomas, adenocarcinoma not otherwise specified (nOS) refers to a salivary malignancy that is generally high grade, has a high rate of metastases, and has a poor survival. They frequently have the morphologic features of adenocarcinomas of the breast and lung. They represent 1 to 9% of salivary malignancies, and occur in minor salivary glands most commonly (68%), followed by the parotid gland (28%) and submandibular gland (8%). The prognosis of adenocarcinoma nos was among the worse of any histologic type with a 10-year survival of 55%; locoregional recurrences and DM were common.

Polyphormous Low-Grade Adenocarcinoma. Distinct from other adenocarcinomas, polymorphous low-grade adenocarcinoma (PLGA) has a much more benign clinical course. It was first described in 1983 and has a strong propensity for minor salivary glands, although it infrequently occurs in the parotid gland as well. It has also been termed terminal duct carcinoma and is thought to be derived from the intercalated duct region of the salivary unit. The palate and buccal mucosa are the most common sites. Its tendency for perineural spread sometimes causes diagnostic confusion with ACC. PLGA frequently presents as an incidental finding on examination: painless mass or change in denture fit.

One hundred sixty-four patients with PLGA were reviewed at the AFIP and evaluated for prognostic factors. There was a 2:1 female to male predominance, and ages ranged from 23 to 94 years (average, 57.6 years). Most presented clinically with a palatal mass that ranged in size from 0.4 to 6 cm (average, 2.2 cm). The neoplasms were characterized by a polymorphous growth pattern, with individual neoplasms demonstrating solid, ductotubular, cribriform, trabecular, and single-file growth. Neurotropism was seen frequently. With a mean follow-up of 115.4 months after presentation, 97.6% of all patients were either alive or had died without evidence of recurrent disease after treatment with surgical excision alone. Batsakis and Luna reported 69 patients with PGLA who demonstrated a 12% recurrence after surgery and a 10% rate of metastases and one death. PGLAs may frequently recur and metastasize, but are characterized by a favorable clinical course with surgical excision as the treatment of choice. There is no established benefit of radiation therapy for patients with this disease.

Salivary Duct Carcinoma. Salivary ductal carcinoma (SDC) is among the most aggressive behaving salivary malignancies. It accounts for approximately 1% of salivary gland malignancies and generally occurs in the parotid gland. Histologically, it is high grade and similar to mammary ductal carcinoma; mitoses are frequent, and DM is the rule. Lewis and colleagues reviewed 26 cases of SDC treated at the Mayo Clinic from 1960 to 1989. The population consisted of 22 men and 4 women (mean age, 66 years). SDC involved the parotid 88% and the submandibular gland 12% of the cases. Only 21% were diploid and 79% were nondiploid. Local recurrence occurred in 35%, and DM developed in 62%. The 5-year survival was only 30% with 77% of the patients dying of the neoplasm at a mean interval of 3 years after diagnosis. Batsakis and Luna reviewed 30 patients, of whom 45% had local recurrences while both regional and DM were found in 66%. Despite treatment with radical parotidectomy, neck dissection and postoperative radiation, survival was dismal.

Malignant Mixed Neoplasm. Malignant mixed neoplasm is an umbrella term that encompasses carcinoma ex-pleomorphic adenoma (CXA), carcinosarcoma, metastasizing mixed neoplasm (MZMT). These constitute 3 to 12% of all salivary gland malignancies. CXPA is by far the most common of the malignant mixed neoplasms. Malignant degeneration may occur in any benign neoplasm; but, because pleomorphic adenoma is the most prevalent salivary gland neoplasm, CXPA most commonly arises from it. It typically presents as a rapidly enlarging mass in the setting of a preexisting lesion. Up to 5 years from presentation, the risk of malignant degeneration is 1.5%; however, after 15 years the risk increases to 9.5%. For those patients with recur-
degeneration is 7 to 10%. Depth of invasion into adjacent tissue has an important impact on survival and recurrence. Tortoledo and colleagues reported in their series of 40 patients that depth of invasion<8 mm yielded a 5-year survival of 100% compared to 50% for those with >8 mm of invasion. When depth of invasion was >6 mm, recurrence was as high as 70% compared to only 16.5% when depth of invasion was <6 mm.

Carcinosarcoma or true malignant mixed neoplasms are extremely rare and contain two malignant components (carcinoma and sarcoma), as opposed to CXPA which only contains one malignant component (carcinoma). These neoplasms have an aggressive biological behavior. The carcinoma component is most commonly either squamous cell carcinoma (SCC) or adenocarcinoma, while the sarcomatous portion is most commonly chondrosarcoma followed by fibrosarcoma. The long-term survival is poor being less than 20% at 15 years.

MZW too are extremely rare. In this instance, both the primary and metastatic neoplasms have a completely benign morphology. The most common cause is multiple local recurrences with eventual metastases to lung and bone. Wenig and colleagues reported 11 cases from the AFIP. Primary sites included the parotid gland (8 cases), submandibular gland (2 cases), and the nasal septum (1 case). At least two recurrences generally occurred prior to identification of metastases. The metastases were discovered from 6 to 52 years following the occurrence of the primary neoplasm. Metastases were identified in bone, lung, regional lymph nodes, skin, kidney, retroperitoneum, oral cavity, pharynx, calvaria, and central nervous system. While some advocate excising accessible DM, this is not uniformly accepted; and despite their benign appearance, patients may ultimately succumb to their disease.

Squamous Cell Carcinoma. Primary salivary SCC accounts for 1 to 2% of salivary malignancies. It is important to exclude synchronous or prior history of cutaneous or mucosal SCC. It must also be distinguished from high-grade MEC. Flynn and colleagues reviewed 40 parotid neoplasms originally classified as SCC but upon careful review only eight were primary SCC arising from the salivary gland; cutaneous metastases or high-grade MECs were the most frequently assigned misdiagnoses. The parotid gland is the most common primary site, followed by the submandibular gland. The usual presentation is a firm painless mass, either with or without facial paralysis. Cervical metastases are frequently present. The largest series described of primary SCC includes 50 patients over a 30-year span; the main limitation to the interpretation of the study is the lack of routine use of postoperative radiotherapy.

Cervical metastases were present in 46% of patients. Five-year survival was 24% for patients with parotid lesions and 20% for those with submandibular neoplasms. As with other malignant salivary gland neoplasms, advanced stage and pain as a presenting symptom were ominous findings. Locoregional recurrence was the most common site of failure in primaries both in the parotid (51%) and in the submandibular (67%) glands. This is an aggressive malignancy where radical parotidectomy, neck dissection, and postoperative radiotherapy are recommended.

Lymphoma. Salivary gland lymphoma may be a localized or systemic disease and most often affects the parotid gland and rarely the submandibular gland. It comprises 4.7% of extranodal lymphomas and 1.7% of salivary gland neoplasms. Although non-Hodgkin B-cell lymphoma is most prevalent, all forms of lymphoma may be observed. They may also be associated with benign lymphoepithelial lesions both in the presence or absence of Sjögren syndrome. Patients with Sjögren disease have 44-fold increased risk of developing primary lymphomas of the salivary glands over the general population; and their lymphomas are biologically more aggressive.

Patients with primary salivary lymphoma fare better than those with systemic disease, and those with primary Hodgkin lymphoma do better than those with non-Hodgkin lymphoma. 5-year survivals of 90% and 48%, respectively, Clinical stage of disease did affect survival. The worse prognosis is for the patient with concurrent Sjögren syndrome who have a mean survival of less than 3 years.

Sarcoma. Sarcomas arising in the salivary glands are extremely uncommon. The two most common types were malignant schwannoma and fibrosarcoma, but a diverse group has been described: malignant fibrous histiocytomas, neurosarcomas, rhabdomyosarcomas, fibrosarcomas, and osteosarcomas. Auclair and colleagues reported 42 patients with sarcoma; 17 experienced recurrences, 16 developed metastases (most commonly to lung), and 15 died of disease. The mean time until death following treatment was 2.4 years. Treatment generally included surgery followed by radiation. Prognosis was based on neoplasm grade and size. For large neoplasms, prognosis is poor, despite aggressive surgical resection and radiation therapy.

SURGICAL MANAGEMENT

For benign parotid neoplasms, a superficial parotidectomy is the treatment of choice to avoid recurrence. Simple enucleation without an adequate cuff of normal tissue for benign neoplasms such as pleomorphic adenomas leads to an unacceptable high rate of recurrence. For a benign neoplasm of the submandibular gland, complete excision of the entire submandibular gland is the recommended treatment. Treatment of benign minor salivary gland neoplasms requires wide resection of the anatomic site where they occur.

For malignant parotid neoplasms, a total parotidectomy is recommended with preservation of the facial nerve, whenever possible. When there is complete encasement of the facial nerve or its branches, sacrifice of the involved portions of the nerve is required. When the extratemporal portion of the facial nerve is sacrificed, primary repair with a cable graft is desired, irrespective of the need for postoperative radiotherapy. For malignant submandibular neoplasms, complete excision of the submandibular gland is the minimum therapy. Because of the proximity of the mandible, a marginal or segmental mandibulectomy may be necessary. The extent of resection of minor salivary neoplasms depends on the anatomic site involved. Frequently, neoplasms of the palate and nasal cavity require a maxillectomy. In general, high-grade neoplasms should be resected with wide margins.

Lymphadenectomy

Whenever there is clinically positive regional adenopathy, a therapeutic neck dissection is performed as part of definitive treatment. For instances of high-grade malignancies, for example, high-grade mucoepidermoid, adenocarcinoma, or SCC, an elective neck dissection is recommended for optimal regional control. For low-grade neoplasms, for example, acinic cell carcinoma, low-grade MEC, PLGA, without radiographic or clinical adenopathy, elective dissection of the neck is not indicated.

RADIATION

While surgical excision is the first-line therapy for parotid neoplasms, radiotherapy has an important role in the postoperative setting for high-risk malignant neoplasms, presence of cervical metastasis, recurrent disease, and unresectable disease. Postoperative radiotherapy has been demonstrated to improve locoregional control, although the impact on survival and DM may be less clear. Armstrong and colleagues compared 46 matched-pairs with malignant parotid neoplasms, one group treated with complete surgical resection whereas the other was treated with surgical excision and postoperative radiotherapy. The 5-year locoregional control for stage III and IV neoplasms in the surgery with postoperative radiotherapy versus surgery alone was 51% versus 17%, respectively; and 5-year survival was 51% versus 10%, respectively. Garden and colleagues reviewed 160 patients with malignant minor salivary neoplasms treated with complete surgical resection with postoperative radiotherapy at MD Anderson Cancer Center. Locoregional recurrence occurred in only 14% of patients; DM occurred in 27%, and 10-year overall survival was 65%.

It is believed that additional benefit may be gained using fast neutron therapy rather than conventional photon radiotherapy for advanced ACC. Douglas and colleagues reviewed 151 patients treated at the University of Washington who had either unresectable disease or gross residual disease (GRD) after an attempted surgical extirpation. The 5-year actuarial locoregional control rate for the 151 patients with GRD was 57%; the 5-year actuarial overall survival rate was 72%; and the 5-year actuarial cause-specific survival rate was 77%. Eight patients with microscopic disease had 100% locoregional recurrence.
CONTROL. The prognostic factors associated with worse outcome were skull base involvement and surgical biopsy versus gross resection. For locoregional control, others have confirmed the promising results of fast neutron therapy, but benefits on DM and consequently long-term survival have not been established. Furthermore, severe long-term toxicities such as osteoradionecrosis, deafness, cerebral necrosis, and other cranial neuropathies must be considered.

COMPLICATIONS OF TREATMENT

Complications that may occur with salivary gland surgery include postoperative hemorrhage, seroma, infection, sensory deficit, and skin necrosis, but the most debilitating complication is facial nerve paralysis from injury during parotid surgery. Wither inadvertent or planned, facial nerve section results in a cosmetic and functional deformity that requires rehabilitation. Certainly, temporary facial nerve paralyis related to neurapraxia may result when the nerve is preserved and able to be stimulated at low voltage at the conclusion of the operation. Gaillard and colleagues reviewed 131 patients in whom a superficial parotidectomy or total parotidectomy with nerve preservation was performed. On the first postoperative day, there was a 42.7% incidence of nerve dysfunction, in whom 100% resolved by 6 months. The most common injury was of one branch (48%), with the marginal mandibular branch being the most commonly affected. Total parotidectomy was associated with an increased incidence of early dysfunction, but there was complete resolution at the end of a 6-month period. When other factors such as the patient’s age, smoking, size of lesion, histology of lesion, and duration of surgery were considered, only the age of the patient had a significant impact on long-term facial nerve weakness in those patients in whom the marginal mandibular branch was the nerve that was most commonly affected. When the facial nerve is severed, primary tension-free anastomosis is recommended whenever possible. Otherwise, a cable graft should be performed with the possible donor nerves including the greater auricular, sural, or anterobrachial cutaneous. Other options include hypoglossal transposition and free tissue transplantation. Favorable results include postoperative hemorrhage, seroma, infection, sensory deficit, and skin necrosis, but the most debilitating complication is facial nerve paralysis from injury during parotid surgery. Whether inadvertent or planned, facial nerve section results in a cosmetic and functional deformity that requires rehabilitation. Certainly, temporary facial nerve paralyis related to neurapraxia may occur, even when the nerve is preserved and able to be stimulated at low voltage at the conclusion of the operation. Gaillard and colleagues reviewed 131 patients in whom a superficial parotidectomy or total parotidectomy with nerve preservation was performed. On the first postoperative day, there was a 42.7% incidence of nerve dysfunction, in whom 100% resolved by 6 months.

REFERENCES

Diseases of the thyroid and parathyroid glands are common and, as with all glands, may present with syndromes related to excessive function, reduced function, hyperplasia, and neoplasia. The majority of patients with abnormal tests of thyroid function suffer from primary thyroid diseases, most commonly hypothyroidism as a result of autoimmune destruction of the thyroid gland or hyperthyroidism as a result of Graves disease, toxic multinodular goiter, or destructive thyroiditis. However, many other factors, both exogenous and endogenous, may affect thyroid function, and these conditions must be considered in the differential diagnosis of thyroid disease.

Disorders of the parathyroid gland include hyperfunction related to parathyroid hyperplasia or adenoma formation; and hypofunction as a result of autoimmune mediated or iatrogenic destruction of the glands. Although parathyroid hyperplasia and adenomas are common, malignant transformation of the parathyroid gland is a rare event. In contrast, thyroid neoplasms, both benign and malignant, are the most frequent endocrine tumors, and thyroid cancer is the most frequently diagnosed and most frequently fatal endocrine malignancy.

Diffuse hyperplasia of the thyroid gland may occur physiologically, for example, during pregnancy; as a result of iodine deficiency; in response to elevated levels of thyrotropin, thyroid stimulating hormone (TSH), or stimulation by thyrotropin antibodies in Graves disease; or as a result of reduced efficiency of thyroid hormone production (dys hormonogenesis). Nodular thyroid disease is also common, mainly the result of hyperplastic processes, including the nodular hyperplasia of multinodular goiter and asymmetric goiter development in glands affected by autoimmune thyroid disease. Nodular hyperplasia may follow prolonged or repeated episodic diffuse hyperplasia, as seen in so-called nodular Graves disease, or it may arise de novo as a multinodular goiter. Although hyperplastic nodules may present as an apparently solitary nodule, more detailed assessment (with ultrasound or on pathologic evaluation) typically reveals hyperplastic changes within the remainder of the gland.

Neoplasia of the thyroid gland is also common, including solitary or multiple adenomas and carcinomas of various histologic types: papillary, follicular, Hürthle cell, medullary, and anaplastic. Solitary thyroid nodules are usually neoplastic nodules, most commonly follicular adenomas. An adenoma to carcinoma sequence is suspected, though not proven, to underlie the development of follicular thyroid carcinoma (FTC), while the more common papillary thyroid carcinoma (PTC) almost certainly arises with no pre-existing benign stage. Both PTC and FTC are derived from thyroid follicular cells, the source of both thyroid hormone and thyroglobulin, a useful tumor marker in these diseases. Medullary thyroid carcinoma (MTC) arises instead from the thyroid C-cells, whose main protein product, calcitonin, is a similarly useful marker of residual MTC in the postoperative patient. The deadly anaplastic thyroid carcinoma (ATC) arises in most cases as a dedifferentiated form of either PTC or FTC.

Treatment of nodular thyroid disease remains surgical, with few medical options for therapy. The management of thyroid cancer requires surgical excision of the disease, extirpation of the thyroid gland, and removal of regional lymph nodes where appropriate. Solitary neoplastic nodules are also treated surgically because the exclusion of malignancy currently requires histologic analysis and therefore mandates excisional biopsy in the form of thyroid lobectomy but also because of the suspected adenoma to carcinoma sequence. Surgery remains an excellent, if now infrequently exercised option, for management of both Graves disease and toxic multinodular goiter although medical treatment, particularly radioactive iodine, is now used in most cases, at least in the developed world.

Surgery is the mainstay of management for adenomatous nodules of the parathyroid glands and for significant autonomous multinodular hyperplasia (primary or tertiary hyperparathyroidism). Medical treatments are effective for secondary hyperparathyroidism caused by vitamin D deficiency or failure of vitamin D activation in renal insufficiency; the increasingly aggressive management of vitamin D deficiency in renal failure seems likely to change the spectrum of renal bone disease in the future. New calcimimetic agents are also becoming available for medical management of primary hyperparathyroidism, but the chronic use of such agents is generally limited to situations where surgery is either ineffective or deemed inappropriate because of a patient's comorbidities.

Diseases of the Thyroid and Parathyroid Glands

Bryan McIver, MB, PhD

THYROID DISEASES

Hyperplastic and Inflammatory Diseases of the Thyroid Gland

Iodine Deficiency and Excess. Worldwide, the most frequent cause of hyperplastic goiter and of thyroid dysfunction remains iodine deficiency, causing endemic goiter and Cretinism. Lesser degrees of iodine deficiency, common even in the developed world, may also contribute to the development of multinodular goiter through its impact on thyroid gland hyperplasia, while altering the spectrum of thyroid cancer toward the more aggressive follicular phenotype. Excessive iodine intake may also trigger thyroid disease, and in the United States this is seen increasingly in the context of cardiac arrhythmia treated with amiodarone, a potent antiarrhythmic agent, which contains large amounts of inorganic iodide. The drug may also have a direct impact on the deiodination of thyroid hormones, altering triiodothyronine (T3) bioavailability and complicating the interpretation of thyroid function tests.

Iodine Deficiency. Goiter, with or without thyroid dysfunction, affects an estimated 190 million people worldwide, the result of dietary iodine deficiency, which causes “endemic goiter.” An estimated 800 million people worldwide are at risk for iodine deficiency disorders, based on population median adult iodine intake of less than 100 µg/d, compared to the recommended daily intake of at least 150 µg/d.

Endemic goiter, associated with hypothyroidism, remains a leading cause of mental retardation, through its impact on the developing fetus and neonate, in whom neurological development, growth, and a number of other developmental processes are dependent on maternal and neonatal thyroid hormone production. Cretinism, the most extreme form of iodine deficiency disorder (IDD), is associated with irreversible mental retardation, deafness, growth retardation, and other developmental abnormalities. This clinical condition is likely to represent the extreme end of a spectrum of IDDs, which nevertheless may affect large segments of the population at risk for IDDs in more subtle, less well-recognized forms.

Under conditions of severe iodine deficiency (intake of less than 25 µg elemental iodine per day for adults), insufficient iodination of thyroglobulin occurs to meet the needs of thyroidal...
production of thyroid hormones. As a consequence, thyroid hormone levels fall, thyrotopin or thyroid-stimulating hormone (TSH) concentrations rise and the thyroid gland is subjected to a growth stimulus that causes thyroid enlargement and goiter. Initially, the enlargement takes the form of diffuse hyperplasia. However, the gland may be exposed to varying degrees of growth stimulation over many years, so that ultimately a more nodular appearance becomes common, resembling the multinodular goiter seen more commonly in North America.

A number of factors other than iodine deficiency may contribute to the development of endemic goiter, including selenium deficiency, which commonly coexists with iodine deficiency, and the consumption of a variety of goitrogenic substances in foodstuffs. These substances include lithium, which interferes with iodide reten-
tion within the thyroid, and a variety of organic molecules that interfere with iodine organification, including thiocyanates, phthalates, and “goitri” (L-5-vinyl-2-thiooxazolidone). These substances may be present in water, milk, cassava, millet, onions, seaweeds, and grasses, and may contribute to endemic goiter even in regions where iodine sufficiency would otherwise be expected, such as coastal China and parts of India. Pregnancy, during which the demands on the maternal thyroid increase substantially, exacerbates the state of iodine depletion, worsening maternal hypothyroidism and goiter, and subsequent pregnancies may occur in the face of more severe iodine deficiency, with increasingly severe consequences on subsequent offspring.

Successful iodine supplementation programs have been implemented in a number of endemic goiter areas, including much of the United States and parts of Europe. These programs have all but eliminated endemic goiter in these countries, although arguably at a cost of an increased incidence of autoimmune thyroid disease, including thyrotoxicosis and hypothyroidism.

However, iodine deficiency remains a widespread problem, and intensive efforts to implement similar iodine supplementation programs among developing-country populations who remain at risk for IDDs. A variety of largely social and political hurdles remains in the way of universal iodine sufficiency.

Iodine Excess. In contrast to iodine deficiency, iodine excess is a disease of developed countries, reflecting the consequences of iodine supplementation in a population previously deficient in iodine, the impact of individual choice or medical necessity. Arguably the most important, and certainly the most common cause of significant iodine excess in the USA is the use of the antitryphtic agent amiodarone (Cardarone). Amiodarone is a di-iodinated benzo-furanate derivative, which contains 75 mg of iodine per 200 mg tablet, of which at least 10% (7.5 mg) is liberated as free iodine during drug metabolism. This compares to normal average daily iodine intakes of between 220 and 450 μg in Western Europe and North America and reflects a more than 20-fold increase in iodine exposure. Chronic treatment causes at least a 40% increase in sustained plasma and urinary iodide, and the drug’s fat solubility ensures a long biological half-life, with increased urinary iodide excretion detected many months after drug withdrawal.

A large intake of iodine from amiodarone, or any other source, causes an acute inhibition of production and release of thyroid hormone from the thyroid, the so-called “Wolf-Chaikoff effect.” This may last a few weeks to a few months and can cause a transient fall in the concentrations of circulating T3 and thyroxine (T4). In addition, amiodarone (but not other sources of iodine) inhibits the hepatic deiodinase, the source of most of the circulating T3 in humans. This action is specific for amiodarone and may reflect the close structural similarity between thyroid hormone and amiodarone, resulting in a competitive inhibi-
tion of the enzyme. As a result of these actions, the TSH rises in the face of falling T3, while T4 remains relatively normal because of reduced deiodination and therefore reduced T4 clearance. These changes may transiently cause symptomatic hyperthyroidism but are rarely severe.

As the acute response to iodine loading fades, the normal thyroid recovers its capacity to produce and secrete thyroid hormone under the control of TSH. However, the high iodine availability may result in a higher proportion of thyroid hormone released in the form of T4, while the amiodarone-induced block on T4 to T3 conversion is maintained. This causes a fall in the circulating T3 concentrations, a rise in circulating T4 concentra-
tions, and a normal TSH, and a different “normal range” for thyroid function has been suggested for other healthy patients receiving treatment with amiodarone.

Among patients with underlying thyroid disease, excessive iodine intake may have additional effects on thyroid function, which can result in both hypo- and hyperthyroidism. The reported rates of each of these depend on the prevailing iodine load, problem, despite amiodarone withdrawal, and presumably the underlying prevalence of auto-
immune or nodular thyroid disease. In populations with low or marginal iodine intakes, hyperthyroidism may affect up to 10% of patients receiving excessive iodine supplementation, while hypothyroidism occurs in around 5% of these individuals. In contrast, in areas with adequate or high iodine intakes, as in the United States, hyperthyroidism in response to iodine excess is substantially less common, at around 2%, while hypothyroidism is frequent, affecting up to 20% of patients treated with amiodarone or other sources of excess iodine.

In iodine depleted populations, chronic nodular hyperplasia is a common finding, with the development of autonomous function of the thyro-
gland in many of these individuals. Iodine loading of autonomously functioning glands results in hyperthyroidism, a reflection of increased substrate for the production of thyroid hormone, known as the “iod-Basedow phenomenon.”
of this approach is questionable if the amiodarone must be continued. Radioactive iodine is largely ineffective in amiodarone-induced thyrotoxicosis because of the low-iodine uptakes, the result of iodine loading.

Ultimately, the treatment of choice for iodine-induced thyrotoxicosis that does not respond to more conservative measures is surgical resection of the thyroid gland, followed by thyroid hormone replacement.26,27 Although many patients who are receiving amiodarone are at high surgical risk because of underlying heart disease, improvements in general anesthesia and monitoring techniques, as well as improvements in surgical techniques, have made thyroid surgery even in this group of patients a relatively safe procedure, with reported mortality rates of <5%.27 This definitive approach should be considered for all patients with persistent symptomatic or progressive amiodarone-induced thyrotoxicosis, particularly those for whom withdrawal from the amiodarone is not an option.

Hyperthyroidism and Thyrotoxicosis. Hyperthyroidism and thyrotoxicosis are common and important endocrine disorders that result from several distinct pathologic conditions of the thyroid gland, or from overt or covert ingestion of thyroid hormone. The incidence of overt and subclinical hyperthyroidism among adults is between 0.05 and 0.1% per year in the United States, with an estimated prevalence of ~1.2% and a female to male ratio of approximately 3:1.28

The term thyrotoxicosis is generally reserved to describe the clinical syndrome that results from elevated levels of T4 and T3 in the circulation. Hyperthyroidism, on the other hand, describes a state of increased production and release of thyroid hormones from the thyroid gland, which may or may not lead to thyrotoxicosis. The most common cause of hyperthyroidism, responsible for almost two-thirds of cases, is Graves disease, an autoimmune process of the thyroid that also exhibits extrathyroidal manifestations.29 A spontaneously functioning nodule within a multinodular goiter become more common with age, often causing mild thyrotoxicosis, which may be manifest by atypical symptoms. Solitary autonomous thyroid nodules, almost always benign, are infrequent causes of hyperthyroidism. Inflammatory conditions of the thyroid, resulting in damage to the gland (thyroiditis), may also induce the release of thyroid hormone with consequent thyrotoxicosis. Although this might occur at any age, it is seen most frequently among young women in the postpartum phase. Overtreatment with thyroid hormone (either deliberately or accidentally) will also, of course, result in thyrotoxicosis in the absence of hyperthyroidism.

The majority of the symptoms and many of the signs of thyrotoxicosis are independent of the underlying cause (Table 1). In many cases, however, certain clinical features will point to the cause. These include most importantly, the size and shape of the thyroid gland and the presence of extrathyroidal features of Graves disease.

Confirming the diagnosis biochemically is rarely complex, and determining the underlying cause is straightforward in most cases. The treatment of thyrotoxicosis is effective but is most commonly directed toward destruction of the thyroid gland and rarely addresses the cause of the hyperthyroidism. In consequence, the majority of patients so treated require lifelong replacement of thyroid hormone, and all patients require lifelong monitoring of thyroid function.

Neonatal Hyperthyroidism. The transplacental passage of TSH-receptor antibodies (TRA b), from a mother with Graves disease, can rarely result in significant neonatal hyperthyroidism, the result of “vertical transmission” of maternal Graves disease to the baby, both in utero and postpartum during breastfeeding.31 Typically, the neonate exhibits goiter, lid retraction without exophthalmos, irritability, low birthweight, poor feeding, and “failure to thrive.” Treatment is supportive, with occasional use of antithyroid drugs. Because the condition is self-limiting, definitive treatment is rarely required, with surgery reserved only for life-threatening thyrotoxicosis and obstructive goiter.30

Pediatric Hyperthyroidism. Approximately one per million young children and three per million adolescents are diagnosed with hyperthyroidism per year, with 95% of cases due to Graves disease. Symptoms include the usual spectrum of symptoms that affect adults, including weight loss, palpitations, tremor, and hyperactivity. In addition, however, behavioral difficulties, deteriorating performance at school and difficulties with socialization are common features of thyrotoxicosis in childhood.32 Treatment options are identical to those in adults, discussed below, although it is common for endocrinologists to avoid the use of radioactive iodine, in an effort to minimize exposure to ionizing radiation, with its theoretical risks of carcinogenesis and fertility changes. Consequently, first-line treatment is typically administered in the form of antithyroid drugs, with surgery as the first-line option for “definitive” therapy.31

Graves Disease. Graves disease is an autoimmune disease of the thyroid and certain other extrathyroidal tissues, most notably the eyes and skin. The hyperthyroidism manifested by these patients is the result of autoantibodies against the TSH receptor, which mimic the effects of TSH on thyroid cells, thereby stimulating autonomous production of T4 and T3. The alteration of immune function that leads to the production of these antibodies is complex, involving the interaction of B- and T cells in the production of antibodies against several autoantigens in addition to the TSH receptor.29 TSH receptor antibodies are detectable in the serum of almost all patients with Graves disease and may be used clinically in making the diagnosis. Lymphocytic infiltrates are commonly seen in the thyroid gland of patients with this condition. A considerable overlap in histologic appearance between Graves disease and Hashimoto disease (autoimmune thyroiditis) exists, with only the presence of hypertrophic follicles characterizing the former.29 It is not surprising then, that some patients with Graves disease undergo spontaneous remission, or develop hypothyroidism in the long term. This may result from autoimmune destruction of the gland, or from the production of TSH receptor-blocking antibodies, which may also be seen in Hashimoto disease or autoimmune atrophic hypothyroidism.34

Lymphocytic infiltrates are also seen in the extraocular muscles of patients with Graves ophthalmopathy (though not in the subcutaneous tissues of patients with dermopathy), emphasizing the systemic nature of the autoimmune process.35 It remains unclear what links these apparently separate manifestations of the disease although the search for common antigens continues. There is also an association between Graves disease and the other organ-specific autoimmune syndromes, including pernicious anemia, diabetes mellitus, vitiligo, Addison disease, and myasthenia gravis.36 These associations support the hypothesis that autoimmunity is the result of a subtle but generalized immune system abnormality.

The most sensitive and specific test to distinguish Graves disease from silent thyroiditis, postpartum thyroiditis, or exogenous thyrotoxicosis is the measurement of the iodine uptake. This test is performed after the oral ingestion of a fixed small dose (usually 1 to 5 mCi) of radioactive iodine. Quantification of the iodine uptake is commonly performed after 6 to 24 hours, by detection of the gamma emissions over the neck at that time. The normal thyroid gland retains approximately 8 to 20% of the administered iodine at 24 hours. In cases of Graves disease, iodine uptake is increased, often dramatically. Similarly, multinodular goiter and solitary hot nodules usually exhibit increased iodine uptake. In contrast, postpartum thyroiditis, silent thyroiditis, and exogenous thyrotoxicosis all result in reduced iodine uptake, either because of gland injury or as a result of TSH suppression.29

Antibodies against the thyrotropin receptor are the proximate cause of Graves disease, and act by binding to, and so stimulating, the TSH receptor, mimicking the action of TSH itself. These antibodies are detectable in 95 to 98% of patients with Graves disease and are absent in all...
but a tiny minority of patients with other causes of thyrotoxicosis.\textsuperscript{37} Although less specific and less sensitive than measurement of radioactive iodine uptake, these assays are useful particularly when radioactive iodine uptake cannot be measured. In addition to pregnancy and breastfeeding, previous imaging, for example, computed tomography (CT) scanning, or treatment with iodine-containing drugs, for example, amiodarone, may interfere with the measurement of iodine uptake. Measurement of TSH-receptor antibody concentrations provides a useful alternative means to confirm a diagnosis of Graves disease.\textsuperscript{38}

TPO antibodies are also commonly found in the serum of patients with autoimmune thyroid disease.\textsuperscript{39} However, the finding of TPO antibodies is relatively nonspecific, and may be positive in as many as 10% of women of childbearing age.\textsuperscript{40} Since postpartum thyroiditis is more likely in women with positive TPO antibodies, this test is not useful in distinguishing Graves disease from postpartum thyroiditis. Ultrasound of the thyroid gland can be helpful to exclude multinodular goiter or a solitary nodule. In Graves disease, the gland may also be enlarged and hypervascular.\textsuperscript{40} In general, thyroid biopsy is not also regarded as a useful tool in this context.

Except in the mildest cases, treatment of thyrotoxicosis can be expected to improve the patient’s symptoms and quality of life and to reduce the likelihood of complications. Symptomatic benefit can be achieved by the use of adrenergic beta-receptor blocking agents, which improve tachycardia, tremor, and sweating, reflecting the sympathetic overactivity common in thyrotoxicosis.\textsuperscript{29,41} Nonselective beta-blockers, for example, propranolol, have a significant advantage over more cardioselective agents in this context. Patients with severe thyrotoxicosis may be extremely resistant and require high doses to achieve symptomatic improvement and control of the heart rate. Starting doses of 40 to 80 mg three times daily are usual, titrated upward according to the heart-rate response. Propranolol may have some inhibitory action on the deiodinase system, slowing the rate of T4 to T3 conversion, but it is likely that this is of minimal, if any, benefit in the treatment of thyrotoxicosis.\textsuperscript{42} Propranolol is generally regarded as safe for use in pregnancy and lactation. It should be used with extreme caution in patients with asthma or coincident heart disease. The drug can be continued during the more definitive treatment of the patient’s thyroid disease and can be weaned gradually as the symptoms remit.

Three treatment options are available for the management of Graves disease. All three are generally safe and effective, but each has unique advantages and disadvantages, and no one treatment can be regarded as better than any other, except in unusual circumstances.

Thyroidectomy for Graves Disease. The first effective therapy for Graves disease, which became available around the turn of the twentieth century, was surgical removal of the thyroid gland. A number of medical and surgical advances in the late 1800s and early 1900s, most prominently the appropriate preoperative correction of thyrotoxicosis and reduction of gland vascularity, made this surgery safe. Modern anesthetic techniques and careful preoperative preparation have lowered the mortality rates for this surgery virtually to zero, at least among young people without other significant illnesses.\textsuperscript{43}

Under rare circumstances, in which the patient’s life is at risk, preoperative preparation with beta-blockers alone (administered intravenously) has been shown to be possible.\textsuperscript{44,45} While this approach lowers the anesthetic risk, however, the risk of significant bleeding from a highly vascular thyroid gland remains high. More commonly, and probably more safely, patients first are rendered euthyroid, most often with antithyroid drugs. Ten to 14 days prior to surgery, the antithyroid drugs are withdrawn, and potassium iodide (Lugol iodine solution) is commenced. This treatment, pioneered by Henry Plummer of the Mayo Clinic, maintains a block on Thyroid hormone production and release (the Jod-Basodow phenomenon) and decreases the vascularity of the gland, improving the safety of the surgical procedure.\textsuperscript{45,46}

In addition to the potential complications of any surgical procedure (scarring, infection, and hemorrhage), thyroidectomy may be associated with injury to the parathyroid glands and the recurrent laryngeal nerves, as discussed in detail below. Total or near-total thyroidectomy is not necessary in the management of Graves disease, and subtotal thyroidectomy (leaving 10 to 30% of the gland in situ) is recommended in many centers, reducing further the risk of these specific surgical complications.\textsuperscript{47} Some surgeons attempt to leave sufficient thyroid tissue in place to render the patient euthyroid without thyroid hormone replacement therapy. This increase in the probability of surgical treatment failure is probably unnecessary in the era of sensitive thyroid function tests and accurate thyroid hormone replacement therapy, and is usually futile, since the majority of patients will go on to develop thyroid failure in the future, from progressive autoimmune thyroid gland destruction.\textsuperscript{48}

Although rarely the treatment of first choice, surgery remains a viable treatment option for carefully selected patients. It remains the fastest and most certain means to achieve euthyroidism.

Radioactive Iodine. By far the most widely used treatment for Graves disease in North America, radioactive iodine is a safe and effective, nonsurgical means of thyroid ablation. Now in use for almost 60 years, this treatment option has proven to be well tolerated and predictable.\textsuperscript{49} Because of the high iodine-concentrating capacity of the thyroid gland, particularly in Graves disease, the vast majority of ingested radioactive iodine is concentrated within the thyroid gland or excreted through the urine within 12 to 24 hours. This minimizes total body exposure to radiation although detectable uptake also occurs in salivary glands, gastric mucosa, colon, and bladder.\textsuperscript{49} Nevertheless, concerns about carcinogenesis have not been substantiated, at least in the doses used for the treatment of thyrotoxicosis, in several large case series.\textsuperscript{50} Despite this objective evidence of safety and a long track record of simplicity and efficacy, concerns about the long-term safety of radioactive isotopes remain the single most frequent reason given by patients (and physicians) in selecting other modalities of therapy.

I-131 is used for the treatment of patients with Graves disease, and acts principally as a beta-particle emitter. Iodine-123, which is a better, albeit more expensive, isotope for imaging, is a gamma-emitter, and these gamma-waves fail to interact adequately with tissue and, therefore, do not cause significant tissue injury. The beta particles released from I-131, however, generate superoxide radicals within the thyroid cell, causing double-strand deoxyribonucleic acid (DNA) breaks and resulting in apoptosis and gland involution.

Initially after treatment with radioactive iodine, thyroid hormone synthesis and release are impaired as the follicular cell responds to injury. Thyroid follicles are later disrupted, and there is often a temporary worsening of thyrotoxicosis, as previously synthesized thyroid hormone is released from thyroglobulin stored within the follicle.\textsuperscript{51} Thereafter, thyroid hormone is cleared with its usual 7-day half-life, and the patient is rendered euthyroid and subsequently hypothyroid.

Permanent hypothyroidism is the expected and accepted outcome of treatment with radioactive iodine in most centers.\textsuperscript{52} Depending on the dose used, between 60 to 95% of patients will be rendered permanently hypothyroid within 2 to 3 months of a single treatment dose. A small number of patients experience primary treatment failure, requiring a subsequent repeat dose. A small proportion of patients may experience temporary hypothyroidism within a few weeks of treatment followed by recurrent thyrotoxicosis as the thyroid remnant recovers. Both of these treatment failure types are minimized by use of adequate doses of I-131.\textsuperscript{53}

In most centers in the United States, some form of dosimetry is used to calculate a suitable initial dose of I-131. Most commonly, this is based on some estimate of thyroid gland weight, assessed clinically or by ultrasound. A planned dose of between 100 and 200 μCi/g of gland weight can be administered, which takes into account the avidity of the gland for iodine. In a few centers worldwide, dosimetry has been abandoned in favor of a single fixed dose for all patients. Most commonly this dose is between 10 and 30 mCi (lower in countries with low iodine intakes), and is expected to render approximately 80 to 90% of patients hypothyroid with a single treatment dose. There is little evidence to favor one approach over the other.

Attempts to titrate the dose carefully to render the patient euthyroid, not requiring thyroid hormone replacement therapy, have generally been disappointing and have the disadvantage of...
leaving many patients thyrotoxic for prolonged periods. These efforts are often doomed for the same reason that "titrated surgery" is ineffective, namely, the progressive destruction of the gland remnant by the underlying autoimmune process. Once again, this approach is hard to justify when thyroid hormone replacement therapy is so straightforward in the majority of cases.

There remain concerns about the impact of radioactive iodine treatment on the natural history of Graves ophthalmopathy. Considerable controversy has taken place over this subject, which remains under debate, but in most centers patients with significant ophthalmopathy are either guided toward alternative treatments, or offered coverage with corticosteroids following their treatment with radioactive iodine.

Radioactive iodine can be safely administered even to most patients who are allergic to topical iodine. However, it is absolutely contraindicated in pregnancy and breastfeeding. In the first trimester of pregnancy, radioactive iodine treatment has been associated with increased rates of spontaneous abortion. Beyond the twelfth week of pregnancy, when the fetal thyroid is capable of concentrating iodine, radioactive iodine would render the fetus hypothyroid. Similarly, radioactive iodine is concentrated in breast milk and would likely injure the infant's thyroid gland. A negative pregnancy test is mandatory prior to treatment with I-131, in all women of childbearing potential. There is no proven teratogenic effect in either males or females at any age, but pediatric endocrinologists have been reluctant to use radioactive iodine in patients under the age of 18 because of concerns on future fertility.

Antithyroid Drugs. The thiourea group of drugs, for example, PTU, methimazole (MMZ), and carbimazole (CBZ), inhibit the intrathyroidal organification of iodine, so reducing iodine retention within the gland and impairing synthesis of thyroid hormone. The gland becomes iodine deficient, and initially, under continued stimulation of the TSH receptor by TSH receptor antibodies, increases the proportion of T3 to T4 secreted. Thereafter, T3 secretion is also impaired, and thyroid hormone levels fall peripherally, with resolution of thyrotoxicosis. PTU, perhaps more so than the other drugs in this group, also inhibits the peripheral conversion of T4 to T3, which may accelerate the return to euthyroidism.

Administered orally, these drugs are rapidly absorbed and inhibit the release of thyroid hormones from the gland almost immediately. Resolution of hyperthyroidism occurs quickly, limited only by the plasma half-life of the thyroid hormones. In any case, return to normal of plasma thyroid hormone levels is expected within 3 to 4 weeks, although suppression of the pituitary thyrotroph may delay a return to normal of the TSH by some weeks.

Antithyroid drugs effectively treat the thyrotoxicosis caused by Graves disease, toxic multinodular goiter, or an autonomously functioning thyroid nodule. They are ineffective in the treat-ment of thyrotoxicosis resulting from silent or postpartum thyroiditis, in which the release of preformed thyroid hormone is the cause of thyroid hormone excess.

Since both multinodular goiter and autonomous thyroid nodules have a low likelihood of spontaneous remission, the use of antithyroid drugs in these contexts is rarely justified and more definitive therapy, either in the form of surgery or radioactive iodine, is generally recommended. However, the situation in Graves disease is rather different. Spontaneous remissions may occur, even in untreated patients. Between 30 and 50% of patients with Graves disease, treated with antithyroid drugs, may remain in long-term remission once those drugs are withdrawn. Patients maintained in the euthyroid state using these drugs, exhibit an increasing probability of long-term remission with increasing duration of antithyroid drug treatment, up to at least 18 to 24 months. Longer-term treatment appears to offer little additional benefit.

Rapid and profound falls in TRAb concentrations have been reported during drug treatment of Graves disease, and both the rate of fall and the final level of TRAb prior to discontinuation of drug therapy predict the likelihood of relapse. Other, more subtle changes in immune system function have also been reported during drug treatment of Graves disease, and several in vitro studies have also suggested a possible immunomodulatory role for these drugs.

Traditionally, treatment is initiated with a high dose of PTU (300 to 600 mg three times daily) or methimazole (40 to 80 mg daily), and the dose is then gradually reduced over a period of several months to a low maintenance dose. Treatment is continued for 12 to 24 months, with thyroid function being monitored at approximately 3-month intervals, and the dose adjusted to maintain thyroid hormones and TSH within their respective normal ranges. Following discontinuation of medication, close monitoring is required to detect early evidence of relapse.

Because of the suggestion of an immunomodulatory effect of these drugs, several controlled trials were undertaken in the 1980s to assess the impact of so-called combination therapy. Consisting of continued high-dose PTU accompanied by thyroid hormone, this treatment was designed either simply to prevent hypothyroidism during PTU treatment (a “block and replace” regimen), or specifically to maintain a suppressed TSH during (and after) antithyroid drug therapy, in an effort to “keep the thyroid asleep.” Despite an exciting positive initial report from a group of Japanese investigators, all other studies have proven disappointing, with no long-term benefit to the patient, and some potential side effects from both the PTU and the thyroid hormone.

Such combination therapies appear to have no major role in the management of patients with Graves disease.

Antithyroid drugs are generally well tolerated, with few side effects except for their impact on thyroid function. True drug allergy is infre-quent, resulting in an urticarial rash in 5 to 10% of patients. Patients who are allergic to one of this group of drugs may tolerate one of the others, although cross-allergy is well recognized. Less common, and much more serious, is the potential for agranulocytosis, a sometimes irreversible bone marrow dyscrasia that results in a reduced white cell count (neutropenia) and susceptibility to infection. Most commonly this presents with a bacterial pharyngitis. Immediate cessation of the drug therapy may permit bone marrow recovery, but trials of granulocyte colony stimulating factor have proven disappointing for the most serious cases. This potentially life-threatening complication is reported to occur with an incidence of approximately 1 per 1,000 to 1 per 5,000 and appears to be idiosyncratic, being clearly related neither to dose nor duration of therapy. A normalities of liver function are relatively common, and rare cases of drug-induced hepatitis have been reported. Regular monitoring of liver function studies and CBC are routinely practiced, though of uncertain utility in detecting pre-symptomatic liver or bone marrow dysfunction.

Use of these drugs in pregnancy and lactation is relatively safe. PTU crosses the placental barrier less freely than CBZ or MMZ and is the drug of choice during pregnancy. Reports of aplasia cutis, a defect of scalp skin maturation, exist for CBZ and MMZ, but this appears to be less of a problem with PTU. However, because these drugs do enter the fetal and infant circulation and affect thyroid function, the use of the lowest possible dose of these drugs is recommended in pregnancy and lactation.

Extrathyroidal Manifestations of Graves Disease. In addition to thyrotoxicosis, Graves disease is frequently associated with a number of extrathyroidal manifestations, including ophthalmopathy, dermopathy, and acropachy. These features of the disease are distinct components of a multorgan autoimmune process so that, although they are seen most commonly in association with thyrotoxicosis, these phenomena can occur independently, and their time course in relationship to the development of thyrotoxicosis may be quite variable. It was recognized many years ago that the eye changes of “exophthalmic goiter” can precede the symptoms of hyperthyroidism by months, or sometimes years, but most commonly become apparent coincident with the development of thyrotoxic symptoms or within the following 6 to 12 months. Similarly, Graves dermopathy often first becomes apparent some time after the onset of thyrotoxicosis.

There remains substantial controversy over the impact of thyrotoxicosis itself on the development and progression of extrathyroidal features of Graves disease. It has been argued that the presence of a source of thyroid antigens (the thyroid itself) sustains the autoimmune process in other organs, and that complete removal or ablation of the thyroid might result in immunomodulation of the systemic process, though not all authors agree. A parallel argument holds that the
increased release of thyroidal antigens, following administration of radioactive iodine, can exacerbate the extrathyroidal autoimmune process, anti-thyroid drugs or surgery might prove beneficial, anti-thyroid drugs or surgery might prove beneficial, or by decreasing the release of this antigen into the systemic circulation (antithyroid drugs). Similarly, hypothyroidism in the aftermath of incomplete thyroid ablation may increase thyroid autoantigen release, and there is some evidence that a rise of TRAb levels and worsening of ophthalmopathy can occur in this situation. The evidence for each of these lines of reasoning is often weak or contradictory, and the practical implications for management of patients are not entirely “evidence based.” Nevertheless, some anecdotal and observational data suggest that treatment of thyrotoxicosis with radioactive iodine is associated with a mild to moderate worsening of established ophthalmopathy, especially when hypothyroidism is permitted to ensue. Whether such changes are clinically relevant in most cases remains in dispute. Many groups however, avoid this treatment for such patients, or use concurrent treatment with corticosteroids to minimize proinflammatory changes. Others prefer to use higher ablative doses of radioactive iodine, ensuring prompt treatment with thyroxine to avoid hypothyroidism. Careful avoidance of postradioactive iodine hypothyroidism is important, particularly in patients with preexisting eye changes.

**Ophthalmopathy.** The ophthalmologic features are the result of inflammatory changes within the orbital space, causing edema and, therefore, enlargement of both muscle and fat. Orbital fibroblasts involved in this process lay down extracellular glycosaminoglycans that contribute to increased retro-orbital pressure. This swelling causes anterior protrusion of the globe (exophthalmos), impaired lymphatic and venous drainage resulting in periorbital edema, and imbalance of retro-ocular muscle function, which causes diplopia and strabismus. Lid retraction and lid-lag are the result of the exophthalmos, involvement of the levator palpebrae superioris muscle in the inflammatory process, and possibly an increase in sympathetic muscle tone caused by the thyrotoxic state. Finally, muscle fibrosis and permanent deposition of glycosaminoglycans, may result in irreversible changes, causing permanent exophthalmos, diplopia, and lid retraction, even when the inflammatory changes resolve. Up to 50% of patients with Graves disease have some evidence for ophthalmopathy at the time of diagnosis of Graves disease, though in only around 20% of patients is it clinically overt, and only a small minority develop sight-threatening changes.

**Dermopathy.** The characteristic lesions of Graves dermopathy occur on the lower extremities, most frequently on the anterior lower third of the shin or on the dorsum of the foot. This condition is relatively uncommon, affecting less than 5% of patients with Graves disease. The lesion is typically well demarcated, nodular, raised, brawny rather than edematous, dusky, and discolored. They blanch to pressure and are nonpitting to pressure. The skin overlying them is pitted and described as peau d’orange (literally “skin of the orange”), an accurate description of its appearance and texture. In most cases these lesions are asymptomatic, but pruritis and mild discomfort may occur and ulceration has been described. In more extreme cases, the dermopathy may become diffuse, occasionally even resembling elephantiasis. Although the lower extremity anatomic distribution is characteristic, dermopathy is recognized to occur at other sites, particularly if there is a history of local trauma (the Koebele phenomenon), including the upper extremities, shoulders, trunk, face, and ears. Histologically, the findings are of subcutaneous infiltration with mucinous material consisting of extracellular glycosaminoglycans, found most prominently in a perivascular distribution. The normal collagen matrix is distorted, but the overlying epidermis is often normal. The pathogenesis of the condition is unknown, but it is seen rarely in the absence of ophthalmopathy and occurs most frequently in patients with high circulating levels of TRAbs. There are data from in vitro studies that implicate serum factors, but it remains unclear whether these represent circulating autoantibodies (presumably to a cross-reacting antigen) or perhaps more likely some other factors that trigger a fibroblast response.

**Acropathy.** Soft tissue swelling also characterizes the thickened extremities of thyroid acropathy, the least common manifestation of Graves disease, affecting fewer than 1% of patients. Swelling and clubbing of the digits is associated with subperiosteal new bone formation and fibrosis of the marrow space. The overlying skin is often pigmented. Histologic findings are virtually identical to those seen in Graves dermopathy.

**Evaluation and Treatment of Ophthalmopathy.** Unilateral eye changes mandate exclusion of a retro-ocular mass lesion. Both carcinoma (most commonly metastatic) and lymphoma have been described as possible causes of unilateral exophthalmos, and the increased retro-orbital pressure arising in these conditions impedes venous and lymphatic drainage and mimics the periorbital edema of Graves disease. Anterior protrusion of the globe results in apparent lid retraction, with secondary conjunctival inflammatory changes and exposure keratitis. Nevertheless, even in a patient with no prior history of thyrotoxicosis, Graves disease is one of the most common causes of exophthalmos, even when it is unilateral. In such cases of euthyroid Graves eye disease, thyrotropin receptor and TPO antibodies are commonly detectable, even when thyroid function is normal, and many such patients will eventually go on to develop thyrotoxicosis.

A detailed ophthalmologic examination is mandatory in the care of Graves patients to document lid placement, proptosis, ocular mobility and alignment, and visual function. CT scanning of the orbits is the investigation of choice in all cases of Graves eye disease and will definitively exclude a mass lesion. In addition, specific features of Graves disease will be identified, most prominently swelling of the muscle bodies and increased retro-orbital fat volume. CT scanning is, of course, essential if decompressive surgery is being considered.

Symptomatic therapy can be effective, particularly in mild or moderate ophthalmopathy, in which mild exposure keratitis and conjunctival irritation predominate. Lid retraction may result in failure of eye closure, particularly during sleep, resulting in dry, gritty, irritated eyes, with discomfort and photophobia. The frequent use of artificial tears during the day, and nonmedicated ophthalmic ointment at night, along with tinted spectacles or sunglasses may go a long way to resolving mild symptoms. Periorbital edema is largely a cosmetic issue, and will often resolve although incompletely as the inflammation settles and venous drainage improves. The use of cold compresses may provide some symptomatic relief.

If lid retraction remains after resolution of any acute inflammatory changes, a relatively minor lid-lengthening procedure can be easily performed. Similarly, minor cosmetic procedures to remove redundant skin, left in the aftermath of periorbital edema, can improve the appearance. Such interventions are generally delayed for at least 12 to 24 months after the development and stabilization of Graves ophthalmopathy, to ensure that any acute inflammatory changes have completely resolved.

More aggressive ophthalmopathy, particularly with severe exophthalmos, exposure keratitis, and conjunctival ulceration, or features of optic nerve compression (manifested by altered color vision, reduced visual acuity, or visual field changes), requires more active acute management. In extreme cases, emergency decompression surgery is indicated to preserve sight. More commonly, high-dose corticosteroids (prednisone 60 mg/d or equivalent) are used initially, reserving surgery for nonresponders or for patients who develop recurrent severe ophthalmopathy at unacceptably high maintenance doses of corticosteroid. Systemic corticosteroids abrogate the inflammatory process, decrease orbital swelling, improve lymphatic and venous drainage, and rapidly relieve optic-nerve compression.

Short courses of corticosteroids are also commonly used as an adjunct to therapy with radioactive iodine, particularly in patients with established mild or moderate ophthalmopathy, to attempt to minimize any posttherapy exacerbation. The known side effects of prednisone may outweigh the benefits in many cases, particularly if the ophthalmopathy is mild.

Even in severe ophthalmopathy, long-term treatment with corticosteroids is generally regarded as an unacceptable risk, because of the high doses required to maintain control of the eye changes. If symptoms and signs fail to resolve, or if they recur when the corticosteroid dose is reduced, alternative therapy is generally recommended, particularly in the form of decompressive surgery.
For many years, the longer-term treatment of choice in moderate to severe ophthalmopathy in which sight is not actively threatened has been orbital radiotherapy. The observation that radiation therapy might be beneficial was made incidentally in patients receiving pituitary irradiation administered as treatment for Graves disease at a time when the condition was thought to originate from pituitary oversecretion. Once the pathogenesis of Graves disease was understood, a re-analysis of the radiation fields showed that a substantial dose was being administered to the orbit, and specific orbital radiotherapy became popular.

Despite its popularity and widespread use, few clinical trials of this modality existed until recently. Somewhat surprisingly to many proponents of the technique, several large randomized controlled trials have shown only minimal improvement in clinical symptom scores in patients receiving orbital radiotherapy compared to a sham control. A carefully controlled randomized double-blind trial, performed by Gorman and colleagues, in which each patient served as his or her own control, and radiotherapy was administered to a single orbit, showed no significant change in any objective measurement of severity following radiotherapy. While this study remains highly controversial, there seems little doubt that orbital radiotherapy is far less effective than previously assumed and that previous apparent improvements might simply have reflected spontaneous resolution of the underlying disease process in many cases.

Orbital decompression is being used increasingly and, in experienced hands, carries an excellent outcome even in severe ophthalmopathy. By removal of the medial, inferior, lateral, and occasionally superior walls of the orbit, the orbital contents are allowed to herniate into adjacent cavities. By increasing the space available for the swollen orbital contents, pressure reduction is achieved, globe position is improved, and improvement is seen in venous drainage with resolution of the secondary changes. A proportion of these patients will develop postoperative diplopia, even when no diplopia existed prior to decompression. While appropriate prism lenses improve visual function, most patients with diplopia will require surgical correction to restore conjugate gaze. This procedure is generally delayed for some months to allow complete resolution of the inflammatory process and is often combined with lid lengthening and other cosmetic procedures.

**Plummer Disease (Toxic Multinodular Goiter).** In contrast to our understanding of the pathogenesis of Graves disease, toxic multinodular goiter remains something of an enigma. A number of factors, including childhood iodine deficiency and unknown genetic factors may be responsible for the development of nodular hyperplasia of the thyroid gland. In contrast to autonomously functioning solitary toxic adenomas, whose etiology may lie in activating mutations of the TSH receptor, the generalized hyperplasia of the gland seen in multinodular goiter remains unexplained, with no recognized genetic influences. Whatever the trigger, progressive hyperplasia results in an increasingly enlarged and nodular gland, which, in many cases, becomes autonomously functional.

Disruption of the normal follicular architecture, with microfollicles, sheets of follicular cells, and isolated islands of cells, makes iodine trapping less efficient, resulting in the production of less iodinated forms of thyroid hormone. Consequently, as autonomy develops progressively, patients may develop gradual onset of "T3-toxicosis." Typically, a suppressed TSH is associated with a normal level of T4, leading to a diagnosis of "subclinical hyperthyroidism," despite what may often be significant clinical features, including a significant risk of thyrotoxic bone disease (exacerbating osteoporosis) and atrial fibrillation. Measurement of T3 typically reveals the degree of thyrotoxicosis which may be severe, particularly in older patients. Iodine excess contributes to the development of thyrotoxicosis by overcoming the relative inefficiency of iodine trapping exhibited by these goiters, so that severe thyrotoxicosis may result from iodine exposure, for example after administration of iodine-containing contrast material for an angiogram or CT scan.

Treatment of toxic multinodular goiters is identical to that of Graves disease, with the exception that antithyroid drugs will only be effective while they are administered, with little chance of spontaneous remission, except in cases that have been triggered by iodine exposure. Iodine uptake, measured as a 24-hour uptake, is often normal or only slightly elevated because of the inefficiency of iodine trapping. Consequently, effective treatment with I-131 requires higher administered doses. Stimulation with recombinant TSH (rTSH) may overcome this problem, and the treatment of toxic multinodular goiter increasingly is being performed with radioactive iodine rather than surgery.

**Hypothyroidism.** Hypothyroidism, resulting primarily from autoimmune destruction of the thyroid gland, is among the most common of endocrine diseases, affecting 1 to 1.5% of all women and up to 0.5% of men. Several community-based surveys show an increasing prevalence with age in both sexes, reaching over 12% among women over the age of 70. M any more individuals of both sexes develop subclinical disease, and some evidence of autoimmune thyroiditis can be found at autopsy in 45% of women and 20% of men in the United States.

The diagnosis of hypothyroidism is generally straightforward, both clinically and biochemically, and treatment with oral thyroid hormone replacement is simple and well tolerated. The widespread availability of sensitive TSH assays, and the broad range of L-thyroxine (T4) doses produced by several manufacturers have made accurate dose titration possible. However, there remains controversy about the dose of thyroid hormone required for replacement therapy, the use of T4 alone or in combination with T3, the need for dose adjustment during pregnancy or intercurrent illness, and the treatment of patients with subclinical hypothyroidism.

Primary hypothyroidism may be caused by damage or destruction of thyroid tissue, or by interference with thyroid hormone synthesis. By far the most common cause is autoimmune thyroiditis, of either atrophic or goitrous type, commonly known as Hashimoto disease.

The symptoms of hypothyroidism are broad ranging but may be quite nonspecific, particularly in mild forms of the disease. Because many of these symptoms are frequent in the population even in the absence of thyroid disease and hypothyroidism is so common, it is frequently the case that a patient complaining of fatigue (for example) may be found to have abnormal TSH, T4, and T3 levels. The symptoms of hypothyroidism are therefore best considered as a result of general slowing, with depression, weight gain, and poor memory all common.

Adapted from reference 107.
Uncomplicated primary hypothyroidism usually begins with a small initial dose of approximately 50 μg daily, and the dose is increased at intervals of 4 to 6 weeks to a full replacement dose of approximately 100 to 150 μg/d. Patients with pre-existing symptomatic coronary artery disease or poorly controlled atrial or ventricular arrhythmias should begin treatment more cautiously because of the increased myocardial oxygen requirements induced by thyroid hormone, and its transient proarrhythmic effect.118 Starting doses of 12.5 to 25 μg/d are used commonly, with gradual increases, guided by the TSH response. The final achieved dose should be the same, however.

Because of the long half-life of thyroxine (~87 days), it is possible to administer thyroxine once weekly, and at least one study has demonstrated satisfactory control of both biochemical and clinical parameters using such an approach.109 More traditionally, thyroxine is administered once daily. If patients forget to take a dose, then the subsequent dose can safely be doubled, or the dose simply omitted, without any major adverse impact on thyroid hormone concentrations or thyrotoxic response.110,111

The long thyroxine half-life and the relatively slow response of the pituitary thyrotrop to changes in circulating thyroid hormone concentrations make frequent adjustments of thyroid hormone dose undesirable.118 Changes in thyroxine dose more frequent than every 2 to 3 months may result in overcompensation, with the risk of symptomatic hyperthyroidism from overtreatment, and apparently unstable dose requirements.

Although rare allergies have been reported to the inert ingredients of specific thyroxine preparations, the drug is otherwise without side effects, except for the impact of over- or under-replacement. Excessive dosing is associated with symptoms of thyrotoxicosis, while inadequate treatment allows persistent hypothyroidism. Occasionally, particularly if the dose is changed rapidly, patients experience concurrent symptoms of both under- and overreplacement; but almost always this will be a transient phenomenon. The goal should be to achieve stable thyroid hormone concentrations.

Other causes of altered dose requirements include patient noncompliance and erratic thyroxine absorption. This arises only infrequently in patients with extensive small bowel disease and malabsorption.112 More commonly, other drugs, minerals, or food supplements are responsible, either by increasing thyroxine metabolism, for example, phenytoin, or by interfering with intestinal absorption, for example, cholestyramine, ferrous sulfate, calcium carbonate. Ideally, thyroxine should be taken along with no other medication, preferably on an empty stomach prior to breakfast.

Following the initiation and stabilization of treatment with thyroxine, repeat thyroid function testing is recommended after approximately 3 months, a further 6 months, and then annually. Hypothyroidism in some patients may be gradually progressive, and dose requirements often change over the first few months of treatment. Thereafter, only minor and gradual changes in thyroid hormone dose are required in most patients, with a slight reduction necessary with aging. As noted below, pregnancy is also associated with significant alterations in thyroid hormone metabolism, and careful monitoring is justified. The clinical conditions most often requiring altered thyroxine dosing are shown in Table 4.

Most patients with long-standing hypothyroidism symptoms notice an improvement with thyroxine replacement within 2 to 3 weeks of starting treatment. Weight reduction, cardiovascular symptoms, changes in metabolic parameters, and many of the neuropsychiatric symptoms improve quite rapidly, while structural changes including

Laboratory testing shows only borderline abnormalities, that appropriate consideration should be given to alternative explanations of the patient's symptoms.

**Treatment of Hypothyroidism.** The mainstay of treatment for patients with hypothyroidism for the last century has been oral thyroid hormone replacement.114 Initially available as an extract of animal thyroid, synthetic T4 and T3 have become widely available in the last 30 years. The total daily secretion of thyroxine from a healthy thyroid gland is proportional to body mass, but typically thyroid hormone is not prescribed on a microgram per kilogram basis. Instead, patients with poorly controlled atrial or ventricular arrhythmias should begin treatment more cautiously because of the increased myocardial oxygen requirements induced by thyroid hormone, and its transient proarrhythmic effect.118 Starting doses of 12.5 to 25 μg/d are used commonly, with gradual increases, guided by the TSH response. The final achieved dose should be the same, however.

Because of the long half-life of thyroxine (~87 days), it is possible to administer thyroxine once weekly, and at least one study has demonstrated satisfactory control of both biochemical and clinical parameters using such an approach.109 More traditionally, thyroxine is administered once daily. If patients forget to take a dose, then the subsequent dose can safely be doubled, or the dose simply omitted, without any major adverse impact on thyroid hormone concentrations or thyrotoxic response.110,111

The long thyroxine half-life and the relatively slow response of the pituitary thyrotrop to changes in circulating thyroid hormone concentrations make frequent adjustments of thyroid hormone dose undesirable.118 Changes in thyroxine dose more frequent than every 2 to 3 months may result in overcompensation, with the risk of symptomatic hyperthyroidism from overtreatment, and apparently unstable dose requirements.

Although rare allergies have been reported to the inert ingredients of specific thyroxine preparations, the drug is otherwise without side effects, except for the impact of over- or under-replacement. Excessive dosing is associated with symptoms of thyrotoxicosis, while inadequate treatment allows persistent hypothyroidism. Occasionally, particularly if the dose is changed rapidly, patients experience concurrent symptoms of both under- and overreplacement; but almost always this will be a transient phenomenon. The goal should be to achieve stable thyroid hormone concentrations.

Other causes of altered dose requirements include patient noncompliance and erratic thyroxine absorption. This arises only infrequently in patients with extensive small bowel disease and malabsorption.112 More commonly, other drugs, minerals, or food supplements are responsible, either by increasing thyroxine metabolism, for example, phenytoin, or by interfering with intestinal absorption, for example, cholestyramine, ferrous sulfate, calcium carbonate. Ideally, thyroxine should be taken along with no other medication, preferably on an empty stomach prior to breakfast.

Following the initiation and stabilization of treatment with thyroxine, repeat thyroid function testing is recommended after approximately 3 months, a further 6 months, and then annually. Hypothyroidism in some patients may be gradually progressive, and dose requirements often change over the first few months of treatment. Thereafter, only minor and gradual changes in thyroid hormone dose are required in most patients, with a slight reduction necessary with aging. As noted below, pregnancy is also associated with significant alterations in thyroid hormone metabolism, and careful monitoring is justified. The clinical conditions most often requiring altered thyroxine dosing are shown in Table 4.

Most patients with long-standing hypothyroidism symptoms notice an improvement with thyroxine replacement within 2 to 3 weeks of starting treatment. Weight reduction, cardiovascular symptoms, changes in metabolic parameters, and many of the neuropsychiatric symptoms improve quite rapidly, while structural changes including

Although the majority of patients treated with thyroxine for autoimmune thyroid disease experience complete resolution of symptoms, a significant minority continues to exhibit symptoms and signs compatible with mild hypothyroidism. Most often the lingering symptoms include fatigue and lethargy, cold intolerance, dry skin, and difficulty losing weight. Although definitive evidence is lacking, these symptoms have been blamed on persistent tissue hypothyroidism.

In normal health, the thyroid gland itself is the source of approximately 20% of circulating T₃, while the remainder is produced by deiodination of thyroxine in the liver and, to a lesser extent, the kidney. The regulation of this process depends on the rate of T₄ transport across the hepatocyte membrane. Following destruction of the thyroid gland by autoimmune disease, surgery or radioactive iodine, all circulating T₃ must be derived from exogenous thyroid hormone. As a result, patients treated with thyroxine alone often exhibit somewhat reduced circulating T₃ concentrations, and the typical profile in such a patient is for normal TSH, free thyroxine in the upper half of the normal range, and a low-normal or even frankly reduced T₃ concentration.

One important study addressed this issue of apparent persistent hypothyroidism in patients receiving thyroid hormone, by comparing replacement using T₄ alone with a combination of T₄ and T₃. This randomized, double-blind, placebo-controlled crossover trial included 33 patients receiving thyroxine treatment for Hashimoto thyroiditis or thyroid cancer. Participants were randomized to treatment with either thyroxine alone (plus placebo), or a slightly reduced dose of thyroxine supplemented with triiodothyronine. After 5 weeks, patients were converted to the other treatment arm for another 5 weeks. The patients receiving combined T₄ and T₃ treatment exhibited higher circulating T₃ concentrations, and the typical profile in such a patient is for normal TSH, free thyroxine in the upper half of the normal range, and a low-normal or even frankly reduced T₃ concentration.

In the presence of mildly elevated TSH, positive thyroid antibodies imply that a patient has autoimmune thyroid disease. A 20-year follow-up study in the North of England demonstrated that over 50% of women with positive thyroid antibodies and a TSH greater than 6 mU/L would go on to develop overt hyperthyroidism, a rate of over 4% per year. Such patients probably warrant thyroxine replacement even in the absence of significant symptoms, because of the likely future need for this treatment.

Subclinical hypothyroidism is accompanied by changes in target organs, which may be reversible. Changes in auditory acuity, left ventricular function, and capillary permeability may be apparent although it is not clear whether these changes justify treatment with thyroid hormone. Similar changes in lipids are associated with subclinical hypothyroidism, and subclinical hypothyroidism has been associated with a risk factor for atherosclerosis. The evidence for this is weak, however, and patients with truly subclinical hypothyroidism (TSH less than 10.0 mU/L and no symptoms) do not exhibit hyperlipidemia. Nor does treatment to restore the TSH to normal significantly affect lipid profiles. As yet, there is no adequate clinical trial assessing the impact of treatment of subclinical hypothyroidism.

It is, therefore, reasonable to consider treatment with thyroxine for patients discovered to have subclinical hypothyroidism as a result of autoimmune thyroid disease. However, those patients should not be led to expect a dramatic resolution of all of their symptoms, and the "trial and error" nature of the treatment should be discussed fully. Other contributory causes for the patient's symptoms also require evaluation.

Autoimmune Hypothyroidism. Hashimoto thyroiditis was originally defined on the basis of characteristic pathologic features, including lymphocytic infiltrates, germinal centers, reduced follicle size, and oxyphilic follicular cells (Hürthle cells). Clinically, patients have a goiter and may become hypothyroid although circulating antibodies and the goiter may predate thyroid gland failure, sometimes by years.

The goiter is firm and slightly irregular, with the surface texture described as bossed. These surface irregularities represent areas of hyperplasia within the gland; and, in some cases, one or more of these regions may enlarge and become a clinically detectable thyroid nodule. Such "hyperplastic nodules" are the most common cause of thyroid nodules in patients (especially women) with autoimmune thyroid disease. These nodules are often poorly defined clinically and may be "cool" or "warm" on isotope scanning, which is therefore not a reliable technique in this setting. Ultrasound examination often reveals a poorly defined nodule, which is isoechoic or hypoechoic, and contiguous with the remainder of the gland. Fine-needle aspiration biopsy (FNAB) reveals thyroid follicular cells but may also show Hürthle cells, which can be easily misinterpreted as indicating a Hürthle cell neoplasm, so leading to unnecessary surgery. Lymphocytes may also be identified, consistent with autoimmune thyroid disease. Occasionally, lymphocytic infiltration is marked, and low-grade lymphoma may occasionally be suspected. A core biopsy or even an open biopsy may rarely be necessary to exclude this diagnosis.

Thyroid nodules developing as a hyperplastic response in thyroid autoimmune may appear and grow rapidly, mimicking thyroid cancer. They will resolve spontaneously in many cases with simple observation. Treatment of hypothyroidism, with consequent reduction of TSH, may speed their resolution. Suppression of TSH is not justified, however, as there is no indication that this approach is any more effective than simply treating the hypothyroidism.

Secondary (Central) Hypothyroidism. Pituitary or hypothalamic disease may reduce or destroy the capacity of the pituitary to manufacture and secrete TSH in response to falling thyroxine levels. Secondary hypothyroidism is usually dominated by symptoms of the underlying pituitary or hypothalamic disease process and by failure of other pituitary hormones. Most
often, the diagnosis is made incidentally during evaluation of hypopituitarism. Nevertheless, management of thyroid status in hypopituitarism is an important aspect of treating these patients. Recognized causes of secondary hypothyroidism are shown in Table 5.

Measurement of circulating TSH has become an important aspect of treating these patients. Recognized causes of secondary hypothyroidism are shown in Table 5.

Transient Hypothyroidism. The majority of patients who develop hypothyroidism require lifelong treatment with thyroxine. However, transient hypothyroidism is increasingly recognized and may cause symptomatic or asymptomatic changes in thyroid hormone concentrations for a few weeks, months, or even years.

Occasionally, spontaneous remission of hypothyroidism associated with autoimmune thyroiditis may occur, and there are several case reports of patients with long-standing hypothyroidism whose thyroid function returns to normal, or who go on to develop thyrotoxicosis secondary to Graves disease. The majority of such cases almost certainly developed hypothyroidism as a result of blocking antibodies, binding to the TSH receptor and preventing its activation by TSH. A shift in the antibody epitope spectrum, perhaps triggered by pregnancy or intercurrent infection, may cause the development of stimulating antibodies, and consequently Graves disease.

Transient hypothyroidism may also be seen following treatment of Graves disease either with surgery, or with radioactive iodine. Incomplete surgical removal of the gland (subtotal thyroidectomy or lobectomy) leaves sufficient tissue in situ to permit regrowth of the gland under the trophic stimulation of TSH receptor antibodies. Similarly, the use of low doses of radioactive iodine may result in incomplete ablation of the thyroid, and regrowth of the thyroid remnant is possible. Recurrence of the hypothyroidism may occur although a few patients do maintain euthyroid status.

More commonly, transient hypothyroidism reflects reversible injury to the thyroid gland by an inflammatory process, or by external factors, including goitrogens and iodine (Table 6). Of these, the most common are silent thyroiditis and postpartum thyroiditis, which are related conditions.

Silent and Post-Partum Thyroiditis. Silent and post-partum thyroiditis are related, autoimmune-mediated, transient inflammatory diseases of the thyroid. The acute or subacute inflammation causes damage and disruption of the thyroid follicles, release of pre-formed thyroid hormone, and later hypothyroidism during gland repair and recovery. Return of normal thyroid function occurs in the majority (>90%) of cases after 3–6 months.

Although postpartum thyroiditis is normally transient, the risk of transient postpartum thyroiditis is increased 100-fold in patients with positive TPO antibodies, and a significant proportion of patients develop persistent autoimmune hyper- or hypothyroidism.

During the thyrotoxic phase, postpartum thyroiditis can be distinguished from Graves disease on the basis of radioactive iodine uptake, since the uptake in postpartum thyroiditis will be low. This reflects the gland injury, with release of preformed thyroid hormone. Alternatively, measurement of TSH receptor antibodies can be used to distinguish these two conditions, avoiding exposure to radioactive iodine. This is particularly important if the patient is still breastfeeding. This thyrotoxic phase is often brief and not severe and may go unnoticed by patient and physician, particularly in the early weeks following the birth of a baby.

Thyrotoxicosis rarely lasts more than a few weeks and is followed in the majority of cases by more prolonged and often symptomatic hypothyroidism. It is during this hypothyroid phase that postpartum depression may first come to light. The distinction between transient and permanent hypothyroidism depends on the history, and there are no diagnostic tests to distinguish between them. The uptake of iodine will be low in both cases, and TPO antibodies are commonly positive in both. In postpartum thyroiditis, hypothyroidism gradually results over a period of 4 to 6 months, and rarely lasts longer than 8 to 12 months in total.

Treatment of the hypothyroidism may be considered if symptoms are sufficiently troublesome. The goal should be to achieve a low-normal TSH, as outlined earlier. Because the hypothyroidism will almost certainly prove transient, a gradual supervised dose reduction, guided by thyroid function testing, is appropriate.

In less severe cases, where the symptoms of hypothyroidism are mild, it is reasonable simply to observe thyroid function until spontaneous resolution. The management of silent thyroiditis follows the same lines but is less likely to require temporary thyroid hormone treatment.

Adapted from reference 132.

Riedel Thyroiditis. Riedel thyroiditis is the least common form of thyroiditis with an operative incidence of 0.06% (37 cases in 57,000 thyroidectomies). The typical age of presentation is between 30 and 50 years with women affected more commonly than men (4:1). This disease is a chronic fibro-inflammatory process which produces a stony hard, painless thyroid mass with potential fibrotic extension into adjacent tissues. The fibrotic process often generates tracheal compression, laryngeal distortion, and pharyngeal and esophageal narrowing. The picture of a rock-hard thyroid mass with associated dyspnea, hoarseness, stridor, or dysphagia raises obvious concern for malignancy.

Functional studies are not helpful in the diagnosis as most patients remain euthyroid although both hypothyroidism and hyperthyroidism have been reported. Other laboratory investigations are nonspecific including sedimentation.
rate and antithyroid antibodies, while imaging features lack diagnostic characteristics. Radio-nuclide imaging reveals findings similar to other forms of thyroiditis with a heterogeneous or low uptake. Ultrasonography reveals a homogeneously hypoechoic pattern and magnetic resonance imaging (MRI) reveals a hypointense appearance on T1- and T2-weighted images. CT is the most useful imaging technique in the evaluation of the thyroid gland with direct extension, infiltration, and encasement of adjacent structures.

Fine needle aspiration is frequently nondiagnostic due to an acellular specimen and the diagnosis will often require an open biopsy. Diagnostic criteria include: (1) grossly visible fibro-inflammatory process involving all or a portion of the thyroid gland; (2) gross and/or histological evidence of extension into adjacent structures; (3) absence of granulomatous reaction; and (4) absence of neoplasm. The characteristic cellular infiltrate progresses from lymphocytes, plasma cells, neutrophils, and eosinophils to a dense fibrous infiltration with hyalinization. It is the extension of the dense hyalinized fibrous tissue, which obliterates tissue planes, that renders safe resection nearly impossible. Based on the clinical history, imaging and benign FNAB, patients who have airway obstructive lesions should undergo a decompensative isthmoectomy only.

The relative rarity of Riedel thyroiditis has precluded any clinical trials to guide medical management. Glucocorticoids and tamoxifen have been reported to provide benefit. Typically glucocorticoids are used as first-line therapy with a variable rate and duration of response. These drugs are often used as first-line therapy because of the progressive perithyroidal infiltration and fibrosis with potentially life-threatening destruction of local structures. In some instances dramatic responses to glucocorticoids have been described as well as lasting benefit even after their withdrawal, while several case reports have suggested subjective and objective improvement in response to tamoxifen, in glucocorticoid resistant cases.

Riedel thyroiditis is most likely to represent a variant of idiopathic multifocal fibrosis, a suggestion supported by its association with retroperitoneal fibrosis, scleromyxoidit cial fibrosis, mediastinal fibrosis, and orbital pseudotumor. Multifocal fibrosclerosis is a disorder apparently related to a plasma cell infiltrate that expresses high levels of IgG4. Biopsy studies reveal T- and B-cell infiltrates with the plasma cells consistently expressing IgG4. The IgG4 plasma cells are diminished in number with glucocorticoid therapy, and elevated serum levels of IgG4 are not consistently identified.

Suppurative Thyroiditis. A cute suppurative thyroiditis (AST) is an uncommon disorder, perhaps because the gland is difficult for bacterial access because of fibrous encapsulation of the gland and represents a hostile environment for bacterial growth because of the high iodine concentration and highly oxidizing state. The most common predisposing factor associated for AST is the persistence of an embryologic connection of the gland to the upper aerodigestive tract via a fourth pharyngeal pouch remnant or a thyroglossal duct remnant. Therefore, it is not uncommon for the onset of AST to follow an upper respiratory or oral infection, especially with lingual involvement. Fourth pharyngeal pouches are only found on the left side. If the right side is the primary site involved, an alternative underlying cause should be considered. In adults, thyroid abnormalities such as goiter or nodular disease may become infected by hematogenous or lymphatic routes, and direct inoculation has also been reported. Bacterial microorganisms are the most common source of AST although fungi, viruses, and parasites have been implicated rarely. The bacterial microorganisms most frequently associated with AST include staphylococcal and streptococcal species.

Symptoms and findings that suggest the development of AST include fever, neck swelling, pain, and leukocytosis. Regional inflammation may also prompt pharyngeal and laryngeal swelling with resultant odynophagia and dysphonia. In young children laryngitis can be a finding in the early stage of abscess formation. Suspicion of a neck abscess should prompt radiological evaluation with both ultrasound and CT scanning providing useful information. A pharyngeal pouch should be considered as a source even in young adults and therefore a barium swallow or CT scanning performed after the administration of oral contrast should be performed. The authors prefer to have these studies completed when the neck is not acutely infected since the regional edema at the time of acute inflammation can obstruct the pouch tract. Thyrotoxicosis is generally not associated with AST, although a few case reports exist of thyrotoxicosis in association with AST, due to the disruption of follicles and the release of preformed thyroid hormone.

Treatment involves supportive care, appropriate antibiotic therapy, drainage of the abscess, and closure of any pharyngeal connection. Closure of this connection requires exposure of the piriform sinus mucosa near the criocothyroid articulation. Identification and preservation of the recurrent nerve is necessary and often the thyroid lobe will be sufficiently involved that a significant portion of the lobe must be removed.

Nonthyroidal Illness (the “Euthyroid Sick Syndrome”). Abnormalities of thyroid hormone concentrations, without evidence of intrinsic thyroid or pituitary gland disease, are seen frequently in a wide variety of nonthyroidal illnesses, including infections, trauma, myocardial infarction, major surgery, malignancy, inflammatory conditions, and starvation. Following recovery from the underlying illness, the thyroid function normalizes, and the “euthyroid sick syndrome” was so named because the abnormalities seem to represent a response to the underlying illness, rather than an abnormality of the thyroid gland itself. The implicit assumption that the patient is therefore euthyroid has led to recommendations to avoid testing the pituitary-thyroid axis during intercurrent illness, and among the majority of hospitalized patients. Whether these patients are truly euthyroid remains unproven, however, and some studies have shown evidence of hypothyroidism at least in some tissues in these patients. Because of these uncertainties, the preferred term for this condition remains “non-thyroidal illness” (NTI).

A variety of patterns of thyroid hormone and TSH concentrations have been reported in NTI, reflecting both the type of illness and its severity. Three patterns of thyroid function are recognized: low T3 syndrome; low T3 and low T4; and low TSH.

Low T3 Syndrome. This is the most common form of NTI, most often resulting from acute illness. The serum T3 concentration falls rapidly within 30 minutes to 24 hours of the onset of the causative illness, and the degree of fall reflects the severity of the disease process. Reversal of T3 (rT3) rises as T3 falls, reflecting altered activity of hepatic de-iodinase, the source of around 80% of T3 in humans.

Low T3 and Low T4 Syndrome. With more severe and more prolonged illness, total T4 concentrations fall over 24 to 48 hours. Once again, the degree of fall in T4 correlates with mortality in a number of conditions. Free thyroxine concentrations are variable, perhaps reflecting an impact of NTI on the assays used to measure free-T4. The fall in T4 reflects a fall in thyroid-binding globulin and, in some cases at least, the presence of an unidentified inhibitor of T4 binding. Transient elevations in free-T4 are seen in some NTI as a result.

Low TSH Syndrome. In the most severe or prolonged forms of NTI, and prominent in cases of starvation and malnutrition, TSH concentrations fall despite the low T4 and T3 concentrations. The TSH response to exogenous thyrotropin releasing hormone (TRH) is blunted within 24 hours of onset of NTI, while TSH pulsatility and the normal nocturnal TSH surge are both impaired, suggesting an effect of NTI on both the pituitary and hypothalamus. During the recovery from NTI, TSH may transiently rise to levels above normal.

A number of possible mediators of NTI have been suggested, most promisingly some of the known mediators of the inflammatory response, particularly members of the interleukin family. Interleukins and tumor necrosis factor-alpha (TNF-α) mimic almost all of the features of NTI, including reduced thyroid hormone and TSH concentrations, a blunted TSH response to TRH injection and impaired thyroid hormone de-iodination. In addition, TNF-α concentrations show a close correlation with T3 concentrations in a number of studies of NTI. However, the precise role of these and other potential mediators of NTI remains speculative.
Whatever the precise mechanism, the triggers for NTI are well recognized. Starvation and malnutrition appear to be particularly potent causes of abnormal TSH and TSH secretion, and altered hypothalamic control seems likely to play a major role. In premenopausal women, other evidence of hypothalamic dysfunction is provided by the presence of secondary amenorrhea, caused by hypogonadotropic hypogonadism, which is an almost universal accompaniment to prolonged NTI.

The challenge remains to determine whether the patients are euthyroid. A suppressed TSH indicates thyrotoxicosis only when the hypothalamic and pituitary feedback mechanism is intact. Hypothalamic or pituitary disease, including tumors, infarction, and trauma, may disrupt this mechanism, and the discovery of apparently "inappropriate" TSH suppression requires further assessment.

Our limited ability to determine thyroid status at a tissue level remains one of the major barriers to understanding the impact of NTI. Several tissue-specific markers of thyroid hormone action are directly correlated with T3 concentrations in NTI, suggesting that at least some tissues experience true "hypothyroidism." It remains unknown whether this tissue hypothyroidism is protective or destructive.

The vast majority of patients with NTI who recover from their underlying illnesses experience prompt recovery also of the hypothalamic–pituitary–thyroid axis. No specific therapy is indicated for their thyroid status. Few human studies have been performed of thyroid hormone replacement in NTI. In a small number of patients in a medical intensive care unit, with NTI caused by a variety of underlying illnesses, intravenous T4 resulted in a more prolonged suppression of TSH and delayed the rise in T3 during recovery from illness, perhaps impairing the recovery of the thyroid axis. Because of the impairment of the hepatic deiodinase discussed above, restoration of T3 concentration to normal would probably require administration of T3 rather than T4.

A double-blind, placebo-controlled, prospective study of 142 patients undergoing coronary artery bypass surgery confirmed improved cardiac output and lower systemic vascular resistance, but no difference was seen in outcomes. In contrast, intravenous T3 in 211 patients undergoing high-risk coronary artery surgery had no impact on any hemodynamic variable and failed to alter the need for postoperative inotropic support, time in intensive care, or time to hospital dismissal. In summary, no convincing evidence exists of therapeutic benefit from the administration of thyroid hormone to patients with NTI. Further trials are certainly justified and necessary but will be large and difficult to perform.

Pituitary TSH-Secreting Adenoma and the Syndrome of Thyroid Hormone Resistance. While laboratory testing of the pituitary-thyroid axis is well developed and highly reliable, there are times when the pattern of thyroid function tests remains confusing. One common anomaly is the finding of a combination of elevated TSH with normal thyroid hormone measurements, or normal TSH with elevated thyroxine concentrations. The most common cause of a pattern of this type is intermittent administration of L-thyroxine, most often the result of variable compliance. Because TSH takes some time to respond to changes in thyroid hormone concentrations, a patient who takes L-thyroxine intermittently may exhibit persistently elevated TSH, reflecting their true thyroid status, but have normal or even elevated thyroid hormone concentrations in the hours following ingestion of the hormone.

The possibility of a laboratory error should also be considered in the setting of test results that do not appear to be compatible. Each of the thyroid hormones is measured routinely by immunologically based assays, and all are prone to error if binding between the antibody and the analyte is altered. One common example is the presence in the serum of antimeouse antibodies, which can interfere with the binding of TSH to the mouse monoclonal antibodies used in many commercial TSH assay systems. In a two-site assay, this can result in spuriously elevated TSH measurements.

Among patients who have not previously been treated with thyroid ablation, a pattern of this type should raise the question of a TSH-secreting pituitary adenoma, a rare cause of secondary hyperthyroidism. This condition causes increased thyroidal production of thyroid hormones, driven by TSH stimulation. The majority of these cases are associated with TSH values within or close to the normal range, but higher concentrations are occasionally seen. However, these patients often exhibit signs and symptoms of thyroid hormone excess, rather than of hypothyroidism. Nevertheless, the possibility of a TSH-secreting pituitary adenoma should be considered in the differential diagnosis of any patient with a goiter, elevated thyroid hormone concentrations, and an inappropriately detectable or elevated TSH. Management of this condition requires treatment of the hyperthyroidism, followed by definitive treatment of the pituitary tumor, either surgically or by radiotherapy.

Thyroid hormone action is thought to be entirely dependent on the binding of T3 to its receptor within the cell, with consequent alteration in the affinity of the receptor for its DNA-binding sites. Consequently, the laboratory findings of a normal TSH in the setting of elevated thyroid hormone concentrations, or an elevated TSH in the face of normal thyroid hormone, suggest the possibility of thyroid hormone resistance syndrome implicating a defective cellular response to T3.

Abnormalities of the T3 receptor have been described, in which ligand (T3) binding is impaired, reducing T3 sensitivity. These abnormalities result in variable degrees of resistance to thyroid hormone, and reflect inherited germ-line mutations of the T3-receptor gene. Homozygous nonsense mutations, resulting in a nonfunctional T3 receptor, are probably lethal in utero, and it is the heterozygous mutations that have largely been described in humans. The severity of the disease correlates with the degree of inhibition of thyroid hormone binding in laboratory assays.

Resistance to thyroid hormone may be generalized resistance to the thyroid hormone (GRTH), isolated only to the pituitary, that is, pituitary resistance to thyroid hormone (PRT). Peripheral tissue resistance to thyroid hormone (PRTTH) is extremely rare. By far the most common, although still exceptionally rare, is GRTH, and the mechanism by which PRT and PRTTH might arise remains unclear, since the same gene is responsible for the thyroid hormone receptor in all tissues, including the pituitary. Nevertheless, several distinct clinical entities have been described and remain largely to be explained. The diagnosis of GRTH should be considered in patients with a history of goiter with elevated thyroid hormone concentrations but lack thyrotoxic symptoms or signs. If the goiter is treated by thyroid ablation, the development of hypothyroid symptoms and signs despite apparently normal or elevated thyroid hormone concentrations is suggestive of GRTH.

Confirmation of the diagnosis can be made in most cases by sequencing of the thyroid hormone receptor. In the meantime, exclusion of other causes of elevated TSH with normal thyroid hormone concentrations is required. Many laboratories are capable of screening patient serum for antimeouse antibodies to exclude the rare case of inaccurate TSH measurements. Imaging of the pituitary by MRI scanning should be performed to exclude a TSH-secreting pituitary adenoma. The majority of these are detectable on MRI scanning although tiny microadenomas have been reported rarely.

Neoplastic (Nodular) Thyroid Disease

Benign Thyroid Nodules. Thyroid nodules are common. Nodules can be detected by careful palpation in almost 10% of the general population in North America and in up to 60% either by high-resolution ultrasound or in autopsy studies. In contrast, clinically significant thyroid cancer is rare, being diagnosed in only around 1 in 10,000 individuals in the United States each year, a prevalence of less than 0.1%. As is the case for most thyroid disease, thyroid nodules are found more frequently in women (approximately 5:1 ratio), and the incidence rises with age, particularly after the age of around 45 years.

The discovery of a thyroid nodule mandates the exclusion of malignancy, and professional guidelines recommend a FNAB as a first-line investigation for this purpose. The vast majority (>75%) of clinically detected thyroid nodules are benign on fine-needle biopsy, making their excision optional. As a result, many patients live with persistent thyroid nodularity. This can make both patient and physician uncomfortable, sometimes leading to a desire to intervene by medical therapy in an effort to shrink the nodule.
Suppression of thyroid nodules with thyroid hormone was first used in the 1950s, and there are numerous studies addressing the efficacy of this approach, with somewhat contradictory findings. Many of the studies are limited by technical inadequacy, failing to define the pathologic process that causes the nodule and estimating, rather than measuring, the size of the nodule. In addition, these studies have included a broad range of nodule types and sizes, both solitary and multiple, and a wide array of thyroid hormone treatment and TSH targets. Consequently, this area of the field is confused.

For nonfunctional, or minimally functional nodules, radioactive iodine offers little chance of benefit, although there is an increasing trend that nodule on TSH for continued growth. Conversely, the surgical approach to benign nodular thyroid disease is well established, effective, and generally safe. The surgical technique is described later, along with risks and precautions.

Thyrotropin Regulation of Thyroid Cell Growth. Thyroid follicular cells depend on the trophic effect of TSH (thyrotropin) for maintenance of gland volume, and perhaps number of cells. TSH acts via a cell surface receptor, the TSH receptor, and activates both the cyclic adenosine monophosphate (cAMP)-dependent and inositol-tri-phosphate pathways. The second messenger systems are responsible both for the increased metabolic activity (thyroid hormone synthesis and release) and the maintenance of cell growth and division. In the absence of TSH, induced either by exogenous thyroid hormone or by pituitary insufficiency, the normal thyroid undergoes atrophy, exhibiting a reduction in extracellular volume (decreased colloid content) and cell mass (reduced cell volume and apoptosis). Suppression of gland volume can be achieved with thyroid hormone, which acts by reducing pituitary TSH secretion, via the pituitary-thyroid negative feedback mechanism.

While the normal thyroid decreases in volume with thyroid hormone suppression, the response of a thyroid nodule is less predictable. That response is determined by the dependence of that nodule on TSH for continued growth. Consequently, some nodules cannot be expected to respond to thyroid hormone suppression, while others may be exquisitely sensitive to a reduction in TSH concentration.

Pathology of Thyroid Nodules. The majority of thyroid nodules are benign. However, this classification includes a broad range of pathologic processes, including solitary adenomas, adenomatous (hyperplastic) nodules within a multinodular gland, thyroid (colloid) cysts, and regenerative nodules within a gland involved by Hashimoto disease.

Solitary Benign Follicular Adenoma. Activating mutations of the TSH receptor gene have been described in a proportion of these nodules. These mutations are somatic rather than germ-line. The TSH receptor in this context functions autonomously, in the absence of interaction with its ligand (TSH). Constitutive activation of the second messenger system within the cell results in development of a truly autonomous, often hyperfunctioning nodule. Ultimately, the nodule will cause excess thyroid hormone production, with consequent suppression of TSH and downregulation of the remaining thyroid tissue. In the presence of a thyroid nodule and a suppressed TSH, a thyroid scan should be performed to assess the function of the nodule.

Other follicular adenomas may be premalignant, and therefore warrant excision in their own right. In any case, FNA cannot reliably distinguish follicular adenoma from carcinoma, and all such lesions should be surgically excised.

Thyroid Cysts. The cause of most thyroid cysts remains obscure. In most cases, they show the histologic features of a simple cyst, with proteinaceous cyst fluid surrounded by a simple cuboidal epithelium. The colloid cyst, by far the most common benign cyst of the thyroid gland, contains material that closely resembles the colloid within a normal thyroid follicle. Less often, a cyst forms in association with a thyroid carcinoma, most often papillary carcinoma, which may form only a small solid nodule on the wall of the cyst.

Benign Adenomatous Nodule. These nodules are nonclonal, arising from a group of follicular cells rather than from a single cell that has undergone neoplastic transformation. The stimulus for the growth of such a nodule is unclear, but in many cases, the serum TSH concentration in these patients is normal, and the follicular cells that make up the nodule are likely sensitive to TSH. Lowering circulating TSH with thyroid hormone may be worthwhile for such a nodule, although it is difficult to know a priori whether any individual nodule is likely to respond to such an approach.

Regenerative Nodule. Perhaps the commonest cause of thyroid nodules, particularly in young women, is Hashimoto disease. In response to the inflammatory process and chronic destruction of the parenchyma, the thyroid’s capacity to secrete thyroid hormone is reduced. TSH begins to rise, and there is increasing evidence that a TSH even in the upper normal range may represent early thyroid failure among patients with Hashimoto disease. TSH stimulates growth of the remaining thyroid cells. However, it is not always possible for the entire gland to respond, particularly in the presence of intraglandular fibrosis. A situation analogous to the hepatic cirrhosis arises. In most cases, a “micronodular” pattern develops, creating the classic clinical features of a bexsagated goiter. In a few cases, however, a “macronodular” pattern develops, with the development of a discrete nodule within the gland. Sometimes these nodules can grow rapidly, and they are clearly under the regulation of TSH or of TSH-receptor antibodies. It is for this group of patients that thyroid hormone suppression is most likely to be of benefit, and a trial of thyroxine treatment is certainly justified in this context before proceeding to surgical excision.

Follicular Cell Derived Thyroid Carcinoma. Follicular Carcinoma and Papillary Carcinoma. Differentiated thyroid carcinoma (DTC) is the most common group of endocrine malignancies, with an estimated annual incidence in the United States of around 30,000 cases, resulting in approximately 1,500 deaths each year. The vast majority of these (85 to 95%) are sporadic follicular cell derived thyroid carcinomas (FCDTCs), either of papillary or follicular histotype, while only 2 to 5% represent the C-cell derived medullary carcinoma (MTC), which can develop as part of the multiple endocrine neoplasia syndrome type 2 (MEN-2).

A fight they represent less than 2% of clinically diagnosed human malignancies, DTC kills more people than all other endocrine malignancies combined. Nevertheless, with a crude mortality rate of only around 7%, the vast majority of patients with DTC, are either cured or live with cancer, often for many years. However, the recurrence rates after apparent surgical cure of the primary tumor range from 10 to 35%. Depending on histotype and stage at diagnosis, the neoplasm may sometimes recur many years after the initial, apparently successful, treatment.

Thyroid carcinomas have a wide range of malignant potential, ranging from the incidentally discovered papillary microcarcinoma, which probably has no impact on long-term survival, to the almost universally lethal anaplastic thyroid carcinoma, with a median life expectancy of only a few months.

There have been many studies designed to identify factors that predict outcome among patients with DTC. Unfortunately, there have been no randomized, prospective trials of thyroid cancer management, largely because of the relative rarity of the neoplasm, its generally slow clinical course with long survivorship, and the difficulty and expense of mounting large
multicenter studies over prolonged periods. Nevertheless, a great deal of information is available from large retrospective reviews from a number of centers, and this information should influence the management of the patient with DTC.

The primary treatment of newly diagnosed DTC is surgical. Nevertheless, several options exist for the postoperative (adjuvant and long-term) management of these patients, and there exists a broad range of opinion regarding the appropriate use of these therapeutic modalities. Similarly, there remains considerable controversy regarding the frequency of follow-up and the techniques best employed to detect recurrent disease.

The therapeutic goals for the primary treatment of DTC are clear. First, we should seek to avoid, or reduce to a minimum, cause-specific mortality from the cancer. Second, it is important to prevent postoperative tumor recurrence. And third, we should avoid treatment-induced morbidity whenever possible.

Tumor Classification. FCDTCs commonly retain many of the features of the parent cell type, including follicle formation and a capacity to concentrate iodine, to manufacture and secrete thyroid hormone, and to secrete thyroglobulin and on occasion even to produce thyroid hormone bodies frequently permit a firm diagnosis of PTC to be made on cytologic analysis of FNA material.

PTC displays a more solid growth pattern, within a fibrous capsule, with formation of irregular follicular structures, surrounded by epithelial cells of rather bland, uniform appearance, which exhibit none of the nuclear features that characterize PTC. The degree of cellular and nuclear atypia is variable, with no clear distinction between benign and malignant follicular neoplasms. This distinction is made solely on the basis of invasion, either of the capsule or of blood vessels, by the carcinoma, a feature that cannot be ascertained from FNA and requires surgical removal of the suspicious nodule for recognition.

The Hürthle cell variant of FTC [also known as Hürthle cell carcinoma (HCC), or as oncocytic or oxyphilic FTC] is the commonest "atypical" FTC, comprising up to 25% of all FTC and may warrant its own classification, distinct from FTC. Histologically, HCC differs from typical FTC only in the proportion of oncocytes within the tumor. These cells are characterized by a granular acidophilic cytoplasm, the result of the presence of large numbers of densely packed mitochondria. Oncocytes represent >75% of the cells in HCC, which may also exhibit a rather more trabecular growth pattern than typical FTC.

Adapted from reference 219.

Most authors accept that the insular variant of FTC is a less well-differentiated tumor, with a consequently adverse prognosis.

However, even for HCC, the most common of the neoplastic variants, controversy persists regarding the clinical implications of this diagnosis, with some authors reporting a worse prognosis, whereas others see no significant difference in outcome between HCC and FTC when tumor stage is taken into account. Recurrence rates are higher for HCC than for FTC, particularly within the thyroid bed and adjacent regional lymph nodes, arguably justifying a separate diagnostic category.

A great deal of progress has been made in the last quarter century regarding the molecular pathogenesis of thyroid cancer in general, and PTC in particular, with the identification of causative oncogenes in the majority of cases. These findings are summarized in Table 8.

Management of Differentiated Thyroid Carcinoma. The primary management of DTC is surgical. Postoperative management of patients with newly diagnosed and treated DTC should include staging and risk assessment. The goal of this approach is to permit accurate prognostication for an individual patient being treated for DTC and to allow individualization of postoperative surveillance and the extent of adjunctive therapy.

American Joint Committee on Cancer and International Union Against Cancer Staging. The pathological Tumor-Node-Metastasis (pTNM) classification system of the American Joint Committee on Cancer (AJCC) and International Union Against Cancer (IUCN) is applicable to patients with tumors of all types, providing a convenient shorthand method to describe the extent of the tumor in an individual patient. This scheme is recommended for use also with patients with thyroid carcinomas.

Using this system, the tumor is assessed according to the size and extent of the primary tumor mass, the presence (N1) or absence (N0) of lymph node metastases, and the presence (M1) or absence (M0) of distant metastases (Table 9). Hereafter the prognosis for many tumor types is determined largely or exclusively by the anatomical extent of disease, described efficiently by the pTNM classification, and the...
success of resection, thyroid tumors of follicular cell origin are unique, in that their prognosis is most strongly influenced by patient age at diagnosis. As a result, the AJCC/UVCC staging system takes into account patient age for defining stage for FCDTC.

In this staging system, all patients under the age of 45 with FCDTC have Stage I disease unless they have evidence of distant metastases, which makes them Stage II. More advanced stages are restricted to patients over the age of 45, with locally invasive tumors (Stage IVA or IVB), or with evidence of nodal (Stage III or IVA) or distant (Stage IVC) metastases.

The pTNM system is the most widely accepted tool to describe the extent of disease in thyroid carcinoma, and this and its associated AJCC staging scheme, are recommended for general use by the American Thyroid Association (ATA), American Association of Clinical Endocrinologists (AACE), and the National Comprehensive Cancer Network (NCCN). The AJCC stage correlates well with outcome of FCDTC, in both retrospective and prospectively collected data, with Stage I and II disease exhibiting a less than 1% overall mortality at 5 years. In contrast, more advanced stages of disease, limited to those patients over the age of 45 with locally invasive or metastatic disease, carries a less favorable prognosis, with Stage IV (metastatic) disease exhibiting a 5-year mortality in excess of 50% in both PTC and FTC.

Despite its simplicity and utility, however, the AJCC Stage does not provide all the information a clinician may need to classify a patient with DTC adequately, and to assist in making therapeutic decisions. It does not take account of several additional prognostic variables and may, therefore, risk misclassification of some patients.

Clinicopathological Prognostic Schemes for Follicular Cell Derived Thyroid Carcinoma. Among patients with FCDTC, age at initial treatment, tumor size, the presence of extrathyroidal invasion, and the presence of distant metastases at diagnosis are the most important risk factors for recurrence and for cause-specific mortality. All of these are included in the AJCC Staging system detailed above. However, unlike almost any other cancer type, the presence of lymph node metastases in PTC has little influence on cause-specific mortality from this disease although it increases significantly the risk of locoregional recurrence.

Several other factors, not included in the AJCC staging scheme, have also been shown to be prognostic variables, in multivariate analysis. These include tumor grade in PTC; extent of microinvasion of capsule or of blood vessels in FTC; DNA aneuploidy in HCC and PTC; delay to initial surgical intervention; and completeness of surgical resection of the primary tumor. These prognostic factors are not of equal importance in predicting mortality or recurrence, with the most predictive factors generally being regarded as the presence of distant metastases, the age of the patient, and the extent of the tumor.

Several prognostic systems have been developed, that include a number of these variables, weighted according to their importance in predicting outcomes, in multivariate analyses, of retrospectively analyzed large cohorts of patients.

All of these schemes permit classification of patients with FCDTC (particularly PTC, the most common type) into low-, medium-, and high-risk groups, accurately predicting long-term outcome for these patients. The use of one or other of these schemes is recommended by the ATA to assist in predicting outcome and deciding initial and long-term management of the disease.175

Each of the prognostic schemes includes a slightly different group of variables, weighted in slightly different ways. However, all have certain features in common, and all include both tumor and patient variables, emphasizing the likely importance of host-tumor interaction in the behavior of this group of cancers. Almost all of the schemes accept the importance of the patient's age as an important (probably the most important) variable predicting outcome. The size of the primary tumor, its histologic type, the presence of extrathyroidal invasion, and the presence of distant metastases are almost universally included. Hay and colleagues223 also found the completeness of surgical excision to be an important independently predictive variable, of both recurrence and cause-specific mortality.

At the Mago Clinic we use the metastases, age, completeness of surgical excision, local invasion and tumor size (MACIS) score, which is named for its predictive variables.223 This numeric score can be calculated using the formula detailed in Table 10. The MACIS equation generates a single score for patient classification, which has proven to be a reliable predictor of outcome over a 20-year period in these patients.

A MACIS score of <6.0, representing the lowest risk group, carries a less than 1% cause-specific 20-year mortality risk from PTC and encompasses more than 80% of patients presenting with PTC to our institution. A score of between 6.0 and 6.9 has an 11% 20-year mortality; scores of between 7.0 and 7.9 have a mortality rate of 44%; and scores of 8.0 and over (fortunately, a fortunately, is rare in FCDTC but heralds a poor prognosis). Typical nonophyllic FTC, however, less often involves lymph nodes, spreading preferentially by a hematogenous route through the neck, lungs and brain. M eta- static spread to other organs also occurs although all of these are rare.

Local recurrence within the thyroid bed occurs mainly ipsilateral to the primary tumor site, as a result of incomplete surgical resection, local invasiveness of the primary tumor, or failure of adjunctive therapy to destroy persistent microscopic tumor deposits. Local recurrence at sites other than the thyroid bed may result from unrecognized local spread of the tumor outside the thyroid remnant or multifocal tumor that has been incompletely resected.202

Regional recurrence occurs more frequently in lymph nodes in the central compartment, often as a result of incomplete initial surgical exploration and resection. These nodes are involved in up to 40 to 60% of patients with PTC at the time of diagnosis,217 and adequate primary surgery should include their resection through a formal sixth compartment node dissection.175 Jugular nodes may also commonly be the site of regional recurrence, presumably as a result of unrecognized micrometastases, present at the time of the original diagnosis. A dequate assessment of the jugular chain nodes is essential prior to primary surgery, using ultrasound.175

The development of distant metastases, fortunately, is rare in FCDTC but heralds a poor prognosis for older patients, with cause-specific mortality rates of up to 60% at 10 years in Stage IV disease.202 By contrast, the presence of distant metastases, particularly micrometastases in the lungs, in young patients need not signal an imminent demise, with long-term survivalship being the norm,220 justifying their classification as Stage II disease.

The risk factors for the development of distant metastatic disease in PTC largely mirror those already established for mortality, with the age of the patient, the size of the tumor, and the presence of local invasion or incomplete surgical resection dominating the picture. In addition, however, the involvement of lymph nodes with PTC, particularly those in the jugular chains, at the time of diagnosis, substantially increases the risk of future regional recurrences, but its role in the development of distant spread remains controversial.223 For FTC, the presence of angio-invasion of the primary tumor, and possibly of extensive capsular invasiveness, substantially increase the subsequent risk of developing distant metastases.232,233

Postoperative Adjuvant Therapy. Two major forms of adjuvant therapy are commonly used following surgical treatment of FCDTC: radioactive iodine and thyroid hormone suppression of TSH.202 Unfortunately, the widespread availability of radioactive iodine (in the form of I-131), its ease of use, and perhaps misconceptions regarding its efficacy have resulted occasion- ally in complacency regarding the initial surgical treatment of these tumors, on the basis that “radioactive iodine will get whatever we miss.” We believe that the importance of the primary surgical procedure cannot be overstated, and that the long-term outcome for the patient depends largely on the adequacy of that procedure, particularly for patients at higher-than-average risk of death or recurrence.

No such systemic modalities of treatment are currently available to reduce the risk of recurrence in the postoperative management of MTC, the treatment of which initially lies entirely in the hands of the surgeon. The adequacy of the primary surgical resection, including accurate, effective lymph node sampling, is therefore even more important in this form of DTC. Patients with MTC who undergo thyroidectomy will, of course, require thyroid hormone replacement therapy.

Thyroid Hormone. The suppression of TSH by administration of supraphysiologic doses of thyroid hormone in the postoperative thyroid cancer patient, is probably the most widely used adjuvant therapy for FCDTC.202 In use for nearly half a century, this treatment is based on the belief that suppression of TSH removes an essential growth factor for cells of thyroid follicular origin, so slowing or preventing altogether the re-growth of the cancer.201

Without doubt, many thyroid cancer cell lines of both rat19 and human234 origin grow more rapidly in media supplemented with TSH, and are growth inhibited when the growth medium is stripped of TSH, and other probably growth factors, by charcoal striping. There is also anec- dotal evidence that at least a proportion of thyroid nodules, eventually proven to be malignant, can shrink somewhat during thyroid hormone suppressive therapy.235 However, firm evidence that

</table>
TSH-suppressive therapy is truly effective in the postoperative management of DTC is hard to obtain, in the absence of any randomized prospective trials.

Initially, the goal of TSH suppression therapy was to attain an absent response to intravenous TSH administration, assessed on a first-generation TSH radioimmunoassay, consistent with essentially complete suppression of the pituitary thyrotrope. With the development of more sensitive TSH assays in the 1980s, it became possible simply to maintain an undetectable TSH, measured using a sensitive (second-generation) immunometric TSH assay, with a lower limit of detection of around 0.1 mU/L. Over the last decade, since the advent of “ultra-sensitive” TSH assays (third and fourth generation), with lower limits of detection of 0.01 mU/L, 0.001 mU/L, or less, it has become possible to titrate the dose of thyroid hormone in the majority of patients to achieve levels of TSH within prespecified ranges. Unfortunately, a paucity of data makes decision-making about the “desirable range” for TSH largely speculative at the present time.

The changes in our ability to measure TSH concentrations over the last quarter century, as well as changes in the surgical and other nonsurgical practices over the same time period, complicate our interpretation of the retrospective data that forms the basis of our current understanding of DTC management. The majority of patients treated for DTC in the last quarter century have undergone surgery extensive enough that thyroid hormone replacement was necessary to avoid hypothyroidism. Comparisons in long-term retrospective studies between patients treated with thyroid hormone and those not treated, therefore, become comparisons between patients operated on in the middle years of the last century by what would now be regarded by most as inadequate surgery, with those treated by more extensive surgery in the last few decades, who also have received thyroid hormone replacement or suppression. Not surprisingly, therefore, univariate analyses of thyroxine therapy show decreases in cancer-related deaths, and a decreased recurrence rate of both PTC and FTC. This effect may be confined to older patients, who are likely to represent more advanced stage disease, and the apparent beneficial effect is reduced or even eliminated when patients with PTC are stratified according to their tumor stage. However, a recent retrospective, multicenter study of 683 patients, stratified by NTCTS stage, who had been treated and followed at 14 institutions over a 10-year period, did show a significantly reduced risk of disease progression (defined as cause-specific mortality or recurrence) in Stage III and IV patients with FCDTC, treated with suppressive doses of thyroid hormone. No such difference in outcome was observed in Stage I and II patients.

The use of supraphysiologic doses of hormone may, however, carry some risk of adverse consequences. A small proportion of patients experience hyperthyroid symptoms of tremor, anxiety, sleep disturbance, heat intolerance, and palpitations which can be intolerable and can sometimes require reductions in thyroid hormone dosage.

More worrying is the possible impact of TSH suppression on bone turnover, especially in postmenopausal women with an increased risk of osteoporosis in older women treated with suppressive doses of thyroid hormone. The danger of this is probably negligible in premenopausal women although it remains unclear whether estrogen replacement after menopause is equally protective. The possible impact of TSH suppression on bone health in men remains unknown.

A suppressed TSH is also a risk factor for the development of atrial fibrillation (AF), with its consequent increased risk of cerebrovascular events. It has been estimated that such a finding increases the odds ratio for the development of AF by three fold over baseline. This finding was based on prospectively collected data from the Framingham cohort and did not distinguish between endogenous and exogenous sources of thyroid hormone as the cause of the suppressed TSH. Since T3 is the active hormone at the cardiac level, and since T3 concentrations are somewhat lower for any given concentration of TSH when exogenous thyroxine is the source of thyroid hormone excess, the actual risk may be somewhat lower than indicated from the Framingham data. Nevertheless, the potential for significant morbidity exists and may not be balanced by an improvement in outcome of the FCDTC, at least for Stage I and II patients.

Our approach to the use of thyroid hormone suppression of TSH in patients with FCDTC, is in keeping with the recent guidelines of both the AAEC and ATA. These suggest a stratified approach, according to both AJCC stage and patient risk as assessed by one of the clinicopathologic prognostic schemes. In patients at low risk (MACIS score less than 6.0, or AJCC Stage I PTC), whose life expectancy is essentially normal and whose lifetime risk of recurrence is less than 5%, we aim to maintain the serum TSH at or just below the lower limit of the normal range (0.1 to 0.3 mU/L in our laboratory, whose normal range is 0.3 to 5.0 mU/L). Since the risk of tumor recurrence in these low-risk patients falls to less than 1% in the 20 years beyond the first 5 postoperative years, we would subsequently permit the TSH to rise into the lower third of the normal range. This strategy avoids the potential morbidity associated with long-term TSH suppression.

Life-long monitoring of thyroid hormone status, by annual measurement of serum TSH concentration, is recommended.

Patients at intermediate risk of tumor recurrence include those patients with PTC whose MACIS score lies between 6.0 and 6.9, AJCC Stages I and II, or Stage III with only lymph node metastases and patients with minimally invasive FTC. These groups almost certainly warrant rather more aggressive management than the low-risk patients, and we aim to maintain the TSH in the subnormal range, without achieving frank hyperthyroidism. Our goal in this setting is a TSH concentration below 0.1 mU/L and ideally in the range between 0.05 and 0.1 mU/L.

Attempts to maintain virtually complete TSH suppression (TSH <0.05 mU/L) are reserved for high-risk patients, including those with widely invasive FTC or HCC, or PTC with MACIS scores over 7.0, Stage IV disease or Stage III disease with local extrathyroidal invasion. These patients may experience hyperthyroid symptoms when TSH suppression is achieved although this may prove to be transient. The potential for morbidity must be recognized, and these patients warrant screening and monitoring of bone density, at least in postmenopausal women, with appropriate prophylactic and therapeutic management of this bone disease.

Radioactive Iodine Therapy. The majority (75% or more) of FCDTC retain the capacity to take up and significantly concentrate iodine although frequently rather less efficiently than normal thyroid tissue. This residual differentiated function permits radioactive isotopes of iodine to be used for both the detection and treatment of residual thyroid follicular cells.

Administered orally, iodine isotopes are absorbed rapidly and reliably from the upper gastrointestinal tract, circulate transiently in the blood stream, and are concentrated in tissues that express a functional sodium-iodide transporter (NIS). These include normal and cancerous thyroid tissue, salivary gland, breast, stomach, and colon. The NIS is also expressed in the kidney which transports as well as filters iodine, and circulating iodine is excreted rapidly through the urine and stool. The uptake of iodine into both normal and cancerous thyroid tissue is dependent on TSH, the result of upregulation of expression and possibly increased function of NIS.

Radioactive isotopes of iodine (I-131, I-123) emit γ rays, which can be detected using an appropriate detection apparatus (a gammacamera), thus permitting imaging of iodine concentrating tissues, and thereby the detection of residual or metastatic thyroid tissue, provided there has been sufficient prior stimulation with TSH. This technique of whole body scanning, following TSH stimulation resulting from the induction of hypothyroidism, has become the mainstay of postoperative surveillance in North America and will be discussed later.

Although γ rays are of high energy, their tissue absorption is low, and the majority of these particles fail to interact with the cell in which the iodine is concentrated or with surrounding tissue. While this is ideal for imaging purposes, treatment of residual thyroid carcinoma with radioactive iodine depends on β particle emission, the major emitted particle released by the decay of I-131. These moderately high-energy β particles travel only short distances, on average around 0.5 cm before interacting with surrounding tissue, and result in ionization and the generation of superoxide radicals, which cause DNA damage, including double-strand DNA breaks. This activates the p53 pathway (commonly intact in differentiated
thyroid carcinoma) and leads to apoptosis of the affected cell. Since cancer cells often lack efficient mechanisms to repair double-strand DNA breaks, there is a theoretical reason to believe that residual thyroid cancer cells might be more susceptible to the effects of β irradiation than the surrounding normal tissue although no in vitro or clinical evidence yet exists to support this.

Radioiodine Remnant Ablation. Postoperative ablation of the thyroid remnant by treatment with 30 to 100 mCi of I-131 is often used to “complete” the initial surgical treatment in FCDTC. Defined as “the destruction of residual, macroscopically normal thyroid tissue following thyroidectomy,” there remains controversy about the optimal dose required to achieve this. Most North American centers use between 30 and 75 mCi, values which have some theoretical and experimental support.

Most often, radioactive iodine is administered 4 to 6 weeks after surgery, with the patient in a hypothyroid state, to maximize TSH-stimulated iodine uptake, and whole-body iodine retention. Some authorities advocate a low-iodine diet during preparation for I-131 treatment and scanning, although there remains skepticism regarding its efficacy. Hypothyroidism may be achieved by avoiding thyroid hormone replacement therapy postoperatively and waiting for at least 4 weeks for endogenous hormone concentrations to fall. Alternatively, initial substitution for 4 weeks with T3 (Cytomel), followed by 2 weeks of withdrawal can be used, and may shorten the duration of symptomatic hypothyroidism. Oral I-131 administration, most often in an outpatient setting, follows confirmation of a serum TSH elevated to at least 30 mIU/L, and a negative serum pregnancy test in women of childbearing potential.

There is little doubt that even quite substantial remnants of normal thyroid tissue can be eliminated by this approach. Whether small amounts of residual thyroid carcinoma are also eliminated by these remnant ablative doses is uncertain, since thyroid carcinoma cells may be several orders of magnitude less efficient than normal follicular cells in the accumulation of iodine. Many groups regard remnant ablation as a necessary first step before proceeding, at a later date, to higher-dose treatment of known residual (or recurrent) disease.

Elimination of the postsurgical remnant may carry two theoretical advantages. First, it may destroy residual normal thyroid tissue, making subsequent neck and whole-body scans easier to interpret, since areas of more subtle uptake, for example, in metastatic tumor within regional lymph nodes, might otherwise be overshadowed. Second, it may simplify interpretation of serum thyroglobulin (Tg) concentrations, since residual normal thyroid tissue will otherwise contribute, to some degree, to the production of Tg, particularly in the stimulated state, that is, with elevated TSH.

Does remnant ablation with I-131 improve the outcomes for patients with thyroid carcinoma? Unfortunately, few data are extant with which to address this vexing question, and this “absence of data fuels strongly held opinions on both sides of the debate.” No randomized trials have been reported of radioactive iodine therapy; and, to our knowledge, none are in progress. Our understanding of the risks and benefits of this widely used therapeutic approach is based entirely on observational, retrospectively analyzed, nonrandomized studies.

In low-risk patients, with small intrathyroidal papillary tumors (pT1-2, stage I disease), I-131 ablation yields no detectable benefit either on cause-specific survival, or on the risk of recurrent disease, provided the primary surgery is adequate. Even in those patients with regional nodal involvement, I-131 does not further improve the already low risk of either death or recurrence in these otherwise low-risk patients. It is, of course, extremely difficult for any adjunctive therapy to improve on survival rates that approach 100% and even more difficult to prove any such benefit, in view of the low overall risk of recurrence and the long (essentially normal) life-expectancy of this group of patients.

The possible benefit of such ablation in higher-risk patients, without evidence of residual disease, continues to stimulate heated debate in national and international meetings and in numerous publications. These arguments are largely fueled by apparently contradictory data from a few major centers. On the one hand are data from Mazzaferri’s group, showing that 30-year recurrence rates, in patients with tumors larger than 1.5 cm, were halved (from 38 to 16%) in the 350 patients who received ablation with I-131, compared to the 802 who did not. Similarly, cause-specific 30-year mortality rates fell from 8 to 3%, with no deaths observed in patients who received I-131 in whom there was no evidence of residual disease. This view is shared by DeGroot and by the MD Anderson Cancer Center group.

On the other hand are data from our institution, reported by Hay and colleagues, which have failed to show any significant benefit of “routine” I-131 ablation in patients with adequate primary surgery, including selective node dissection, in whom no evidence of residual disease was detected. A analysis of a total of 1,542 patients with PTC, treated at the Mayo Clinic, of similar stage to those reported by Mazzaferri and colleagues, showed recurrence rates (16.6% vs 19.1%; p = .89) and mortality rates (5.9% vs 7.8%; p = .43) that were no different with or without I-131 remnant ablation. These data have recently received support from a large, prospectively collected data-set, in which patients with tumors up to 4 cm, including both local invasion and cervical nodal involvement, though without distant metastatic spread, showed no evidence of benefit from I-131 remnant ablation. Indeed, the authors concluded that remnant ablation provided no benefit “and may actually be harmful” to these low-risk patients.

The recurrence rates reported in this Mayo Clinic study, and in others from the now over 2,000 patients accumulated by Hay and his colleagues, are considerably lower than those reported from several other institutions, even in the absence of routine I-131 ablation. This almost certainly reflects the completeness of surgical excision of the primary tumor, achieved in this highly specialized surgical center, and emphasizes the importance of the primary surgery in determining outcome. It should be noted, however, that the surgical procedure of choice here remains a near-total thyroidectomy, and that these low rates of recurrent disease and mortality have been achieved while maintaining low rates of permanent hypoparathyroidism and recurrent laryngeal nerve injury (2% and 1%, respectively, for near-total thyroidectomy).

It may be that I-131 ablation has proven useful in other studies because of the presence of unrecognized residual disease, almost certainly within regional lymph nodes, the site of the majority of recurrences in several studies. With adequate preoperative assessment (using ultrasound), and careful intraoperative exploration of these affected nodes, the rate of later recurrence can almost certainly be reduced substantially. The ATA cancer management guidelines, published in 2006, support the selective use of I-131 ablation in low-risk patients with PTC.

Although long-term data suggest that ablative doses of I-131 are safe and are not associated with significant side effects or carcinogenic risk, the financial cost and inconvenience to the patient may outweigh any potential benefit, at least in low-risk patients, who have undergone adequate primary surgery. This group represents over 80% of patients with PTC at our institution, and consequently, we strongly favor highly selective use of I-131 remnant ablation as adjunctive therapy following adequate primary surgery. Rather, we reserve its use for those patients at moderate or high-risk of tumor recurrence (based on postoperative risk assessment), who will require follow-up by isotope scans and stimulated Tg concentrations and who may need treatment for residual or recurrent disease. Since FTC, and particularly its Hurthle-cell variant, appears to carry somewhat higher risks for recurrent and metastatic disease than PTC, we favor the use of I-131 ablation and treatment in the majority of these patients.

Radioiodine Therapy for Local Residual Disease. In contrast to the controversies surrounding routine remnant ablation, outlined above, there is widespread agreement that treatment with I-131 can be effective for the elimination or control of residual disease in some patients. A approximately 75 to 85% of FCDTCs concentrate iodine appreciably when sufficiently stimulated by TSH, and adequate doses of orally administered I-131 can induce apoptosis in these cells and in surrounding tissue in a radius of up to 2 mm.

Microscopic residual disease is likely to remain after resection of locally invasive (pT4) tumors, even if adequate clearance of gross residual disease is achieved surgically. This may be detected histologically, as tumor presence at the surgical margin at the time of the
initial resection, even in some tumors initially thought to be contained within the thyroid. Such microscopic disease substantially increases the risk of true FTC thyroid-bed recurrence and of cause-specific mortality at least in older (Stage III) patients.279 Similarly, invasive Hurthle-cell variant of FTC is more likely to recur within the thyroid bed and can prove difficult or impossible to eradicate.280

Both local recurrence and 20-year cause-specific survival rates in patients with microscopic residual disease were improved by either I-131 and/or external beam irradiation, in a multicenter review from North America.244 Traditionally, treatment of residual disease is a two-step process, with a relatively low dose (30 to 75 mCi) administered for ablation, and a higher treatment dose (100 to 200 mCi) given, at a later date, for treatment. There is no empirical evidence that this approach is superior to administration of therapeutic doses on the first occasion, and this is now the preferred approach for high-risk patients. It does have the drawback, however, that a significant thyroid remnant may overshadow the presence of subtler uptake in extrathyroidal tissues and mask the presence of residual disease on the posttherapy scan.

A few patients present with locally advanced disease, which makes complete surgical resection difficult or impossible, and a small number of these patients have gross residual disease in the neck despite an optimal surgical procedure.223 We advocate an aggressive primary surgical approach for these patients, including partial resection of trachea or esophagus, if necessary, to achieve local control.222 When this is not possible, the presence of gross residual disease is an independent risk factor for both recurrence and cause-specific mortality.222

Radioactive iodine provides a therapeutic option in this setting, and divided doses of up to 500 mCi may be necessary in an attempt to achieve local control. Some groups advocate even higher total doses of I-131, guided by dosimetry studies, to achieve the maximum dose possible to a point just short of bone marrow toxicity.281 Consequences of high-dose I-131 therapy include significant lifelong xerostomia, dysphagia, bone marrow suppression, and increasingly realistic risks of secondary malignancy, including leukemia, lymphoma, transitional cell bladder carcinoma, and colon carcinoma282 (Table 11).

Unfortunately, dosimetry is fraught with a number of significant problems, making it prone to substantial error in predicting the radiation dose received by tumor tissue in response to a dose of I-131.283 The estimated volume of the residual or recurrent tumor to be treated is, at best, only an approximation. The uptake of iodine may vary from one area of residual tumor to another and, indeed, may be heterogeneous within a single focus of recurrence. Additionally, the effective half-life of I-131 may vary substantially between patients, and even within a single patient, between the tracer and the therapeutic dose. And finally, the use of a prior tracer dose of I-131, necessary to calculate dosimetry, may result in "stunning" of the tumor tissue,284 and decrease the uptake of a subsequent therapeutic dose.285 Nevertheless, dosimetry remains a controversial tool in the administration of therapeutic I-131 and is used only by a minority of endocrinologists and nuclear medicine specialists.

Recurrent FCDTC, even in the presence of gross residual disease, is often slow-growing, may be alternatively treated (in rare selected cases) by external beam irradiation, and may be amenable to local control by intermittent repeat surgical neck exploration.202 High-dose I-131 therapy is of unproven efficacy, beyond that of more standard doses (<500 mCi), and has significant associated morbidity; and dosimetry may be unreliable, as noted above. We prefer, therefore, to pursue alternative approaches once total doses of administered I-131 exceed approximately 500 to 800 mCi.

Radioiodine Therapy for Metastatic Disease. As outlined above, metastatic FCDTC may concentrate iodine in up to 80% of cases, and TSH can stimulate this uptake. Treatment with I-131 is, therefore, used widely to treat distant metastases, whether they are present at the time of the original diagnosis or appear at a later time.

In the treatment of microscopic pulmonary metastases, I-131 appears effectively to minimize further growth, and possibly induce regression, at least in children and young adults.290 This approach may lower the serum Tg concentration and reduce or eliminate iodine trapping although the chest X-ray may never return entirely to normal and later recurrences remain a possibility.287 Whether I-131 improves survival in these cases remains unproven but seems likely, and certainly long-term survival is expected in younger patients with PTC, treated with adequate surgery and I-131, even when presenting with pulmonary metastatic disease.288

There are also anecdotal reports and case series showing significant shrinkage of pulmonary and other distant metastases in older patients after effective I-131 treatment.291 Once again, however, there are no prospective data showing an improvement in survival with this treatment. Larger metastases (over ~1 cm in maximum diameter) appear to be significantly less responsive to I-131, perhaps because of the limited tissue penetration of the emitted beta-particles.289 Hypoxia within these larger tumor masses also induces relative radioresistance, possibly by limiting the production of superoxide radicals, so reducing the impact of radioactivity on tissue injury.290

Initial enlargement of treated metastases occurs commonly in response to the trophic effect of the elevation of TSH necessary to induce iodine trapping and due to the edema that occurs in response to effective therapeutic tumor injury.292 Such enlargement can cause significant problems from a space-occupying effect, particularly in critical locations such as within the central nervous system and close to the spinal cord.293 Prophylactic corticosteroid administration may be helpful, and the use of exogenously administered recombinant human TSH (rhTSH) (rather than thyroid hormone withdrawal) has been suggested as an alternative approach to stimulate iodine uptake, while avoiding the growth stimulation of more prolonged elevations in TSH concentrations.299

It should also be noted that the whole body retention of iodine is lower after the use of rhTSH than after thyroid hormone withdrawal, however, since hypothyroidism decreases renal I-131 clearance, increasing its effective biological half-life. This effect does not occur with rhTSH; and, therefore, more attention to dosimetry may be necessary when treating after rhTSH use.295 The efficacy of I-131 therapy after rhTSH stimulation has not been evaluated, and it currently represents an unlicensed use of this product, except for compassionate use in selected patients. A different therapeutic modality, including surgery and localized external beam irradiation, may also play a role in the management of metastases from FCDTC, and I-131 should be viewed as merely one component of a multimodal therapeutic approach.

There is no role for the use of radioactive iodine in the treatment of medullary thyroid carcinoma, since these tumors do not express NIS and are incapable of iodine accumulation. Rare mixed FTC/MTC tumors may concentrate I-131, although it is not known whether such treatment alters the long-term outcome.294

External Beam Irradiation as Adjunctive Therapy for Follicular Cell-Derived Thyroid Carcinoma. The use of external beam irradiation for thyroid cancer is an unresolved management issue, and the current available information is not high-level data. Several retrospective studies report benefit for patients with differentiated thyroid cancer who receive external beam irradiation.295-298

Patient selection has in general included pT4 lesions, gross residual disease, microscopic residual disease, or advanced neck disease. Factors that limit firm comparisons and conclusions include: small numbers of patients treated, variable dosages and delivery techniques, and quality of detection methods to establish local and regional recurrence. Regardless, the identified benefit is limited to improved local regional control in papillary thyroid cancer (no benefit has been identified for follicular thyroid carcinoma). Unfortunately, neither overall survival nor cause specific survival is improved. The decision-making must balance the benefit of local regional

| Table 11 Reported Complications of High-Dose Therapy with I-131 |
|-------------|------------------|
| Salivary glands | Xerostomia |
| Lung | Pneumonitis |
| Bone marrow | Bone marrow suppression/aplasia |
| Bladder | Lymphoma |
| Bladder | Transitional cell carcinoma of bladder |
control and the morbidity of irradiation. The general side effects of external beam irradiation include xerostomia, skin and soft tissue fibrosis, and telangiectasia formation. Irradiation of the larynx will generate variable degrees of edema and risk of chondritis. Chondroradionecrosis, fortunately rare, is a challenging problem that may respond to corticosteroids, antibiotics, and hyperbaric oxygen therapy but can relentlessly progress and require laryngopharyngectomy.

Consistently, the most important factor in local and regional control is the completeness of resection (no residual disease vs microscopic residual disease vs gross residual disease). Conservation surgery of the larynx, trachea, pharynx, and esophagus is complex but can address invasive disease while preserving voice, swallowing, and avoidance of a tracheostomy. Rarely does one need to consider a laryngopharyngectomy. The impact radiation therapy has on wound healing significantly increases the risk of wound breakdown, specifically in areas in direct contact with saliva (pharynx and esophagus) or in tissues composed largely of cartilage (larynx, subglottis, and trachea). Segmental tracheal resection in the setting of prior surgery and irradiation likely should not be considered. Therefore, prior to the administration of external beam irradiation, it should be determined that further surgery is not an option. Once it is determined that surgery is not an option (based risk or patient preference), the potential for retreatment with radioactive iodine should be established. Noniodine-avid disease with evidence of progression warrants consideration of external beam irradiation. It is not clear that all patients with residual disease warrant treatment with external beam irradiation. The clinical behavior (growth rate, invasive characteristics) of the tumor and the age of the patient should be considered.

Postoperative Surveillance and Follow-Up. After apparently successful initial therapy, recurrence rates range from 10 to 35% in most series of FCDTC, with rather higher rates observed in MTC, as detailed above. Although the majority of such recurrences occur within the first 5 to 10 postoperative years, 288 recurrences have been reported as long as 25 years after apparently successful primary treatment. 201 Long-term follow-up for these tumors is therefore necessary. Many of the recurrences are easily amenable to treatment, particularly if detected early, before vital structures are compromised, 217 and some form of sensitive surveillance is therefore desirable to detect such recurrences before they become clinically apparent.

The vast majority of patients with PTC, however, are at low-risk of recurrence, and these patients are even less likely to succumb to their disease. Follow-up surveillance must therefore involve negligible risk, minimal morbidity or discomfort, and must be financially responsible. We believe that such follow-up should be tailored to the patients’ level of risk, with high-risk patients being offered more intensive assessment, directed to the likely sites of recurrence, while low-risk patients should be reassured and offered much less intensive (and less expensive) follow-up. The clinical staging and risk assessment schemes detailed above provide a logical and accurate basis for determining an appropriate follow-up strategy.

Anatomic Evaluation. The majority of recurrences of FCDTC and MTC occur in regional lymph nodes in the neck or thyroid bed. Ultrasound examination, using modern high-resolution 10 MHz transducers, permits accurate anatomical evaluation of the postoperative neck, and should be the imaging modality of choice for postoperative surveillance for locoregional recurrence. 217 Tumor deposits as small as 2 mm can be detected within the thyroid bed, and tumor deposits of a similar size within lymph nodes may also be reliably detected. Recurrent PTC, in particular, may exhibit ultrasonographic features that are highly characteristic, with intrasosseal calcifications that result in multiple tiny bright echoes within the tumor deposit. 300 Lymph node architecture is also a highly sensitive marker of nodal metastases, which result in enlargement, rounding, and loss of the normally visible, hyperchoic hilar structures. Ultrasound has a major added advantage over other imaging modalities, in that ultrasound-guided FNA can be undertaken reliably, providing cytologic confirmation of the presence of metastatic cancer. 302 The only limitation of this technique is the need for a skilled and dedicated thyroid ultrasonographer since the technique is highly operator dependent. Nevertheless, in our experience, ultrasound is by far the most sensitive and specific method of surveillance of the postoperative neck, permitting detection of small tumor deposits at a stage well before other currently available, more expensive, anatomical imaging methods. The technique is more sensitive than the more widely used radioactive iodine scanning and is better for the detection of thyroid bed and neck nodal recurrences, the site of the majority of recurrences in DTC of all types. 284, 285

MRI and CT scanning are also widely used to assess the postoperative neck. CT scanning is usually performed without contrast, since the iodine loading from the contrast material otherwise obviates the subsequent use of radioactive iodine therapy for at least 8–12 weeks, until the iodine load can be cleared. 302 While either of these techniques can be used to detect recurrences in the neck, their resolution is less good than ultrasound, in part because thyroid carcinoma exhibits similar spin-decay kinetics and similar X-ray density to other soft-tissue structures in the neck. The minimum detectable size of recurrent tumor deposits within the neck using these techniques is around 0.5 to 1.0 cm. These techniques are also substantially more expensive than ultrasound.

Spiral CT scanning (without contrast) may be useful to detect the pulmonary metastases that may occur rarely in DTC. However, although the lungs and mediastinum represent the most frequent distant metastatic sites for DTC of all types, the majority of patients are at low-risk of this event, and a chest X-ray may be sufficient on a routine basis, to exclude pulmonary metastases, in the majority of low-risk patients. 302 In higher-risk patients, radioactive iodine scanning may prove even more useful than CT scanning, since it also provides evidence regarding the possible future treatment of the detected disease with I-131.

Functional Evaluation Isotope Scanning. Functional scanning with radioactive iodine (I-131 or I-123) remains the most widespread, and often the only, postoperative surveillance undertaken in many centers. Although less efficient than normal thyroid, the majority of (~80%), but not all, FCDTCs retain the capacity to concentrate iodine and its isotopes. 301 Use of a gamma-camera permits visualization of the neck within 24 hours of ingestion of oral I-131 or I-123, while whole body scanning requires clearance of the physiologically accumulated gastrointestinal and renal iodine and, therefore, requires 48 to 72 hours between administration of the isotope and imaging. Positive imaging demonstrates functional thyroid tissue and implies that it may be amenable to destruction with the beta-emitter I-131. It must be noted again, however, that not all functional thyroid tissue is amenable to such treatment, whose efficacy depends on achieving an adequate intrasosseal dose of I-131, without inducing systemic toxicity.

Whole-body scanning is commonly performed using doses of 1 to 5 mCi I-131, although a variety of larger doses has also been used. Recently, several reports have demonstrated a “stunning” effect of doses above around 3 mCi, resulting in reduced uptake of subsequent I-131 doses, thereby perhaps diminishing the potential efficacy of treatment with radioiodine following such a scan. The cause of this stunning effect remains in doubt, although it likely results from follicular cell injury, and might represent either reduced activity of NIS, increased iodide leak from the cell, or both. Consequently, we recommend the use of I-131 tracer doses of 3 mCi or less, for diagnostic whole-body scanning purposes. Alternatively, though more expensive, the use of I-123 for the scan appears to eliminate stunning, almost certainly a beta-particle effect, but it may not significantly improve the quality of whole-body imaging. 285

Follicular cell iodide concentration is a TSH-dependent process, both in normal and malignant tissue. Preparation for scanning has traditionally required withdrawal of thyroid hormone therapy for several weeks, to allow high levels of endogenous TSH to develop, thus stimulating uptake. Serum TSH concentrations of over 30 mU/L are recommended for scanning and treatment purposes. During the withdrawal of thyroid hormone, which lasts 4 weeks or more, patients will develop hypothyroidism, with all its attendant morbidity, and efforts to mitigate against this, by conversion to T3 (Cytomel) prior to thyroid hormone withdrawal, are incompletely effective. 304 In addition, a small number of patients are unable to mount an adequate endogenous TSH response because of...
hypopituitarism or may be particularly sensitive to the effects of hypothyroidism because of various nonthyroidal illnesses. 

The precise role for rhTSH-stimulated radioiodine scanning in the routine postoperative follow-up of patients with DTC remains unclear at this time. While the small difference in sensitivity may have minimal clinical impact, the inability to follow a positive scan immediately by administration of therapeutic radioiodine remains a significant hurdle to its widespread use. For high-risk patients, in whom therapy with I-131 is felt likely to be required, withdrawal scanning seems more appropriate, to allow treatment to follow immediately. In low-risk patients, isotopic scanning is not typically advocated. Intermediate-risk patients who might best benefit from this new approach remain to be clearly defined. It has yet to be determined whether the additional cost and logistical complexity involved in reducing the hypothyroid symptoms for most of these patients is justifiable.

Tumor Markers. Serum Tg is a highly specific product of the thyroid follicular cell and is detectable in the circulation of patients with residual normal or abnormal thyroid tissue.

should be used in the postoperative surveillance of these patients, remain uncertain at this time. It may, however, in the future provide an alternative approach to Tg measurement, at least for patients who exhibit interfering anti-Tg antibodies.

Calcitonin, the normal product of thyroidal C cells, provides a similarly highly sensitive and specific marker for postoperative monitoring in MTC. Elevated concentrations are seen consistently in patients with nodal or metastatic recurrence, and a rising concentration over time predicts disease that may be progressing. A thyroid stimulator does not represent a significant problem for this assay, which is both reliable and predictive. Once again, however, a significant proportion of patients may live for many years or even decades with elevated calcitonin concentrations derived from relatively stable and non or slowly progressive disease, most commonly within cervical lymph nodes.

Carcinoembryonic antigen (CEA) also provides a sensitive, though rather less specific, marker for neuroendocrine tumor progression, including MTC. The combination of a rising CEA and stable or falling calcitonin in a patient with known MTC may herald a de-differentiation of the tumor and predict more rapid progression and a fatal outcome.

Combining the available postoperative therapeutic and surveillance options in an optimal and cost-effective manner, continues to challenge patient and physician alike and is the substrate for heated debate at every regional, national, and international endocrine meeting. As stated elsewhere in this chapter, the appropriate management of these patients must take certain fundamentals into account, recognizing the natural history of the disease and the wide range of malignant potential, which is largely predictable. We use the tumor histology, clinical stage and MACIS prognostic score to place the patient into one of several risk groups. A definitive therapy with radiiodine remnant ablation, radiiodine therapy, and the TSH goals of suppressive thyroid hormone withdrawal in a patient with known MTC may herald a de-differentiation of the individual patient's risk, both of mortality and of recurrence of the disease. Similarly, the intensity of follow-up and the modalities of assessment are based both on the risk of recurrence and on the natural history of progression and spread of the disease. In the absence of prospective randomized clinical trials, this strategy strives to balance the risks of disease recurrence with the costs and morbidity of both treatment and follow-up, while avoiding both under- and overtreatment of individuals with this disease.

The majority of patients with PTC, who represent most patients in the United States with FCDTC, are at minimal risk of cancer-related mortality and at low risk of recurrence following adequate surgery. Adequate surgical treatment alone is curative in this majority, and adjuvant therapies can rarely be of additional benefit. Similarly, postoperative surveillance for this group of patients should be inexpensive, noninvasive, and carry negligible morbidity. Postoperative therapy in these patients should consist of TSH suppression to the lower limit of normal but not necessarily below the normal range. In this group of patients with PTC, with MACIS scores less than 6, radioactive iodine remnant ablation or treatment has no routine role to play. Subsequent surveillance in this group of patients should take the form of careful neck examination by palpation and high-resolution ultrasound, serum Tg (measured while taking thyroid hormone), at 3 to 6 months postoperatively and at annual intervals for 3 to 5 years. Thereafter, annual clinical assessment and serum Tg measurement may be sufficient for this group, whose subsequent risk of developing recurrent disease is almost zero.

Intermediate-risk patients, representing older patients, those with FTC, and those with more extensive disease, require rather more aggressive management. Also in this group might be included those patients with extensive cervical nodal metastases, whose risk of mortality remains low but whose risk of regional recurrence within cervical lymph nodes is rather higher. In this smaller group of patients, we recommend thyroid remnant ablation with outpatient doses of I-131 (30 to 75 mCi), and thyroid hormone suppression to achieve TSH concentrations marginally below the normal range. Posttherapy surveillance also needs to be rather more aggressive and prolonged, with thyroid hormone withdrawal stimulated radiiodine whole-body scans at 6 to 12 weeks postoperatively (prior to remnant ablation), and on one or perhaps two annual return visits thereafter. This group of patients may be suitable candidates in the near future, for rhTSH stimulated isotope scans, after remnant ablation, to avoid the morbidity of annual thyroid hormone withdrawal. In addition, neck ultrasound at 3 to 6 months postoperatively and annually for at least 5 years is indicated, as well as annual chest X-ray, and measurements of serum Tg both on and off thyroid hormone therapy, at the times of hormone withdrawal for whole body scanning.

Patients at the highest risk of recurrent PTC, with MACIS score of 7 and above, including elderly patients, with locally invasive disease or large primary tumors, probably warrant still more aggressive therapy. We recommend either one- or two-stage treatment with I-131, in the form of ablation of the thyroid remnant, if present, at 6 postoperative weeks, followed by treatment dose I-131, of 100 to 200 mCi, I-131 induced injury, can cause increases in local compressive symptoms. This may be a significant problem in certain sites, particularly the brain and spinal cord.

SUMMARY

FCDTC is the most common of the endocrine malignancies, representing almost 2% of all reported human cancers, and is responsible for more deaths than all other endocrine malignancies combined. Nevertheless, the vast majority of patients with this disease are destined to be cured or to live with their disease for many years, and these patients have an essentially normal life expectancy. Thyroid carcinoma, however, exhibits one of the widest ranges of malignant potential of any known cancer, making management of these patients complex. Fortunately, clinical, surgical, and pathologic features allow accurate disease staging and prospective for individual patients, rapidly and with minimal effort. This staging process should influence all aspects of the management of these patients, and should determine the aggressiveness of postoperative therapy and surveillance for recurrent disease. This process permits the identification of low-risk individuals, whose primary treatment can be limited simply to surgery, and whose follow-up requirements are simple, noninvasive, and inexpensive. Similarly, higher
risk patients can be targeted for progressively more aggressive management with radioactive iodine, thyroid hormone suppression and other modalities. These higher risk patients also warrant more active and more frequent surveillance for recurrent disease.

Effective postoperative adjunctive therapy is available for patients who require it, and recurrent local and metastatic disease is amenable to both surgical and medical intervention. Even in the rare patient with advanced and progressive disease, useful palliative therapies can often extend life and improve its quality for many years.

**Anaplastic Thyroid Carcinoma.** A nodule in the neck of a rapidly growing goiter, the majority of anaplastic carcinomas are regarded as inoperable by the time of diagnosis because of extensive local invasion into the structures of the neck. Almost half of all patients diagnosed with ATC have evidence of metastatic spread of the tumor at the time of diagnosis, making a surgical cure impossible, even when the disease in the neck makes surgery technically feasible. Unfortunately, these tumors are poorly responsive to traditional postoperative adjunctive therapies of external beam irradiation and chemotherapy. As a result, most patients with ATC are essentially untreated, and death ensues rapidly from progressive locally invasive disease involving major structures in the neck or from the rapid and inexorable growth of distant metastases in multiple sites.

Of the approximately 1,500 deaths per year attributed to thyroid cancer annually in the United States, almost half result from anaplastic carcinoma although it represents less than 5% of all clinically recognized cancers of the thyroid gland. Most studies of ATC show cause-specific mortality rates of 70 to 95% with a median survival of less than 6 months, and only a tiny proportion of patients with long-term survival.

Our understanding of the pathogenesis of these rare tumors is improving slowly although much remains unknown. However, advances in our understanding of these tumors cannot yet be translated into improved clinical management, and the prospects for such knowledge-based therapies seem remote. In the meantime, the optimal approach to treatment of patients presenting with ATC remains a subject of debate. Thyroid surgery, radiation, and chemotherapy may have only limited roles in the majority of these patients, for many of whom palliation may be the best available option. Novel therapeutic approaches are desperately needed for this horrific disease.

**Clinical Presentation.** The typical presentation of a patient with ATC is with a rapidly enlarging, often painful neck mass, seen commonly in the context of a preexisting goiter or apparently benign thyroid nodule. In a series of 134 patients prior to our institution over 50 years, 97% presented in this way, with a small minority being detected as a result of symptomatic distant metastases. The rate of growth of a neck mass resulting from ATC is often terrifying with anecdotal reports suggesting a doubling in size in as little as a few weeks.

As they grow, these tumors aggressively invade local tissues, tracking along and destroying fascial planes. It is often difficult to distinguish the primary neck mass from nodal metastases, which are also common, being present in virtually all patients at diagnosis. The primary tumor and its nodal metastases may form a single extensive mass, the extent of which may be almost impossible to define, even with modern imaging procedures. Examination reveals a solid, almost stony mass, which may encase and invade the trachea and larynx and distort local structures. The average size of the resected tumors in the Mayo Clinic series was almost 7 cm whereas many of the unresectable tumors were estimated to be much larger (unpublished data). Consequently, an overall tumor size of 10 to 20 cm is not uncommon, often only a few weeks after the initial discovery of a thyroid nodule, reflecting the almost explosive growth of ATC.

CT scanning reveals a large heterogeneous mass, distortion of the tissue planes, and extensive local infil tration. As the tumor extends beyond the thyroid gland, laryngeal fixation and esophageal invasion occur, causing dysphagia. Tracheal deviation, compression and invasion lead to stridor and dyspnea, while involvement of the recurrent laryngeal nerves causes hoarseness and dysphonia. The massive goiter may lead to thoracic outlet compression, resulting in a positive Pemberton sign. Infiltration of the skin causes necrosis, while growth of the tumor around and through the site of a tracheostomy has been described, with consequent respiratory compromise. Pain, reflecting aggressive local infil tration, is a prominent feature in the late stages of the disease. Invasion of the great veins of the neck can cause superior vena cava syndrome, while invasion of the carotid artery may result in massive hemorrhage, sometimes precipitating death.

If the patient survives the local disease, death is likely to occur from rapidly progressive distant metastases, most often pulmonary, mediastinal, skeletal, or cerebral. Distant metastases are detected at some stage of the illness in the majority of patients (80%), and in almost half of patients, evidence of metastases can be found at the time of the original diagnosis. In many cases, however, a search for metastases is not undertaken, because the obvious lethality of the primary tumor makes further evaluation pointless.

For most patients the mode of death involves local invasion, a painful and merciless process. For those lucky enough to gain control over the primary tumor, death always ensues rapidly either from respiratory failure, as a result of pulmonary metastases, or from brain metastases. Demographics. In studies published before the early 1980s, ATC was thought to represent as much as 10 to 20% of all thyroid cancers. Other studies published within the last two decades, with the advent of more sophisticated immunologic techniques in histopathology, it has been increasingly recognized that the majority of small cell “anaplastic” tumors are in fact primary non-Hodgkin lymphoma of the thyroid. Others represent de-differentiated medullary carcinoma or “insular” variants of follicular carcinoma. These tumors carry a better prognosis than anaplastic carcinoma, and lymphoma in particular, may show an excellent response to radiation and chemotherapy. True ATC, by modern histologic criteria, represents a diminishing proportion of thyroid carcinoma in the Western world.

In recent studies, ATC represents between 1 and 3% of thyroid carcinoma in both clinical series and national surveys. The estimated annual incidence of ATC should therefore lie between 200 and 600 cases in the United States. Consequently, ATC may represent as much as 50% of the overall thyroid cancer mortality, a total of approximately 1,500 deaths in 2001. The median age at diagnosis is between 60 and 70 years in most series although patients as young as 40 may be diagnosed with this disease. There is a female preponderance of approximately 1.5:1, less than the female excess seen in other forms of thyroid cancer. Most true anaplastic cancers are so-called “large cell tumors,” which exhibit giant cells, spindle shaped cells, or cells resembling osteoclasts. Cytologic and nuclear atypia are common, and cells may be multinucleated, with frequent mitotic figures, suggesting a rapid rate of cell division. Vascular tissue can be detected...
within these tumors, suggesting that angiogenesis is activated. However, extensive necrosis is also seen, with continued tumor growth around blood vessels and the periphery of the tumor mass, while expression of vascular endothelial growth factor, a major determinant of neoangiogenesis, is lower in ATC than in differentiated thyroid carcinomas.

As previously noted, it is now recognized that as many as 25% of tumors previously classified as ATC, in fact represent other thyroid cancer types, often with a better prognosis. In particular, so-called “small cell” ATC often stains for lymphocyte markers, while being negative for keratin or thyroglobulin. These tumors are now classified as thyroid lymphoma and should be treated accordingly. Immuno-histochemical and other stains for calcitonin and amyloid also distinguish poorly differentiated medullary thyroid carcinoma from true ATC, while poorly-differentiated (“insular”) follicular carcinoma can be recognized by careful histological examination.

True ATC stains positively in most cases for cytokeratin, confirming an epithelial origin, but only a minority stains positively for thyroglobulin. Many, perhaps most, ATC arise in the context of preexisting benign or malignant thyroid disease, and a step-wise process of “de-differentiation” from thyroid carcinoma has been proposed, during which sequential genetic changes lead to progressively more aggressive biological behavior, ultimately resulting in the anaplastic phenotype.

As a result of these data, it has been claimed that ATC always arises in the context of preexisting differentiated thyroid carcinoma and that it represents a de-differentiated form of FCDTC. Although this is an attractive hypothesis, it remains unproven. It is important to recall that small foci of papillary carcinoma may be found commonly at autopsy in patients without clinical evidence of thyroid cancer, while follicular adenomas and other benign thyroid nodules affect a substantial proportion of patients in the age group most commonly affected by ATC.

Consequently, the coexistence of differentiated cancer or adenomas in the thyroid of patients with anaplastic cancer may be nothing more than coincidence. Nevertheless, the intimate coexistence of differentiated and undifferentiated carcinoma, in some patients, supports the hypothesis that at least a proportion of ATC may be derived from preexisting differentiated thyroid carcinoma.

Unfortunately, the concept that an inadequately treated papillary thyroid carcinoma in a young patient might de-differentiate and “become anaplastic” continues to be used to justify aggressive surgical and post-surgical management for patients with otherwise low-risk thyroid tumors. It is sobering to note that, in the recently reported Mayo Clinic series, only 6 of the 134 patients (4.5%) had previously been diagnosed with differentiated thyroid cancer. Furthermore, fewer than 5 patients have been documented to develop ATC after treatment for differentiated thyroid cancer, out of a total experience of over 2,000 patients managed for this disease at Mayo Clinic, and followed for an average of more than 20 years (personal communication, Dr Ian D. Hay). Patients who have been successfully treated for DTC should be reassured that the risk of anaplastic transformation is negligible.

Pathogenesis and Etiology. The precise pathogenesis of ATC remains unknown. The rarity of the tumor has limited experimental study to small numbers of specimens, and the majority of studies are based on data derived from cell lines, which may not completely reflect the behavior of the tumor itself.

In many cases, differentiated thyroid carcinoma is seen in close proximity to the anaplastic tumor, which in some cases forms merely a “focus” of ATC within an otherwise differentiated carcinoma. This close proximity is consistent with the hypothesis that ATC arises from preexisting DTC, although clear evidence for this concept remains scant.

Aneuploidy is seen commonly in ATC, as it is in FTC, and its Hurthle cell variant, adding support to the hypothesis that ATC may be derived from FTC. However, the most common cancer type seen in association with ATC is the papillary histotype, itself most often euploid. The RET/PTC gene rearrangements, known to be the cause of a proportion of FTC, may also be present in a proportion of ATC, a finding that is consistent with the derivation of ATC as a de-differentiated form of FTC (Figure 1).

Mutations and expression changes of the p53 tumor suppressor gene are found commonly in ATC, in contrast to findings in differentiated thyroid carcinoma, where such mutations are rare. The rate of such mutations is increased in vitro by radiation exposure, although p53 mutations alone are insufficient to cause transformation to ATC, since biallelic loss is required to inactivate the p53 tumor suppressor gene fully. The combination of RET/PTC rearrangements and p53 inactivation in mice is sufficient to induce anaplastic thyroid carcinoma in a mouse model. As is the case in almost all other tumor types in which p53 mutations are seen, these mutation events appear to be sporadic but are made more likely by a high cell-turnover state. Presumably, this explains at least in part the association between the anaplastic thyroid carcinoma and preexisting benign as well as malignant thyroid disease. In cell lines derived from ATC, re-expression of wild-type p53 is sufficient to induce apoptosis, decrease the rate of cell division, and restore some differentiated
follicular cell functions, including thyroglobulin expression. 320

Little additional information is available on the molecular pathogenesis of this tumor, but the advent of gene expression array techniques, which provide the capability to probe expression of many thousands of genes simultaneously, raises the likelihood that more answers will be forthcoming in the next few years. This knowledge will be essential if we are to begin to improve our treatment options for ATC.

Prognosis and Staging. A number of moderately large retrospective studies of ATC have been published over the last decade, documenting the almost universal lethality of the tumor when the diagnosis is confirmed by modern histologic criteria. 323,324,325,331,333,336,341,342,343,344 Unfortunately, those few cases of ATC previously reported as curable are perhaps more likely to have represented thyroid lymphoma, and the survival rate for ATC in modern series is impressively small. 326 Because of the extremely high mortality rates, it is difficult to identify any relevant prognostic factors, and such factors in any case would be unlikely to improve our ability to manage individual patients with this disease. The reported median life expectancy in most modern studies ranges from 3 to 12 months, with almost 25% of patients surviving less than one month. 324 Only around 10% of patients survive more than one year from the time of diagnosis, and true long-term survivors, apparently cured of their disease, are a rarity.

Even among patients diagnosed with a small anaplastic focus within an otherwise differentiated thyroid carcinoma, outcomes are extremely poor, with 7 out of 8 patients dying of their disease an average of only 11 months from diagnosis in one study. 327 One report of 17 patients with small anaplastic foci within differentiated thyroid carcinoma showed improved long-term outcome following complete tumor resection, compared with larger ATCs. 328 Perhaps not surprisingly, small tumor size may be associated with a more favorable prognosis, at least in some studies. 329,369,370 Nevertheless, death results in almost all cases of ATC, from continued growth of unresectable tumor in the neck or from the growth of distant metastases in vital structures including the lung and brain. Small tumor size (<5 to 6 cm) and an absence of metastases at the time of diagnosis appear to favor long-term survival although the majority of patients still fare poorly. 329,344 Presumably, these rare instances represent patients with tumors, caught at an early stage, in whom resection has the opportunity to be curative.

Few patients with ATC are fortunate enough to be diagnosed at an early stage, with fewer than 20% of patients with tumors being less than 5 cm in maximum dimension in most series. 324,339 Of the 15 (11%) of patients with "small" tumors in the Mayo Clinic series, only half were free from distant metastases at the time of diagnosis and were felt to have been completely resected following surgery. It was from among these 8 patients (6%) that all four long-term (>24 months) survivors were derived, suggesting that adequate resection of truly localized disease, may provide the only real opportunity for "cure" of this disease, at the present time. Even in this optimal setting, however, the 2-year survival was only 50%.

Patient age, the most important risk factor in differentiated thyroid carcinoma, appears to have little bearing on outcome of ATC 323,329,340 with young patients faring equally poorly as older individuals. Similarly, patient gender has no detectible influence on outcome, whereas the presence of lymph node metastases and perhaps also distant metastases are so frequent that their impact on outcome becomes impossible to measure. 324,339,370 As a consequence of the bleak outlook for virtually all patients with this disease, ATC are classified by the WHO as Stage IV disease, regardless of the tumor size, nodal status, presence of metastases, or age of the patient. 320

Treatment

Surgery. The discovery of a large, rapidly growing, malignant mass in the neck fuels an almost irresistible desire, in both patient and physician, to seek a surgical solution. In many cases however, such surgery proves impossible; and, at best, a debulking procedure can be offered. In the Mayo Clinic series, fewer than 30% of patients were deemed to have "surgically curable" disease; and, of those, only 25 (19% of the total) achieved apparently “complete resection” following the operation, 324 figures that closely resemble those of other large institutional series.

Surgical resection significantly prolongs survival, compared to that following biopsy alone or biopsy and thyroceotomy from a median of 3 weeks to 3.5 months from diagnosis. 324 However, it remains unclear whether this improvement is truly the result of the surgical resection or merely reflects the less advanced stage of the disease among patients with "resectable" tumor, compared to those more advanced tumors that are not amenable to surgery. Indeed, outcomes differ little between disease that is “completely resected” during surgery, with a median survival of 4.0 months, and that in which “gross residual disease” is left behind by the surgeon, with a median survival of 2.3 months, a difference that is not statistically different (p = .3). 324 Even among patients with apparently complete surgical resection, local recurrence in the neck occurred in over one-third (37%), although this recurrence was unlikely to be the cause of the patient’s death. 324

The extent of the primary surgery, beyond resection of the primary tumor and local involved lymph nodes, is probably of little relevance, and the arguments that still rage about the appropriate extent of surgery for differentiated thyroid carcinoma have little bearing on the management of ATC. There has been no demonstrable advantage of more extensive surgery in ATC. 324,336,339,370 Nevertheless, patients in whom local control of the disease can be achieved surgically gain both slightly prolonged survival and, arguably more worthwhile, are less likely to die as a result of direct invasion of the upper aerodigestive tract, at least when external beam irradiation is administered postoperatively. 324 Without doubt, an improved “quality of death” is a worthwhile goal, but this should not encourage surgeons to undertake inappropriately heroic surgery. Our view, and that of many other centers, is that debulking surgery should be offered to patients with ATC only when such surgery can reasonably be expected effectively to debulk the tumor without threatening major vital structures. Even then, however, such surgery is most often likely to be palliative rather than curative.

External Beam Irradiation. When surgery is deemed impossible, external beam irradiation is used frequently, in an effort to gain some control locally of the disease. Although often regarded as “second best,” in fact radiotherapy may offer similar outcomes to surgery. Of the 29 patients (22%) in the Mayo Clinic series treated with external beam irradiation as primary treatment of ATC, median survival was 2.3 months, compared favorably with the outcome of surgical resection, with a 3.5 month median survival, a difference that was not statistically significant. 324 External beam irradiation is most commonly delivered in a fractionated dose of up to 20 Gray (Gy), over 4 to 6 weeks, however, so that much of the patient’s remaining life expectancy is involved in receiving this treatment. More aggressive radiotherapy protocols, including hyperfractionated radiation, with a total dose of 35 to 45 Gy, have not yielded demonstrably better outcomes, but are associated with increased toxicity. 321 Side effects of radiation are common and well recognized, including dysphagia, xerostomia and skin burns, whereas higher-dose treatments may also result in neutropenia and cervical myelitis. 321

Radiation therapy may play an adjunctive role following primary surgical resection of ATC. In the Mayo Clinic series, complete or near-complete resection of the primary tumor was achieved in 54 patients. Local recurrence within the neck was documented in 20 of these patients (37%), after a median of 2.5 months, a rate that was no different, whether or not the patient underwent postoperative radiotherapy. However, the time to develop that local recurrence was slightly longer, 5 months versus 3 months, ensuring that a greater proportion of treated patients died from complications of metastatic disease, rather than locally progressive disease in the neck. 324

Radiotherapy may also be used to treat local recurrences or metastatic disease, particularly in the skeleton and brain. However, such treatment should certainly be regarded as end-of-life palliation, since in only a single patient in the Mayo Clinic series was a local recurrence or a metastatic deposit demonstrated to decrease in size following such radiotherapy. 324 In the majority of patients experiencing local recurrence after initial effective surgery, death ensued rapidly, with a median survival following local recurrence of a mere 66 days. There was no difference in survival between those patients whose recurrence was treated with external beam irradiation and those treated conservatively (p = .44).
Chemotherapy. Because ATC is so often metastatic by the time of diagnosis, systemic therapy will be essential to achieve a cure in the majority of patients. At present, however, there are no proven systemic therapies available for the treatment of ATC. Because the tumor does not concentrate iodine, radioactive iodine plays no role in its management. Similarly, there is no evidence of TSH responsiveness, so that TSH-suppression, used commonly in the postoperative management of differentiated thyroid carcinoma, is of no possible benefit.

No evidence exists of benefit from chemotherapy alone in the management of ATC, but "multimodal therapy," including surgical debulking, followed by chemotherapy and external beam irradiation, has gained some acceptance as a viable treatment scheme for patients with ATC. This has largely been based on small pilot studies and case reports, but the largest study to date included 37 patients with ATC. Combination treatment was feasible in only 14 of these patients, largely because of the previously noted difficulties achieving useful surgical debulking. Among these 14 patients, treated with aggressive surgery, doxorubicin and radiation, survival was significantly prolonged, to a median of eight months. Unfortunately, other studies have been less promising, with a reduction in survival duration observed for patients receiving combination treatment with preoperative doxorubicin and hyperfractionated radiotherapy in one retrospective study.

In the Mayo Clinic series, 13 patients since 1980 were treated with debulking surgery and postoperative radiotherapy and radio-sensitizing chemotherapy with doxorubicin. The median survival among these patients did not differ (p = .32) from the group as a whole, suggesting that such a combined approach was no more effective than surgery alone in the management of patients with ATC. Despite that, a greater proportion of long-term (>1 year) survivors was seen in this group (n = 3), a rate of 23%, compared with less than 10% in the group as a whole. Although not statistically significant (p = .19), this result may justify further study in selected patients.

Newer chemotherapeutic agents might also prove beneficial. Paclitaxel has been shown to inhibit the growth of ATC cell in vitro and in xenografted nude mice, while a combination of paclitaxel, 5-fluouracil and radiation therapy was shown to induce a useful preoperative clinical response in one patient with a large ATC, who showed "no evidence of viable tumor" at subsequent thyroidectomy. A new targeted therapy, using thalidomide, is also currently under evaluation, whereas redifferentiation therapy, using gene therapy approaches based on the reintroduction of the p53 tumor suppressor gene may ultimately provide a novel therapeutic opportunity.

Novel approaches, using alternative chemotherapeutic agents in the short term and gene therapy approaches in the long term, are desperately needed for this almost universally lethal disease. These therapies will require clinical trials, and the rarity of ATC makes such clinical trials difficult to organize, fund, and complete. Without them, however, the outlook for patients with ATC remains grim.

Summary. ATC is among the most aggressive of human malignancies, and death by choking, aspiration, or hemorrhage is almost universal if surgical resection cannot be achieved. Extensive surgery does not seem to carry any benefit beyond debulking, and placement of a tracheostomy followed by external beam radiation may be almost as effective in many cases. Postoperative radiotherapy may delay local recurrence but does not prevent or delay death from the disease. More aggressive combination treatments, including chemotherapy, remain disappointing in the majority of patients, with no clear impact on survival.

Nevertheless, a small proportion of patients do survive, and an occasional patient may live disease-free for decades. Good prognostic factors seem to include the absence of metastatic disease at the time of presentation, small tumor size, complete or almost complete tumor resection, and postoperative radiotherapy, with or without chemotherapy. For patients with ATC to survive long-term, the disease must therefore be diagnosed early, before metastatic spread has occurred, and treated aggressively. For the majority of patients, who exhibit metastatic disease or extensive invasive disease within the neck at the time of diagnosis, the most humane approach may be to protect the airway, to treat with radiotherapy, and to ensure adequate end of life care.

Unfortunately, our ability to treat ATC lags far behind our capacity to diagnose it, and we have seen no improvement in outcome in this disease in over one-half century. Surgery alone is insufficient to extend life, and more aggressive management provides no clear additional benefit in the majority of patients. New approaches to the management of this disease are desperately needed.

Thyroid Lymphoma and Secondary Malignancies of the Thyroid Gland.

Thyroid Lymphoma. Primary lymphoma of the thyroid is rare, representing a mere 1% of thyroid malignancy, and only around 2 to 3% of lymphomas. As discussed above, thyroid lymphoma may easily be confused with small cell anaplastic carcinoma although modern histologic methods, including immunostaining for epithelial and lymphoid markers have simplified the diagnosis considerably. Nevertheless, the clinical presentation is easily mistaken for that of ATC, with rapid growth of the tumor, involvement of lymph nodes, and symptoms of local compression.

The majority of thyroid lymphomas are B-cell non-Hodgkin lymphoma, which may arise in association with Hashimoto thyroiditis. Presumably the development of lymphoid tissue within the thyroid gland in Hashimoto disease provides the substrate in which the lymphoma arises, and rates of thyroid lymphoma are estimated to be as much as 80-fold higher among patients with Hashimoto disease. Nevertheless, lymphoma remains a rare complication of Hashimoto disease.

Unlike ATC, effective systemic treatment is available for thyroid lymphoma and there remains little role of surgery as primary treatment for this condition. As is the case for all lymphomas, the prognosis depends largely on the extent of disease at the time of diagnosis.

Clinical Presentation and Diagnosis. The presentation of thyroid lymphoma closely resembles that of ATC, with a rapidly growing thyroid mass, often arising on a background of a longstanding benign goiter or Hashimoto disease. In contrast to ATC, however, the goiter is often painless, but it may still be associated with hoarseness, stridor, dysphagia, dyspnea, and thoracic outlet obstruction as a result of compression of surrounding structures. The gland may be fixed to adjacent structures, in part the result of fibrosis. Lymphadenopathy is common in the neck and may be present elsewhere, depending on the stage of the disease. Destruction of the thyroid gland may occur with consequent hypothyroidism in a proportion of patients although many patients have preexisting thyroid failure as a result of Hashimoto disease.

Presumably because of its association with Hashimoto’s disease, the majority of patients are female with a female to male ratio of approximately 3:1. As is the case for other non-Hodgkin lymphomas, thyroid lymphoma most often presents between the ages of 60 and 80 years, an age range that overlaps extensively with that of ATC.

The distinction between thyroid lymphoma and ATC can usually be made on FNAB, but open biopsy is still sometimes required to distinguish lymphoma from Hashimoto disease. That distinction depends on identifying the monoclonal cell proliferation characteristic of lymphoma, which produces a restricted set of immunoglobulin light chains, in contrast to the polyclonal features of inflammatory thyroid disease. Staining for immunoglobulin light chains is straightforward using immunohistochemistry but takes both time and tissue, sometimes delaying the diagnosis and requiring a core biopsy or even an open biopsy in some cases, although modern molecular techniques may render this unnecessary in the future.

Pathology and Staging. The vast majority of thyroid lymphomas are B-cell derived non-Hodgkin lymphomas. The tumor cells are uniform, forming sheets of cells that displace and destroy the normal thyroid parenchyma. Nuclear atypia is less commonly seen than in ATC, but mitotic figures are frequent, consistent with the rapid growth of this tumor. As already noted, thyroid lymphoma is thought to be monoclonal, and a restricted set of immunoglobulin light chains helps to confirm the diagnosis.

The staging of lymphoma is currently based on the extent of disease. Stage I represents intrathyroidal disease, without other manifestations; Stage II is disease confined to the thyroid and cervical lymph nodes; Stage III involves both sides of the diaphragm; and Stage IV is defined as disseminated lymphoma, often including the bone marrow.
The prognosis of thyroid lymphoma is determined principally by disease stage, with 5-year survival rate of 80% for Stage I, 50% for Stage II, and 35% for Stages III and IV. Recurrence after initial successful therapy may occur in up to 30% patients with of Stage I and II disease, usually within the first 3 to 5 years, raising the question of whether a systemic approach to treatment might be justified even in apparently localized disease. The prognosis is also influenced by the extent of local disease, with worse prognosis for large primary tumors (>10 cm), for patients exhibiting local compressive symptoms in the neck, and for those with mediastinal involvement, reflecting direct extension of the primary tumor.

Treatment. Like other forms of lymphoma, the treatment of thyroid lymphoma should probably be tailored to the stage of the disease. Surgery, chemotherapy, and external beam irradiation all may have a role to play in the management of this disease. However, in most patients with advanced lymphoma, surgery should be restricted to whatever biopsy is necessary for diagnosis since the benefits of surgical resection of the thyroid gland are probably minimal. One exception, of course, is protection of the airway, and a tracheostomy should certainly be considered for patients with significant airway obstruction.

Stage I lymphoma, limited to the thyroid, represents a minority of thyroid lymphomas, and a surgical approach to this localized disease has been advocated by some. However, it is likely that the alternative treatments of chemotherapy and radiotherapy are equally effective. Chemotherapy also has the theoretical advantage of treating undetectable systemic lymphoma, which may reduce the risk of later relapse. This theory remains unproven but attractive to some. Nevertheless, there remains a strong case for surgical debulking, particularly of bulky disease localized to the neck (Stage I and Stage II) since the risk of relapse is closely correlated to the extent of residual disease in the neck. Improved survival has been documented following surgical resection and the combination of surgical debulking followed by external beam irradiation leads to an excellent rate of remission, approaching 90% in Stage I and Stage II disease.

Unfortunately, moderately high rates of relapse have been reported following apparently successful localized treatment for Stage I and Stage II disease, with up to 30% of patients suffering a systemic relapse after apparently successful initial therapy. Consequently, chemotherapy with cyclophosphamide, vincristine, doxorubicin, methotrexate, and prednisone, in various combinations, has been recommended, even for apparently well-localized disease.

This approach has not yet been tested formally in a clinical trial, and our approach remains one of localized treatment for localized disease, after an extensive staging process, while chemotherapy is reserved for patients with Stage III or Stage IV disease, or for those who suffer a relapse.

For Stage III and IV disease, the surgical role should probably be limited to biopsy alone and protection of the airway, and treatment should be focused on systemic chemotherapy, as outlined above, with irradiation of bulky deposits, including the thyroid gland.

Thyroid Metastases. Metastatic spread to the thyroid gland, of nonthyroid malignancy may occur in up to 25% of widely metastatic malignancies although most studies suggest a rather lower rate, closer to 5%. Some malignancies are particularly likely to involve the thyroid, including melanoma, breast, renal cell, lung, and squamous cell carcinoma of the head and neck.

Clinically important metastases are less common, however, probably affecting fewer than 1% of patients with disseminated malignancy. Much more commonly, the possibility of thyroid metastasis presents a diagnostic dilemma, in a patient with a known malignancy who is discovered incidentally to have a thyroid nodule. Fortunately, FNA is generally a reliable method to distinguish primary from secondary malignancies in the thyroid. When diagnostic confusion remains, thyroglobulin and calcitonin immunostaining can often clarify the situation. The exception is in the case of an undifferentiated malignancy, when the distinction between a primary ATC and a metastatic deposit of undifferentiated carcinoma can be difficult or impossible. A careful search for other sites of metastases and for the primary neoplasm may provide the answer; but, in the case of possible ATC, the treatment for the (presumed) primary neoplasm must not be inappropriately delayed while searching for a possible alternative site of origin.

The treatment of metastases in the thyroid should be determined by the nature of the primary neoplasm and the presence or absence of other metastases. Surgical resection of solitary thyroid metastases may improve the prognosis, at least for some neoplasm types, including breast and renal carcinoma.

Medullary Carcinoma of Thyroid Gland and the Multiple Endocrine Neoplasia Syndrome Type 2. MTC develops from parafollicular C cells which are of neural crest origin and make up approximately 1% of thyroid cells. These cells are present throughout the gland but are concentrated in the posterior and lateral upper third of the gland, the most common site of medullary cancer. Parafollicular C cells produce calcitonin that serves as a tumor marker and is associated with the endocrine symptoms (pain, flushing, and diarrhea) that are often associated with MTC. A approximately 5 to 10% of thyroid cancers are medullary and sporadic MTC accounts for 75% with familial forms accounting for the remainder.

MTC generally presents as a slow growing firm thyroid nodule. On histologic examination, amyloid may be found in one-third of the cases. C-cell hyperplasia is a precursor to MTC most commonly seen in hereditary forms. Lymph node metastases are common and may be widely distributed at diagnosis independent of tumor size. Approximately 50 to 80% of patients with MTC presenting with a thyroid nodule have lymph node metastases at the time of diagnosis, and the distribution of lymph node metastases can be wide spread. Central compartment nodes are the most frequent sites involved, but all areas of the neck and mediastinum may be involved. The contralateral neck may be involved in up to 50%. Distant metastases must also be considered and may be difficult to identify due to small size and lack of unique imaging characteristics. The lungs, liver, bone, brain, and soft tissue may be affected by hematogenous metastases.

Surgery remains the primary mode of therapy for MTC due to the lack of impact on survival by either radiation or standard chemotherapeutic agents. Ideally the initial surgery would be delayed to address the primary neoplasm and nodal metastases appropriately. Preoperative imaging of the neck with ultrasound and CT imaging are useful in identifying nonpalpable adenopathy and atypically located nodal metastases. A preoperative calcitonin level is useful to correlate with postoperative levels. In general a total thyroidectomy, central compartment and ipsilateral neck dissection should be planned for MTC that presents with a palpable thyroid mass. Preoperative identification of bilateral adenopathy by ultrasound or computed tomography should prompt bilateral neck dissections.

Calcitonin levels are a key element in postoperative surveillance of MTC. Levels typically drop quickly after resection and usually reach baseline in 72 hours. Delayed decreases have been noted. In patients presenting with palpable disease, 50% will have persistent evidence of biochemical disease. A symptomatic or borderline elevation of calcitonin presents a dilemma since radiographic quantification of disease can be challenging and individuals may do well for long periods of time. New elevations in calcitonin level, onset or recurrence of symptoms, and the development of a neck mass should prompt a metastatic work up of the neck, chest, and abdominal regions. In the case of the not infrequent inability to accurately image metastatic disease (low sensitivity and significant false positive rate).

Adjuvant treatments to this point remain lacking. Since C cells do not concentrate iodine, I-131 is not useful. A retrospective review of 73 patients deemed to be at high risk for local recurrence (microscopic residual disease, extranodal extension, or lymph node involvement) demonstrated that those patients who received external beam irradiation had a significantly higher locoregional relapse-free rate (86% at 10 years vs 52%, p = .049). However, it remains difficult to balance the morbidity of external beam irradiation (xerostomia, neck fibrosis, increased difficulty with revision surgery) with the known high rate of late recurrence.

Primary prognostic factors for MTC include age and disease stage at time of diagnosis. Post-thyroidectomy calcitonin level is an indicator of prognosis for both local recurrence and long-term survival. Importantly, overall survival is...
in the intracellular region (Figure 1).

six codons as RET 630 and 634 in exon 609, 611, 618, and 620 in exon 10 and codons 609, 618, and 620 in exon 10 and codons 630 and 634 in exon 11). These mutations activate the tyrosine kinase receptor by ligand-independent dimerization and cross-phosphorylation. Point mutations at codons 609, 618, and 620 may exert a dual effect with resultant loss of kinase function.

Perhaps there is no better example of molecular medicine impacting the care of surgical patients than in the management of hereditary MTC. Specific germ-line point mutations on chromosome 10q11.2 in the RET (rearranged during transformation) proto-oncogene (a membrane bound tyrosine kinase receptor) result in activation of the associated tyrosine kinase. These autosomal dominant mutations are associated with abnormal development of cells derived from the neural crest (parathyroid, chromaffin cells of the adrenal medulla, thyroid parafollicular C cells, and enteric autonomic plexus) and generate the clinical findings associated with multiple endocrine neoplasia type 2 (MEN2). Three clinically distinct forms of MEN2 exist with all three demonstrating MTC as a common and often earliest clinical feature: MEN2A, MEN2B, and familial medullary thyroid cancer (FMT C). In patients with FMT C, only the thyroid gland is involved. MEN2A is characterized by the potential development of pheochromocytomas (50%) and hyperparathyroidism (30%). Other uncommon manifestations of MEN 2A include cutaneous lichen amyloidosis and Hirschsprung disease. MEN2B has unique features in addition to MTC including mucosal neuromatosis, intestinal ganglioneuromatosis, and a marfanoid habitus but does not include hyperparathyroidism.

The RET proto-oncogene ligand is glial cell derived neurotrophic factor, and RET activation requires the formation of a multimeric receptor complex that includes GDNF as ligand and a glycosylphosphatidylinositol-anchored protein termed GDNF receptor that functions as coreceptor. Missense mutations in the extracellular cytosine rich domain frequently involve one of six highly conserved cysteines (codons 609, 611, 618, and 620 in exon 10 and codons 630 and 634 in exon 11). These mutations activate the tyrosine kinase receptor by ligand-independent dimerization and cross-phosphorylation. Point mutations at codons 609, 618, and 620 may exert a dual effect with resultant loss of kinase function (Hirschsprung disease) and gain in kinase function (FMT C, MEN2A, or MEN2B).

The majority of MEN2A cases have germ-line missense RET mutations involving codons 609, 611, 618, and 620 in exon 10 and codons 630 and 634 in exon 11. In patients with FMT C, RET mutations are mainly detected in the same six codons as for MEN 2A and also in codon 768 (exon 13), or in codon 891 (exon 15), which lies in the intracellular region (Figure 1).

The majority of MEN2B mutations involve codon 918 in RET exon 16, which lies within the intracellular RET tyrosine kinase domain. This mutation appears to alter the substrate specificity of the RET tyrosine kinase. Several studies have identified the presence of RET mutations in sporadic MTC (codons 918 and 768) and pheochromocytoma (codon 918) tumor tissues but not in constitutional DNA from the same patient (Table 12).

Presently, the morbidity and mortality of MEN2A, MEN2B, and FMT C are primarily associated with MTC because the identification and management of pheochromoctomases has advanced significantly. In MEN2B, MTC typically is more aggressive than in MEN2A or FMT C. Patients develop C cell hyperplasia, transformation to MTC as well as metastatic disease on a much earlier time line. Guidelines for the timing of total thyroidectomy and area VI nodal dissection have evolved formulated on the concept that molecular identification of individuals in whom a solid organ cancer will develop provides the opportunity to prevent the development of cancer or foster early treatment by gland/or gan removal prior to disease identification. For this approach to be successful, there must be a clear correlation of the mutation and the development of disease, and the gland or organ must be expendable. Ideally the procedure to remove the organ should not carry excessive risk and there should exist mechanisms to closely monitor disease.

Total thyroidectomy and area VI node dissection for MEN2A, MEN2B, and FMT C should be considered at an age that would precede malignant transformation and metastasis. For many of the identified mutations, guidelines have been developed. The challenge can arise when mutations which have not been characterized are identified. Counseling patients in this setting is difficult. An additional consideration in MEN2A is the management of the parathyroid disease which occurs in 30% of the patients and is managed in a fashion similar to MEN1.

MEN2 consensus summary statements follow:

1. MEN2A has distinctive variants. MEN2A and MEN2B are the MEN2 variants with the greatest syndromic consistency.
2. FMT C is the mildest variant of MEN2. To avoid missing a diagnosis of MEN2A with its risk of pheochromocytoma, physicians should diagnose FMT C only from rigorous criteria.
3. Morbidity from pheochromocytoma in MEN2 has been markedly decreased by improved recognition and management. The preferred treatment for unilateral pheochromocytoma in MEN2 is laparoscopic adrenalectomy.
4. Hyperparathyroidism (HPT) is less intense in MEN2 than in MEN1. Parathyroidectomy should be the same as in other disorders with multiple parathyroid tumors.
5. The main morbidity from MEN2 is MTC. MEN2B variants differ in aggressiveness of MTC, in decreasing order as follows: MEN2B > MEN2A > FMT C.
6. MEN2 carrier detection should be the basis for recommending thyroidectomy to prevent or cure MTC. This carrier testing is mandatory in all children at 50% risk.
7. Compared with RET mutation testing, immunohistochemistry of basal or stimulated CT results in more frequent false positive diagnoses and delays in the true positive diagnosis of the MEN2 carrier state. However, the CT test still should be used to monitor the tumor status of MTC. It can be the first index of persistent or recurrent disease.
8. RET germline mutation testing has replaced CT testing as the basis for carrier diagnosis in MEN2 families. When performed rigorously, it reveals a RET mutation in over 95% of MEN2 index cases.
9. The RET codon mutations can be stratified into three levels of risk from MTC. These three categories predict the MEN2 syndromic variant, the age of onset of MTC, and the aggressiveness of MTC.
10. Detailed recommendations about aggressiveness of interventions for MTC are derived from knowledge about the specific RET codon mutated and/or from a clear familial pattern.
11. Thyroidectomy should be performed before age 6 months in MEN2B, perhaps much earlier, and before age 5 years in MEN2A. Policies about central lymph node dissection at initial thyroidectomy are controversial and may differ among the MEN2 variants.

13. Tests (in tumor tissue) for somatic RET mutation in sporadic MTC or in sporadic pheochromocytoma are generally not recommended for clinical use.

14. Periodic screening for tumors in MEN2 carriers is based upon the MEN2 variant, as characterized by the RET codon mutation and by manifestations in the rest of the family.

SUMMARY

MTC is uncommon, representing only a minority of thyroid cancers. However, its involvement in the various genetically determined syndromes noted above, and rapid advances in our understanding of the mechanism of both familial and sporadic disease have led to significant improvements in our ability to detect the disease early, and even to identify and treat individuals before the onset of the malignant transformation in some cases. Sporadic MTC remains a challenge, because of the absence of effective systemic therapy and the disease remains essentially incurable once it has spread beyond the thyroid gland. However, rapid advances in small-molecule targeted therapies hold out the promise for more effective chemotherapeutic agents in the near future.

PARATHYROID GLAND DISEASES

Parathyroid Gland Neoplasia

Primary hyperparathyroidism (PHPT) is one of the most common endocrine syndromes, especially in postmenopausal women, in whom it reaches a prevalence of 2 to 3%. PHPT has an expected incidence of 1 in every 500 women and 1 in every 2,000 men older than 40 years of age and is usually a sporadic disorder. Sporadic PHPT results from a single parathyroid adenoma in 80 to 85% of cases, multiglandular hyperplasia in 15 to 20% of cases, and carcinoma in less than 1% of cases.

In a minority of cases (<10%), PHPT is part of hereditary syndromes, namely, multiple endocrine neoplasia types 1 and 2A (MEN1 and MEN2A), hyperparathyroidism-jaw tumor (HPT-JT) syndrome, or familial isolated hyperparathyroidism (FIH). Hereditary HPT-JT is an autosomal dominant disease that has recently been mapped to chromosomal region 1q21-q32 (HRPT2). The syndrome is characterized by fibro-osseous tumors of the jaws, parathyroid adenomas, and rarely parathyroid carcinoma. Renal abnormalities may also develop including Wilms tumors, hamartomas, and polycystic kidney disease.

12. Testing (in blood leukocytes) for germ-line RET mutation should be performed in all cases with apparently isolated and nonfamilial (ie, sporadic) MTC or with apparently isolated and nonfamilial pheochromocytoma. A germline mutation is found only occasionally, but such a discovered mutation is important.

Figure 2 Illustration of the key serology manifestations of primary hyperparathyroidism. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)

Diagnosis of Primary Hyperparathyroidism.

PHPT is diagnosed by persistent hypercalcemia in the presence of inappropriately normal or elevated levels of PTH (Figure 2). The modern clinical profile of asymptomatic PHPT is a disorder in which there are neither signs nor symptoms typically associated with hypercalcemia or parathyroid hormone excess. Prior to the advent of the automated serum screening chemistry panel, the clinical profile was characterized by hypercalcemic symptoms, kidney stones, overt bone disease, or neuromuscular dysfunction. Importantly, not all patients with PHPT have hypercalcemia each time serum calcium levels are measured. Some may have elevated ionized calcium or even completely normal calcium levels. As PTH is incorporated in evaluation for skeletal health, a group of patients with an elevated PTH with normal calcium levels has been identified (normocalcemic PHPT). Potential causes of secondary elevations of PTH need to be ruled out, particularly low calcium intake due to a gastrointestinal disorder, renal insufficiency, vitamin D deficiency (as defined by serum levels of 25-hydroxyvitamin D <20 ng/mL), or hypercalcemia of renal origin.

The target organs of parathyroid hormone, the kidneys and skeleton, require evaluation in patients diagnosed with PHPT. The skeleton is best evaluated by bone densitometry using dual energy X-ray absorptiometry. As kidney stones are still the most common complication of PHPT, a baseline assessment with renal ultrasound and/or abdominal X-rays is reasonable. Twenty-four-hour urinary calcium measurement can be useful not only in helping to distinguish between PHPT and FHH, but also in giving a general measure of the renal burden for handling calcium.

PHPT may be associated with neuropsychological disturbances. Complaints include weakness and easy fatigability (in the absence of overt muscular weakness), depression, intellectual weariness, and increased sleep requirement. In addition, some centers have reported on patient-related outcome variables in PHPT that can negatively influence estimates of quality of life. Improvement in some of these indexes may be noted after successful parathyroidectomy, but it is not possible at this time to predict which patients will benefit.

A typical laboratory investigation for a patient with probable hyperparathyroidism includes serum calcium (total), phosphorus, alkaline phosphatase, PTH, vitamin D, and 24-hour urine collection for calcium. Additional information from the patient’s history should also consider other causes of hypercalcemia/hyperparathyroidism including parathyroid malignancy, medications (lithium, thiazide diuretics), milk alkali syndrome, and hypervitaminosis D.

Familial hypercalcemic hyperparathyroidism is an autosomal dominant disorder characterized by modest elevation of the serum calcium concentration that is generally asymptomatic, relative hypocalciuria, and parathyroid hormone (PTH) levels that are not suppressed by the hypercalcemia and are inappropriately normal. This condition can be identified by the low urinary calcium losses, in contrast to high losses seen in primary hyperparathyroidism. Measurement of a fractional calcium excretion provides the best way to rule out FHH, prior to surgery for presumed primary hyperparathyroidism. FHH is associated with heterogeneous inactivating mutations in the calcium-sensing receptor (CASR) gene located at chromosome 3q13.3-21. The CASR protein, encoded by six exons of the gene, is a G protein-coupled receptor well expressed in parathyroid and renal tubule cells. A bout 100 inactivating mutations in the CASR that cause a decreased sensitivity to extracellular calcium, impairing the ability to respond to normo- and hypercalcemia by appropriately inhibiting PTH secretion and renal calcium reabsorption have been described in patients with FHH and/or neonatal severe hyperparathyroidism (NSHPT). The most common are missense mutations. The recent finding of inactivating mutations of the MEN1, CASR, and HRPT2 genes in FHPT families suggests that at least some kindreds may represent a variant of these syndromes.

TREATMENT

Surgery is the only definitive treatment for hyperparathyroidism. Patients with complications of hyperparathyroidism (severe bone disease, fractures, renal stones, or overt neuromuscular dysfunction) should undergo parathyroidectomy. Management of asymptomatic patients is guided by consensus guidelines most recently modified in 2002. The guidelines for selection of asymptomatic patients for surgery are outlined in Table 13. It should be noted that the any individual under the age of 50 should be considered for parathyroidectomy regardless...
Secondary Hyperparathyroidism. Secondary hyperparathyroidism is an adaptive increase in the production of parathyroid hormone in response to a known clinical stimulus, usually via hypocalcemia and hyperphosphatemia. The most common cause is chronic renal failure. Other causes are vitamin D deficiency, calcium deficiency, malabsorption, and low serum magnesium. The parathyroid glands show hyperplastic changes resembling those of primary chief cell hyperplasia. These are not treated surgically unless parathyroid hormone secretion has become autonomous.

Tertiary Hyperparathyroidism. Tertiary hyperparathyroidism is apparently autonomous parathyroid hyperfunction on a background of known secondary hyperparathyroidism. Most cases result from diffuse or nodular chief cell hyperplasia affecting multiple glands, but about 5% of patients have adenomas; carcinoma may occur on rare occasions.

Multiple Endocrine Neoplasia Type 1. MEN1 is a hereditary syndrome characterized by the development of multiple endocrine neoplasms frequently involving the parathyroid, pancreatic islets, and pituitary. It is important to note that tumors may develop in other nonendocrine sites (Table 15).

MEN1 is an autosomal dominant familial disorder with current evidence supporting a tumor suppressor role of menin, the MEN1 gene, located on chromosome 11q13, product. Patients with a mutated nonfunctional gene are thought to develop disease when the nonmutated allele is lost [loss of heterozygosity (LOH)]. Over 400 mutations of the menin gene have been identified. Multiple functions have been suggested for menin largely based on animal studies. These include: regulation of gene transcription by affecting histone methyl transferases and histone deacetylases, regulation of cell proliferation via cyclin-dependent kinases, and augmenting transforming growth factor beta (TGF-β)-induced inhibition of cell cycle progression, promoting apoptosis possibly via caspase 8, and regulation of genomic instability by associating with various DNA repair genes. The precise mechanism by which menin fosters tumor development has yet to be determined.

The information obtained from genetic testing for MEN1 is not clearly as helpful in patient counseling as it is for MEN2 as outlined in Table 16.

Parathyroid Tumors in Multiple Endocrine Neoplasia Type 1. Although MEN1 is an uncommon diagnosis, MEN1 HPT accounts for 2 to 4% of HPT, HPT is the most common endocrine abnormality in MEN1 and is typically the first clinical expression of the disease. The onset of HPT in MEN1 occurs at 20 to 25 years of age, approximately 30 years earlier than sporadic HPT. HPT in MEN1 reaches nearly 100% penetrance by age 50 years. In contrast to sporadic primary HPT, there is an equal male to female ratio of disease. HPT in MEN1 must be considered multilobular since most patients have tumors in three or all four glands.

The clinical diagnosis is established in a patient with primary HPT and either a pituitary tumor or an islet cell tumor. Genetic counseling should be provided to patients and offered to family members. Laboratory studies documenting PTH, serum calcium, and 24-hour urine calcium are consistent with primary HPT. In suspected carriers, annual calcium determinations beginning at age 20 should promote identification of disease prior to the loss of bone mass which can occur as early as 35 years of age in patients with MEN1 and HPT. The indications for parathyroidectomy in children with MEN1 have not been determined. In adults, hypercalcemia increases gastrin secretion from gastrinomas, and effective parathyroidectomy will lower gastrin release. However, pharmacotherapy for Zollinger-Ellison syndrome (ZES) is so successful that ZES plus HPT is not an indication for parathyroidectomy in MEN1.

Treatment is not indicated until clinical or biochemical evidence of disease is identified. The specific procedure performed for MEN1 HPT is controversial and requires consideration of the morbidity of the effects of HPT balanced against the risks of surgery, postoperative hypoparathyroidism, and the likely recurrence of HPT. This has led to the traditional recommendations for a subtotal parathyroidectomy (3.5 glands) with transcervical near total thyromectomy for the initial operation or total parathyroidectomy with transcervical near total thyromectomy and autotransplantation. Subtotal parathyroidectomy with transcervical near-total thyromectomy is the commonest initial neck operation performed in patients with MEN1. Parathyroid cryopreservation is wise due to the 5 to 10% risk of hypoparathyroidism. Total parathyroidectomy with autograft provides similar results.

Recurrent HPT is a significant problem since 50% of MEN1 patients with a “successful” parathyroidectomy will develop recurrent HPT within 8 to 12 years. Placement of the autograft at distant sites facilitates imaging in the setting of recurrent HPT. To prevent late recurrence, another alternative is total parathyroidectomy followed by lifelong treatment with vitamin D analogs, a challenging endocrinologic problem. Relatively unexplored is the opportunity to utilize intraoperative PTH measurement to stratify the procedure, especially given the potential to avoid hypoparathyroidism.

It is important to note that MEN1 generates significant morbidity through hormone excess (PTH, gastrin, others) and malignant tumors (gastrinoma, islet cell tumors, foregut carcinoma). The care of patients with MEN1 relies on several principles. In contrast to MEN2, surgery has not been shown to prevent or cure MEN1 related cancer. Surgery does play a role in the management of hormonal excess for PTH and insulin. Medications manage most other tumor-related symptoms. PTH develops at least 90% of patients with MEN1, and the preferred parathyroid operation in the HPTH of MEN1 is subtotal parathyroidectomy (with or without autograft) including a transcervical, near-total thyromectomy performed simultaneously. Parathyroid tissue can be cryopreserved to retain the possibility of subsequent autograft. It is not clear whether parathyroid surgery should be performed for different indications in MEN1 than in sporadic HPT.
sis in 56%, bone disease in 91% and both nephro-
thyroid hormone levels were elevated in 21 of 21
serum calcium and serum phosphorus levels were
45% had a palpable neck mass. The mean
symptomatic, often have renal or bone disease,
and parathyroid hormone levels, are frequently
patients have significant elevations in calcium
422 Unfortunately, these findings are not uni-
formly present and can also be found in benign
parathyroid adenomas. At the initial operation,
the local histologic findings that support mali-
gency include invasion of local tissues, perineural
invasion, and vascular invasion. Regional nodal
metastasis is confirmation of malignancy but is
rare, distant metastases being more common.
The key molecular mechanisms responsible
for the development of parathyroid cancer have
can not have been established. The H P T T 2 gene, associated
with the H P T - J T syndrome, has been suggested to
to contribute to the development of sporadic parathy-
radiology 428 In the H P T T 2 gene encodes
a 531 amino acid protein, parafibromin. 425 Parafib-
primarily located in the nucleus and
downregulates the expression of cyclin D1. Mutations
inactive parafibromin have been identified in
77% of sporadic parathyroid carcinomas
with the loss of immunoreactivity
most. A recent study investigating the correla-
tion of parafibromin immunostaining and H R P T 2
mutations and L O H found that loss of parafibro-
smening had a sensitivity of 100%, greater
than that of H P T T 2 mutations and L O H . How-
ever, the finding of L O H or mutation was more
specific. 426 Although parathyroid carcinoma is
rare, in patients in whom the differentiation from
atypical adenoma and carcinoma is in question,
immunostaining for parafibromin holds promise.

Hyperparathyroidism. Aplasia or Hypo-
plasia. Hyperparathyroidism due to congenital
absence or hypoplasia of the parathyroid glands
typically is diagnosed neonatally and may be
associated with several genetic abnormalities. The
triad of hyperparathyroidism, thymic hypoplasia,
and recurrent infections was initially termed the
D I G eorge syndrome, described in 1965. Velo-
cardiofacial syndrome and conotruncal anomaly-
face syndrome are two separate syndromes which
include the component of aplasia or hypoplasia of
the parathyroid glands. A common element
in 90% of these syndromes is microdeletion on
chromosome 22q11. 432 Currently, all three syn-
donors are included in single genetic classifica-
tion, chromosome 22q11 deletion syndrome. The
acronym C A T C H 22 has been used to summa-
ize the major components of these syndromes
(cardiac defects, abnormal facies, thymic apla-
sia, cleft palate, and hypocalcemia). A associated
abnormalities of the third and fourth pharyngeal
pouches are common; these include conotruncal
defects of the heart in 25%, velopharyngeal insuf-
sufficiency in 32%, cleft palate in 9%, renal anom-
Alasies in 35%, and aplasia of the thymus with severe
immunodeficiency in 1%. The specific cardiac
anomalies are conotruncal defects (tetralogy of
Fallot, truncus arteriosus, double-outlet right ven-
tricle, subarterial ventricular septal defect) and
branchial arch defects (coarctation of the aorta,
interrupted aortic arch, right aortic arch). Con-
genital airway anomalies such as tracheomalacia

</table>
and bronchomalacia are sometimes present. The characteristic facial features associated with this syndrome have been described as prominent nose with hypoplastic nasal alae, midface hypoplasia, minor auricular anomalies, and micrognathia. This syndrome occurs in 1 per 7,500 newborns and is the most common contiguous gene deletion syndrome. Most cases arise de novo, and approximately 25% are inherited from a parent. This syndrome has also been reported in a small number of patients with a deletion of chromosome 10p13, in infants of diabetic mothers, and in infants born to mothers treated with retinoic acid for acne early in pregnancy.

Hypocalcemia in chromosome 22q11 deletion syndrome most frequently manifests during the neonatal period430,431 probably due to the interruption of the active transport of calcium from the mother to the fetus and an insufficient intake of calcium in the first few days of life. Hypocalcemia occurs in 60% of affected patients and is transitory in the majority. A spectrum of hypocalcemia may develop ranging from hypocalcemia to normal PTH levels and normal calcium.432–437 Late onset hypocalcemia, presents at times of calcemic stress (cardiac surgery and medication related altered vitamin D metabolism) and accounts for diagnosis in late adolescence and adults.438 The majority of asymptomatic adults are identified as parents of affected children.

Autoimmune Polyendocrinopathy Related Hypoparathyroidism. Autoimmune hypoparathyroidism can occur as an isolated clinical abnormality, as part of autoimmune polyendocrinopathy syndrome 1 (APS-1) or, less commonly, as part of APS-2.439 APS-1 most commonly comprises mucocutaneous candidiasis, hypoparathyroidism, and A-dsion disease. APS-2 includes two or more of the following: Addison disease, Graves disease, autoimmune thyroiditis, type 1 diabetes mellitus, primary hypogonadism, myasthenia gravis, or celiac sprue.

APS-1, also known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), is a rare autosomal recessive disorder caused by defects in the autoimmune regulator (AIRE) gene on chromosome 21.440,441 The disorder is manifested as chronic mucocutaneous candidiasis (100%), hypoparathyroidism (79%), and Addison disease (72%). All three elements are expressed in 51% of patients. Mucocutaneous candidiasis is often the earliest presenting symptom (during childhood) followed by hypoparathyroidism and Addison disease. Not all elements of the syndrome may be expressed, and the onset of hypoparathyroidism and Addison disease may be delayed requiring long-term follow-up. Dysfunction of other glands may be identified as well.442 Gonadal failure (60% in women, 14% in men) and hypoplasia of the dental enamel (77%) were also frequent findings. Ectodermal dystrophy (pitted nails, keratopathy, and enamel hypoplasia) are not attributable to hypoparathyroidism and enamel hypoplasia may develop before or after the onset of hypoparathyroidism.443 Recurrent candidiasis commonly affects the mouth and nails and, less frequently, the skin and esophagus.

A target antigen for the autoantibodies found in autoimmune hypoparathyroidism was described by Li and colleagues.444 It was noted that 56% of 25 patients, 17 with APS-1, reacted to the extracellular domain of a membrane-associated antigen of 120 to 140 kDa, which was identified as the calcium-sensing receptor. Similar results have been documented in patients with non-APS autoimmune hypoparathyroidism.

Iatrogenic Hypoparathyroidism. Hypoparathyroidism occurs most commonly as a complication of thyroid surgery and has been reported to occur transiently in up to 30% of cases and permanently in up to 4% of cases.445–449 In a large prospective study of 5,846 patients, multivariate logistic regression analysis identified the extent of thyroidectomy (total thyroidectomy), site of ligation of the inferior thyroid artery (proximal vs peripheral), and number of identified parathyroid glands as significantly associated with the development of permanent hypoparathyroidism. Transient hypoparathyroidism was found to be associated with Graves disease, female gender, site of arterial ligation, and extent of surgery.450 It is clear that preservation of well-vascularized parathyroid glands (two or more) should minimize this complication.

Identification of patients at risk of postoperative hypocalcemia has traditionally relied on serial determination of serum calcium levels (6 to 12-hour intervals) and close observation for the development of symptoms or signs of hypocalcemia. Postoperative hypocalcemia may develop 24 to 48 hours after thyroidectomy and prompts observation in the hospital to monitor the potential development of hypocalcemia. The introduction of rapid PTH measurement and the economic pressure for early dismissal has fostered the use of rapid PTH measurement to identify patients at risk for symptomatic hypocalcemia.452 This study identified an 80% sensitivity and 100% specificity for a postoperative level (at the time of wound closure) of less than 10 mg/ml for the development of symptomatic hypocalcemia. Further increase sensitivity to 88% was noted when the rapid PTH was measured in the postanesthesia care unit (PACU).453 Close observation and initiation of calcium and vitamin D supplements immediately after surgery for patients at risk are warranted (greater than 75% decrease or a level less than 12 mg/ml). A suggested starting regimen is 500 to 1,000 mg calcium carbonate (OsCal, GlaxoSmithKline, Research Triangle Park, NC) orally four times daily and 0.25 µg calcitriol (Rocaltrol, Roche Pharmaceuticals, Nutley, NJ) orally twice daily, which should be titrated as necessary by monitoring serial calcium levels. The development of tetany should be treated with intravenous calcium gluconate via a central line. This avoids the risk of calcium-related tissue necrosis should a peripheral line infiltrate during intravenous calcium administration. In this study, patients with PACU rapid PTH levels 12 mg/ml or more or a 75% or lesser decline in PACU rapid PTH had a low risk of hypocalcemia. These patients should nonetheless still be counseled on symptoms of hypocalcemia and instructed to report for follow-up evaluation if these occur.

THYROID GLAND SURGERY

Modern thyroid surgery traces its origins to the work of Emil Theodor Kocher, who in 1909 received the Nobel Prize for his contributions to medicine, physiology, and surgery. As Professor of Surgery in Bern (1872–1917), Kocher contributed more than any other surgeon to the development of safe thyroidectomy and the science of thyroid surgery. His results for goiter surgery were remarkable for the time, with overall mortality in more than 2,000 cases a remarkable 4.5% and by the end of the nineteenth century for simple goiter that mortality rate was 2%. Following Kocher came several surgeons who pioneered advances in the art of thyroid surgery. Identification of the role of the parathyroid glands, establishing the importance of preserving the recurrent laryngeal nerve, employing preparative iodine in patients with Graves disease, and advancing the role of subtotal thyroidectomy in advanced thyrotoxic patients were problems faced by subsequent surgeons and physicians. Halsted, Mayo, Crile, L ahey, and Dunhill all played prominent roles in the development of modern thyroid surgery.

Surgery for diseases of the thyroid gland requires understanding of the anatomy of the mediastinum and neck as well as the embryology of the branchial apparatus and laryngopharyngeal physiology. This knowledge must be integrated with an understanding of the pathophysiology of the specific disease process affecting the thyroid gland. The preceding sections of the chapter outline the diseases of the thyroid gland and the role surgery has in each. This section will review the key steps in a standard thyroidectomy, consider specific indications for thyroidectomy, intraoperative PTH monitoring, wound drainage, nerve monitoring, and review specific issues in thyroid surgery.

Steps in Standard Surgery of the Thyroid Gland

Consent. Informed consent for thyroid surgery requires a discussion addressing the risks of the type of anesthesia (general vs sedation with local anesthesia), incisions, the consequences of the absence of thyroid tissue, the risk of injury to neck structures, removal of area VI, VII, and lateral nodes, extension of surgery based on intraoperative findings, convalescence, hospital stay, and follow-up.

Preoperative Preparation. Patients are instructed to avoid aspirin for 7 days and nonsteroidal anti-inflammatory medications for at least 2 days. Patients on Coumadin are appropriately bridged to heparin if indicated. A prothrombin time international normalized ratio (INR) is determined
prior to surgery in patients receiving Coumadin or heparin therapy.

In the operating room, the patient is anesthetized and intubated. A midline incision is made from the sternum to the suprasternal notch and the strap muscles divided to expose the anterior surface of the thyroid lobes. Identification of the structures in the tracheoesophageal groove provides greater separation of the larynx and trachea from the prevertebral space aiding in the identification of the structures in the tracheoesophageal groove.

Positioning. The patient is placed supine with neck extension accomplished by a shoulder roll (Figure 3). Appropriate support of the occiput must be maintained. In patients with severe rheumatoid arthritis, flexion and extension views of the cervical spine should be obtained to assess stability. Patients with Down syndrome may also have cervical spine abnormalities.

Skin Preparation. For patients who will undergo postoperative I-131 therapy, it is advisable to avoid Betadine since significant iodine absorption may occur.454

Thyroidectomy. Performing a thyroidectomy involves a skin incision of appropriate size to address the clinically expected pathology. This may be a limited incision or an incision of sufficient length to allow bilateral lymph node dissections as far superior as area II and as far posterior as area V. Lateral to the platysma will provide a superficial landmark for flap elevation. Medially, the platysma is absent and the plane of dissection is superficial to the anterior jugular veins. Typically flap elevation is extended to the level of the anterior superior edge of the thyroid cartilage and inferiorly to the sternum. The strap muscles are identified and separated in the midline, exposing the isthmus and area VI.

Evaluation of the extent of the thyroid pathology should be ongoing during the course of the procedure. Elevation or division of the sternothyroid and sternothyroid musculature provides exposure of the anterior surface of the thyroid lobes. Identification and ligation of the middle thyroid vein are followed by the mobilization of the lateral border of the thyroid gland superiorly and inferiorly. At this point, the inferior parathyroid gland could be seen and, if noted, preserved. The superior pole of the thyroid is then isolated allowing identification of the external branch of the superior laryngeal nerve and ligation of the superior thyroid artery and vein. Dissection of the inferior pole then facilitates mobilization of the gland anteriorly. The recurrent nerve can be identified in several locations. The cricothyroid articulation is a consistent landmark rarely obscured by thyroid disease. The recurrent nerve will enter the larynx just posterior and superior to the joint. Alternatively, identification of the recurrent nerve in the tracheoesophageal groove after elevation of the thyroid lobe medially may require dissection and mobilization of fat. Palpation of the nerve and location of the inferior thyroid artery provide clues to finding the nerve. At this point review of the location of the parathyroid glands is followed by ligation of the inferior thyroid artery and associated veins, taking care to preserve blood supply to the parathyroids if not limited by thyroid pathology.

Once the parathyroid glands and the recurrent nerve have been identified, the thyroid lobe can be elevated off the trachea which requires division of the ligamentous attachments of the thyroid gland to the trachea (Berry ligament) located near the junction of the trachea and cricoid cartilage (Figure 4). The size of the lobe, the presence of gland inflammation, and the proximity of the nerve to the Berry ligament influence the difficulty of this dissection and the ability to remove all thyroid tissue. Careful use of vessel clips or fine suture ligature is favored over bipolar cautery. The surgeon should be aware of the potential for the presence of a pyramidal lobe and include this tissue in the resection. When the thyroid resection is performed for malignancy, the fat and lymph nodes located between the recurrent nerves laterally and from the superior border of the thyroid cartilage to the sternal notch are removed again preserving the inferior parathyroid gland (level VI dissection).

Once the thyroidectomy is completed, the wound is examined for the quality of hemostasis.
via a small incision has been completed in large series of patients and studied in a randomized fashion. Three elements facilitate performance of the thyroidectomy via limited access: improved visualization with angled telescopes, hemostasis with the harmonic scalpel, and an additional assistant for retraction or holding the scope. Limited access has less flexibility to manage problematic bleeding, large masses and address adenopathy and therefore requires careful patient selection. An example of guidelines for patient selection include the following: thyroid nodule less than 35 mm in largest diameter, ultrasound estimated thyroid gland volume less than 20 mL, no thyroiditis, no prior neck surgery, and no history of radiation. Malignancies other than low-risk papillary thyroid cancer, presence of enlarged lymph nodes, and goiters greater than 20 mL are considered contraindications to MIVAT. Benefits confirmed include less pain and improved cosmesis. An issue yet to be resolved is the efficiency and efficacy of central compartment node dissection.

Harmonic Scalpel (HS). The HS is an instrument that uses vibration at 55.5 kHz, that is, mechanical action, to cut and coagulate tissue simultaneously and generates minimal lateral thermal tissue damage, less smoke formation, no neuromuscular stimulation, and no electrical energy to or through the patient. Multiple studies have identified various advantages compared to standard methods. The primary advantage is the ability to effectively coagulate the vasculature encountered in routine thyroid surgery with decreased access thus facilitating minimal access surgery and decreased operating time (10 to 35%) when compared to standard techniques. Other reported benefits include decrease drainage and less pain. The importance of decreased drainage is uncertain since the need for drain placement in routine thyroid surgery has not been supported by large studies. Whether decreased pain will be further substantiated and found to be clinically significant remains to be determined. One disadvantage is the cost associated with the disposable instrument. When using the instrument, one must appreciate that the functional end of the surgical tome, "Al-Tasrif," in 952 AD. The concern regarding the safety of thyroid surgery in the mid-nineteenth century was characterized by the opinion of Diffenbach in Germany who in 1848 condemned such surgery to be, "one of the most thankless, most perilous undertakings which, if not altogether prohibited, should at least be restricted," dismissing such operations as "foolhardy performances" (Diffenbach JF. Die Operative Chirurgie II. Leipzig: FA Brockhaus; 1848. p. 331). The position of Liston in 1846 was similarly pessimistic suggesting one "could not cut the thyroid gland out of the living body in its sound condition without risking the death of the patient from haemorrhage. It is a proceeding by no means to be thought of." Liston R, Mutter TD. Lectures on the operations of surgery and on diseases and accidents requiring operations. Philadelphia: Lea Blanchard; 1846. p. 318). In 1866, Gross also denounced thyroid surgery as "horrid butchery deserving of rebuke and condemnation," and that "no honest and sensible surgeon would ever engage in it" (Gross SD. A System of Surgery. 4th edition. Philadelphia: Lea Feibiger; 1866. p. 394). Fortunately, pioneers in the field of thyroid surgery persevered, and today thyroid surgery is considered safe and effective.

As with any surgical procedure involving a skin incision and formation of a surgical wound or cavity, potential exists for hemorrhage into the wound and postoperative wound infection. The incidence of wound infections typically occurs in less than 1% of cases. This seems to be independent of whether antibiotic prophylaxis or antibiotic prophylaxis and subsequent antibiotic therapy are administered. Hemorrhage is similarly uncommon, occurring in less than 2% of patients and noted at a higher rate in bilateral procedures than in unilateral procedures. Hemorrhage is a particularly worrisome complication due to the potential for airway obstruction. If noted, emergent airway evaluation and drainage are required.

Hypocalcemia is the most common complication following thyroid surgery occurring in 10 to 33% of patients, and the highest rates of hypocalcemia are associated with total thyroidectomy. Hypocalcemia is related to transient hypoparathyroidism in the vast majority of cases (>95%). Preservation of the vascular pedicle to the parathyroid glands provides the best insurance of avoiding permanent hypocalcemia. The number of parathyroid glands necessary to maintain normal serum calcium levels has not been determined. During thyroidectomy, if the parathyroid glands are anatomically well separated from the thyroid in the parathyroid capsule, the surgeon may easily preserve them without significant manipulation. In contrast, if they are attached to the thyroid capsule, as is often the case, they must be accurately separated, and pericapsular ligation of the branches of the inferior thyroid artery must be carefully executed. The posterolateral branch of the superior thyroid artery should be ligated only after having determined that it does not supply the superior parathyroid gland. A devascularized parathyroid gland is minced and reimplanted in a muscle body and localized with a nonabsorbable suture.

Early identification of patients at risk for postoperative hypocalcemia would facilitate institution of vitamin D and calcium therapy in appropriate individuals. Because the onset of symptomatic hypocalcemia tends to occur 24 to 48 hours after resection, early dismissal places patients dismissed within 24 hours at risk of developing symptoms in a nonhospital setting. Recent studies provide strong support that intraoperative parathyroid hormone levels can provide this stratification. The results of these studies suggest that patients with decreases of 75% or greater from baseline PTH at either ten or 20 minutes postresection should be considered for administration of calcium and vitamin D.

Laryngeal nerve injury is perhaps the most frustrating complication following thyroid surgery due to the impact on the patient's quality of life. Identification of either recurrent nerve injury or injury of the external branch of the superior laryngeal nerve requires careful laryngeal postoperative examination. Postoperative nerve injury in a large study from Italy was noted in 3.4% of 14,934 patients. This accounted for 22% of the noted complications. As expected, when both lobes of the thyroid were manipulated, a greater number of laryngeal nerve injuries were identified. Approximately half of the injuries were permanent. At least one large series supports the routine identification of the recurrent laryngeal nerve to minimize nerve injury.

Laryngeal nerve monitoring may be employed to aid the surgeon in nerve identification and preservation as well as provide some estimate of postoperative vocal fold mobility. Nerve monitoring in thyroid surgery focuses on recurrent laryngeal nerve with muscle activity identified by hook wire electrodes placed in the vocal fold, electrodes imbedded in an endotracheal tube, a paddle placed in the postricoid region, or a finger placed in the region of the arytenoid cartilage. Regardless of the method of monitoring, anatomical knowledge and a principled approach to the procedure are required as each monitoring system has limitations and potential for system failure. It is not clear whether the use of a nerve monitoring system decreases the rate of nerve injury. The potential benefits of nerve monitoring should be balanced with the costs. Some data exist to support utility of predicting postoperative recurrent nerve function with nerve stimulation and palpation of arytenoid cartilage motion. Alteratively, others conclude that the sensitivity and specificity were insufficient to be useful. The low percentage of patients with postoperative nerve injury following routine thyroid surgery requires that a large population be studied to determine whether nerve monitoring in some form will provide a significant reduction in nerve injury or be sufficiently accurate to differentiate temporary versus permanent vocal fold dysfunction. A selected group of patients undergoes nerve monitoring by one of the authors (J.L.K), specifically patients in whom risk of nerve injury is particularly high, such as advanced malignancy, large benign lesions, or revision surgery, with the goal of facilitating nerve identification in challenging operative fields.

Well-Differentiated Follicular Cell Derived Thyroid Cancer: Extent of Thyroidectomy. The principles and concepts driving surgical
readily applicable to the substernal extension of risk of malignancy (ultrasound and FNA) are not the techniques that facilitate the stratification of Substernal Goiter.

management of thyroid cancer. This approach also characterizes the surgical management recommended by several professional organizations in recently published guidelines for the treatment of thyroid cancer, and possibly decreasing the recurrence rate and increasing survival. A near-total or total thyroidectomy may not hold an advantage over lobectomy in low- or high-risk patients, however, and lobectomy generates less risk of recurrent laryngeal nerve injury and postoperative hypocalcemia. In the United States, most patients are treated with a near-total or total thyroidectomy. It is likely that in Stage I disease the extent of thyroid surgery does not impact survival.

SUMMARY

To optimize the quality of care for the patient with thyroid cancer, the pre-operative assessment, surgical approach, adjuvant therapy and post-operative surveillance should involve an integrated, consistent team-based approach. These authors find that patients with thyroid cancer are best managed with an initial near-total thyroidectomy, central neck dissection for those patients with PTC, Hürthle cell variant FTC or MTC, and more extensive compartmental node dissection guided by pre-operative ultrasound findings. This approach also characterizes the surgical management recommended by several professional organizations in recently published guidelines for the management of thyroid cancer.

Substernal Goiter. A challenging problem in a small population of patients with multinodular goiter is extension of the disease into the mediastinum (Figures 5 and 6). Symptomatic patients often present with dyspnea, dysphagia, choking, and hoarseness. The following issues require consideration in this group of patients: risk of malignancy, correlation of the mass with the thyroid bed with a goal of microscopically free margins. Therefore, an appropriate preoperative evaluation combined with a surgeon or surgical team skilled should result in complete resection of the disease and preservation of voice and swallowing. To accomplish this goal, skills in conservation and reconstructive surgery of the larynx, trachea, pharynx, and esophagus are invaluable.

Characteristic symptoms and findings which should prompt investigation of invasive and aggressive disease and require an advanced surgical skill set include the following: pain decision-making for well-differentiated FCDTC are plagued by high-level data deprivation, and debate ensues based on large retrospective studies. Data support improved cause-specific mortality and recurrence with a transition from lobectomy to near total or total thyroidectomy. This issue has come into greater scrutiny in part due to the earlier identification of thyroid carcinomas due to the routine use of ultrasonography. The earlier identification has likely prompted the increased incidence noted for thyroid cancer recently. In this group of patients, one must keep in mind the behavior of PTC, which is usually a slow growing, indolent tumor. As noted elsewhere in this chapter, reliable prognostic indicators exist to predict the outcome in PTC in particular. Some authorities recommend performing a total thyroidectomy in all patients because of advantages such as removing contralateral microscopic disease, improving the specificity of serial postoperative thyroglobulin measurements, allowing radioactive iodine to be administered to ablate residual thyroid tissue and treat residual cancer, and possibly decreasing the recurrence rate and increasing survival. A near-total or total thyroidectomy may not hold an advantage over lobectomy in low- or high-risk patients, however, and lobectomy generates less risk of recurrent laryngeal nerve injury and postoperative hypocalcemia. In the United States, most patients are treated with a near-total or total thyroidectomy. It is likely that in Stage I disease the extent of thyroid surgery does not impact survival.

The procedure requires some modifications from standard thyroid surgery. A larger incision is required to allow egress of the mass, the strap muscles will likely require division, and identification of the recurrent nerves and parathyroid glands may be more challenging (Figures 7 and 8). Nerve monitoring may be of help not only to identify the nerve but also to detect stretch induced nerve stimulation. Identification of the nerve near the cricothyroid articulation may be technically easier when the substernal extension and goiter size prevent rotation of the gland anteromedially, limiting access to the tracheoesophageal groove. The need for a thoracotomy is rare as most cases can be elevated into the neck. A suspicion of malignancy, prior surgery, and previous external beam irradiation increase the potential need for a sternotomy. The sternotomy can be limited to the upper one-third of the sternum and is generally well tolerated by the patient. Drain placement should be considered routine. Tracheomalacia is rarely a problem and can preliminarily be assessed by fiberoptic examination on extubation which would also allow evaluation of vocal fold mobility. Extubation over an airway exchange catheter is a safe option.

Conservation and Reconstructive Surgery of the Larynx, Pharynx, Trachea, and Esophagus in Advanced Thyroid Cancer. It is indeed fortunate for patients with thyroid cancer and for the head and neck surgeon that the majority of thyroid carcinomas are PTCs. This provides a patient population which, in the vast majority of cases, will likely survive the cancer being treated but may unfortunately mute the suspicion of aggressive disease. Ideally, the patient’s initial surgery should be the only procedure required in the thyroid bed with a goal of microscopically free margins. Therefore, an appropriate preoperative evaluation combined with a surgeon or surgical team skilled should result in complete resection of the disease and preservation of voice and swallowing. To accomplish this goal, skills in conservation and reconstructive surgery of the larynx, trachea, pharynx, and esophagus are invaluable.

Characteristic symptoms and findings which should prompt investigation of invasive and aggressive disease and require an advanced surgical skill set include the following: pain...
Sites of Invasion. Sites of early extracapsular invasion of thyroid cancer include the upper three tracheal rings, the anterior and lateral border of the cricoid cartilage, posterior inferior aspect of the thyroid cartilage, the recurrent laryngeal nerve, and on the left the esophagus. As cancer volume expands, extension into the cricothyroid, retrotracheal, and retropharyngeal space develops. The perichondrium and cartilage provide a relatively strong barrier to tumor extension into the airway lumen while natural gaps in continuity or loss of cartilaginous integrity from shave resections may provide access to the lumen or the cartilaginous space. The nonstructural factors determining invasion are not well defined but likely involve interactions between the immune system and tumor derived cytokines and angiogenic factors.

The surgical approach to upper aerodigestive tract invasion by thyroid cancer is guided by the concepts of conservation surgery but requires an approach based on the pathway of invasion that is different from mucosally derived aerodigestive tract cancer. Knowledge of laryngeal anatomy and physiology and experience with mucosal malignancies provide the essential grasp of the structural requirements and resection limits allowing organ preservation. For example, knowledge of partial laryngeal surgery (partial vertical, supraglottic, and supracricoid laryngectomy) will vastly impact the ability to approach complete resection of invasive thyroid cancer with voice and swallowing preservation. Thus, the need to consider a laryngopharyngectomy is a rare event even in advanced cancers. Options for conservation surgery are limited, however, by external beam irradiation due to its effect on tissue vascularity. Although conservation surgery can be considered after external beam radiation, there is a much greater risk of chondritis and wound breakdown.

Invasion of the pharynx and esophagus is much less common than invasion of the larynx, cricoid cartilage, and trachea. When the invasion is limited to the muscular coat, a myectomy preserving mucosal integrity is practical. When mucosa is invaded, the potential for a salivary fistula is established and the tolerance of primary closure is site dependent. The hypopharynx has a greater surface area and a larger defect can be closed primarily while resections at the level of the cricopharyngeus or upper cervical esophagus are more likely to result in some degree of stenosis. In this setting, preoperative planning for reconstruction of the defect helps limit the tendency to fail to resect disease.

Larynx and Pharynx. The attachment of the strap musculature to the oblique line of the thyroid cartilage positions a superior-lobe neoplasm directly adjacent to the perichondrium of the thyroid alae. Laryngeal invasion can occur through cartilaginous perforations following blood vessels or can reach the piriform sinus by extending posteriorly and medially to the thyroid ala (Figures 9 and 10).

Figure 9 An upper pole tumor with superiorly directed growth meets resistance at the oblique line. Subsequent growth extends posteriorly and invades through the pharyngeal constrictors to begin to fill the piriform sinus. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)
This relates to the key role the cricoid cartilage plays in serving as the foundation of the larynx and the transition from the generous surface area of the piriform sinus region to the limited surface area of the cricopharyngeal region. The posterior part of the cricoid cartilage supports the thyroid and arytenoid cartilages and provides the origin of the posterior cricoarytenoid muscle. Resections in this area are necessarily intimate with the recurrent nerve and readily impact arytenoid function and the position of arytenoid and thyroid cartilages with potential airway narrowing. Mucosal resections in this area of a limited extent can be tolerated. Based on the residual lumen, one should expect a need for augmentation of the lumen at the time of resection or dilatation of a post-surgical stenosis. The optimal flap to consider is a microvascular free radial forearm flap due to the thin pliable tissue available.

Trachea and Esophagus. Tracheal invasion is most commonly identified in the anterior two-thirds of the tracheal circumference due to the approximation of the thyroid gland to this area of the trachea (Figures 12 and 13). The surface area involved will determine the required resection. If limited in extent, a wedge resection and primary closure without resecting the posterior wall of the trachea may be all that is involved. When the defect requires mobilization of the trachea for closure, a segmental resection with primary closure is utilized. Extention of the resection into the subglottis generates a greater risk of glottic edema, and the need for a tracheostomy is significantly increased.

On the left side, posterior extension generates potential for esophageal involvement. Tumor can fill the potential space between the trachea and esophagus and potentially invade both structures. With esophageal muscle involvement only, a myectomy preserving intact mucosa is completed. This resection should not generate significant symptoms of dysphagia, but patients may note pharyngeal reflux similar to that following a cricopharyngeal myotomy. When mucosa is involved to a limited extent, primary closure can be accomplished. The team should be prepared for a radial forearm microvascular free flap reconstruction.

Occasionally, tumor will insinuate between the trachea and esophagus with an opening developing in the posterior wall of the trachea and a defect in the trachea (Figures 14 and 15). If small in diameter, primary closure with interposition of a muscle flap should promote healing and prevention of a tracheoesophageal fistula. Larger defects are best managed with a microvascular free flap (Figures 16 and 17).

Lymph Nodes. Lymph nodes with extracapsular extension of tumor can be the source of invasive thyroid cancer (Figure 18). When the larynx, pharynx, trachea, or esophagus is involved, principles outlined above will generally facilitate successful management. As disease extends farther inferiorly, the surgical team should be prepared to improve access and vascular control with a partial sternotomy (Figure 19).

A well-prepared surgical team should rarely need to consider a laryngopharyngectomy when treating advanced thyroid cancer unless significant posterior cricoid and interarytenoid invasion are not amenable to preservation of the larynx. Replacement of large areas of hypopharyngeal mucosa would generate a risk of aspiration due to the loss of sensitive mucosa. Comorbidities must be considered when aspiration may be generated. For example, limited aspiration that may resolve with swallowing therapy would likely be tolerated by an individual with normal pulmonary reserve but could be life threatening in a patient with severe chronic obstructive pulmonary disease.

Anaplastic Thyroid Carcinoma. Surgery for ATC should be considered for two primary reasons, obtaining tissue for diagnosis and palliation. Often, FNA will establish the diagnosis, but not infrequently cases occur where the cytology does not clarify whether a high-grade lymphoma, high-grade metastatic lesion or ATC is present (Figure 20). In that setting, an open biopsy is indicated. The issue of whether a tracheostomy should be performed should be individualized. If there are significant comorbidities and evidence of metastasis, consideration should be given to avoiding a tracheostomy as the challenge of caring for a tracheostomy may significantly detract from the patient’s quality of life. Often

Figure 10 This figure demonstrates routes of invasion into the larynx and pharynx by tumor in the upper pole of the left thyroid lobe. Direct invasion through the thyroid ala reaches the anterior part of the piriform sinus or the paraglottic space of the larynx. When the tumor extends posteriorly to the thyroid ala, it accesses the posterior part of the piriform sinus and has proximity to the prevertebral fascia. (Copyrighted and used with permission of Mayo Foundation for Medical Education and Research.)
the large volume of tumor renders creation of a tracheostomy site a procedural challenge, and the site will be seeded with high-grade cancer cells likely to enlarge promptly. High-quality hospice care should be able to facilitate a graceful end of life even in the setting of airway obstruction.

Perhaps the most challenging situation is when the diagnosis has been established, and the decision required is whether surgery provides benefit, particularly in younger healthy patients. Most patients who survive ATC have small primary tumors identified at the time of resection of an initial papillary or follicular carcinoma and undergo postoperative chemoradiation. Resectability or unresectability may be difficult to define or establish. Resection should be undertaken with the understanding that the procedure is palliative and that residual microscopic disease is likely locally or regionally. For example, a 44-year-old father of three children has a large thyroid and neck mass recently biopsy-confirmed as ATC. His tumor is growing out the biopsy site in his neck lateral to the sternocleidomastoid muscle. The tumor has not encased the common carotid artery, and the prevertebral space and the esophagus appear normal. No metastatic disease was noted on PET/CT imaging. This patient was offered resection to reduce local and regional disease and alter his mode of death. Postoperatively, his voice and swallowing were normal and he underwent chemoradiation. Within 6 months abdominal metastases occurred and proved to be the cause of death. The goal of preventing gross cervical disease creating a wound care problem and death by asphyxiation was accomplished.

Controversies in Thyroid Surgery

Extent of Lymph Node Dissection for Papillary Thyroid Cancer. As previously discussed, PTC has a high incidence of lymph node metastasis (40 to 60%). Spreading from the thyroid gland, the central and lateral lymph node compartments on the side of the thyroid tumor represent the first echelons of lymphatic drainage. The opposite lateral and the mediastinal lymph node compartments then follow suit. Despite the recognized sequence of lymphatic dissemination, discontinuous lymphatic spread or skip metastasis is not uncommon in node-positive papillary thyroid cancer. However, in stark contrast to other head and neck cancers, nodal metastasis does not have an impact on survival in low-risk groups. This generates two approaches to the scope of nodal dissection for low-risk PTC. One approach is to accept the nodal persistence or recurrence rate and perform neck dissection when these metastatic nodes become clinically evident. Alternatively, nodal dissections of variable extent can be part of the initial procedure. Arguments for the more conservative approach include the lack nodal dissection positively impacting survival and the morbidity of the surgical procedure. Also, some would anticipate radioactive iodine to provide an opportunity to eliminate nodal disease. Proponents for nodal dissection argue that...
nodal dissections carry minimal morbidity and provide the opportunity for a patient to avoid further treatment.

Technological advances have impacted these decisions as well. The consistent use of high-resolution ultrasound and increasingly sensitive thyroglobulin detection provides identification of much smaller tumor volumes in both the primary and recurrent setting. To provide a greater degree of efficiency for the patient and facilitate follow-up, a total thyroidectomy combined with an area VI nodal dissection is a reasonable initial treatment. This is based on the inability of the ultrasound to image the nodes posterior to the thyroid gland effectively, and this dissection would treat the most likely sites of nodal metastases. Frozen section information can also be used to expand the scope of surgery. Preoperative identification of suspicious nodes in the neck (either by clinical examination or ultrasound) should be addressed with a compartmental dissection.

PARATHYROID GLAND SURGERY

Surgical Anatomy

The normal location of the parathyroid glands is the foundation for surgical management of hyperparathyroidism (Figures 21 and 22). The study by Akerström remains a useful guide to the location and number of parathyroid glands. This was an autopsy study of 503 unselected cases in which the tissues were dissected from the base of the tongue to the diaphragm. Gross and histological characteristics were characterized as was the number and location. The shape of the gland was described as oval, bean, or spherical in 83% of cases. An elongated shape was noted in 11%. Bilobed and multilobulated glands were noted in 5 and 1% of cases, respectively. Four parathyroid glands were found in 84%, more than four glands were identified in 13%, and only three glands were found in 3%. In cases in which only three glands were identified, the lower weight of the parathyroids suggested a gland had been missed. Supernumerary glands were classified as three types: supernumerary rudimentary glands were small nubbins closely approximated to a normal-sized gland (2%), supernumerary split glands appeared divided (6%), and a proper supernumerary gland weighed more than 5 mg and was located well away from the other four glands (5%). In the cases of proper supernumerary glands; 18 had five glands, 3 had six glands, 1 had seven glands, 1 had eight glands, and 1 had eleven glands.

The locations of the superior parathyroid glands were correlated to the intersection of the recurrent laryngeal nerve and the inferior thyroid artery. Eighty percent of the superior parathyroid glands were located within an area 2 cm in diameter centered approximately 1 cm above the intersection of the nerve and artery. The glands were commonly found in the fascial fibers on the posterior edge of the thyroid gland. Occasionally the normal superior gland was located inferiorly (4%), in some cases obscured by the artery, nerve,
or the tubercle of Zuckerkandl. Rarely was the superior gland located higher in the neck. Ectopic locations were detected in 1% with identification in the retroesophageal or retropharyngeal space. True intrathyroidal glands were rare, and typically noted in cases of goiter in which the gland was hidden in the nodules and could often be dissected along a fascial cleavage plane.

The majority of the inferior parathyroid glands (61%) were associated with the posterior, inferior, or lateral surface of the lower pole of the thyroid gland (below the inferior thyroid artery). Inferiorly displaced glands were commonly associated with the thyrothymic ligament or in the cervical portion of the thymic glands (26%). In 2%, the inferior parathyroid was located in the mediastinal portion of the thymus, and 0.2% was found below the thymus in the mediastinum. The embryologic origin of the inferior parathyroid from the third pharyngeal pouch and its association with the thymus gland (also a third pharyngeal pouch...
operative sestamibi scintigraphy is less accurate and often does not detect the abnormal parathyroid gland(s). Single gland disease can also be difficult to image on sestamibi imaging if the adenoma is small in volume and located in the upper position. Adenomas with a higher percentage of oxyphil cells are more easily imaged.486

The limited anatomic detail available from SPECT images has prompted the pursuit of other imaging techniques. Ultrasound has been confirmed to contribute preoperative localization and may be combined with sestamibi scanning.487,490,491 An additional potential benefit of a preoperative ultrasound is the identification of any associated thyroid pathology that could be addressed under the same anesthetic. Sestamibi imaging and ultrasonography may still be inadequate for preoperative localization in patients with a history of previous neck surgery, in patients with coexisting thyroid disease (eg, thyroid nodules or Hashimoto thyroiditis), and in patients with an unfavorable body habitus (eg, obesity, short neck, or kyphosis). These challenges foster new imaging modalities, such as four-dimensional CT to be applied to parathyroid adenomas.492 The application of more detailed imaging information will continue to impact minimally invasive parathyroid surgery.493

Radio-guided minimal access parathyroidectomy includes a 99 mTc-Sestamibi injection preoperatively to facilitate intraoperative localization of the adenoma with a hand held gamma counter. Typical preoperative studies are completed including localizing studies. The incision and dissection are similar with the dissection directed by intraoperative measurement of radioactivity. Decrease in radioactivity subsequent to resection is used to document cure. For example, ten minutes (alternate times have been used) before the beginning of the surgical procedure 37 MBq of 99 mTc-Sestamibi is injected intravenously. Prior to surgical incision, the patient’s neck is scanned with a collimated gammaprobe to identify the maximum activity count area corresponding to the anticipated parathyroid adenoma. A transverse neck incision is appropriately placed. The gammaprobe is repeatedly inserted through a 2 to 2.5 cm skin incision guiding the direction of the dissection. Radioactivity is measured keeping the gammaprobe on the presumed parathyroid adenoma, thyroid gland and background. After removal of the target tissue, radioactivity is measured to evaluate success of parathyroid surgery. Intraoperative PTH (ioPTH) measurement is sometimes added to the procedure to assess cure.

A crucial ioPTH measurement is a key element in minimally invasive parathyroidectomy. Initially introduced in 1998, practical applicability required reduction in the 1 hour processing. Currently, the test can be completed in as little as 15 minutes and measures the active component of PTH (1–84 or intact-PTH). The site and timing of the blood draw for ioPTH sampling has been debated as has the appropriate postresection level to confirm cure. In general the same site should...
Currently, minimal access parathyroidectomy has been applied to assess removal of sufficient parathyroid tissue in secondary and tertiary hyperparathyroidism. In summary, parathyroid surgery has and continues to evolve with several options available to assess cure and facilitate minimal access surgery rapidly. Local expertise and resource availability will influence practice since ioPTH is not uniformly available and radiographic expertise varies. The best practice will continue to evolve with technological advances.

**Parathyroidectomy. Consent.** Informed consent for parathyroid surgery requires a discussion addressing the risk of the type of anesthesia (general vs sedation with local anesthesia), incisions, the risk of injury to neck structures, extension of surgery based on intraoperative findings, possible recurrent hypercalcemia, convalescence, hospital stay, and follow-up.

**Preoperative Preparation.** Patients are instructed to avoid aspirin for 7 days and nonsteroidal antiinflammatory medications for at least 2 days. Patients on Coumadin are appropriately bridged to heparin if indicated. An INR is determined prior to surgery in patients receiving Coumadin or heparin therapy. In the operating room, the patient is anesthetized and intubated if a general anesthetic is planned. Laryngeal mask anesthesia is an option and has been employed to facilitate visualization of the vocal folds in response to nerve stimulation. Alternatively, an endotracheal tube with implanted wire electrodes can be placed to facilitate recurrent and vagal nerve monitoring.

**Positioning.** Positioning of the patient is the same as in thyroid gland surgery.

**Procedure.** Following routine skin preparation and antibiotic prophylaxis, the incision is planned. The incision should be placed to provide exposure to the site suggested by preoperative localization studies with the flexibility to access adjacent areas and be incorporated for bilateral exposure if necessary. An incision 2 cm in length lateral to the midline at the approximate level of the lower border of the cricoid cartilage will typically provide sufficient access. When the adenoma is expected in the location of the superior parathyroid gland, an approach lateral to the sternohyoid and sternothyroid muscles but medial to the omohyoid muscle facilitates exposure posterior to the thyroid gland and to the region of the tracheoesophageal groove. If the adenoma is suspected to be in the location of the inferior gland, an approach medial to the sternohyoid and sternothyroid muscles is used.

After elevation of skin flaps and mobilization of the musculature, the lateral border of the thyroid gland is identified and inspected, and the carotid sheath structures are identified (Figures 23 and 24). An ioPTH can be obtained from the jugular vein or a peripheral site followed by systematic examination of the anticipated location of the adenoma (superior vs inferior to the inferior thyroid artery). This process should involve identification of the recurrent nerve unless the adenoma is obvious with minimal dissection. If not identified after thorough examination, the carotid sheath, tracheoesophageal groove, and superior thyrosus should be examined (Figure 25). If unable to identify an adenoma, consideration of a false positive localization study should be considered and the opposite side explored in a similar systematic fashion. If an adenoma is still unable to be identified, consideration should be given to an ectopic parathyroid (Figure 26). Removal of a thyroid lobe on the side where normal parathyroid tissue is not identified should be considered. Preoperative imaging may provide clues to this ectopic location as well.

**Intraoperative cytology and/or conventional frozen sections** merely confirm tissue type rather than functional status and are of limited benefit in minimal access parathyroidectomy. However, the surgeon must be alert to features that suggest parathyroid carcinoma. This may be suspected preoperatively, but the classic clinical picture is not always seen. A thick fibrous capsule around the gland with adhesion to and/or overt infiltration of adjacent tissues including the thyroid gland should prompt consideration of parathyroid carcinoma, and frozen section analysis should be performed. If a parathyroid hyperplasia
or adenoma has undergone previous hemorrhage or degeneration, this can induce a potentially misleading dense irregular fibrotic capsule, possibly with "pseudoinvasion," but this is usually accompanied by hemosiderin deposition, which is absent in carcinomas. This is in contrast to an adenoma, which has a smooth thin capsule, making dissection easy.

CONCLUSIONS

Patients with diseases of the thyroid and parathyroid glands benefit from integrated care by physicians with a broad knowledge base including the anatomy, physiology and pathophysiology of the thyroid gland, parathyroid glands, and aerodigestive tract. This chapter presents information that reflects many current principles followed in an integrated academic practice. Clearly changes should be expected as higher-quality data are obtained, further advances in molecular medicine become applicable, new technology is developed, and cost contraints increase.
