After implantation, a patient would not be able to hear any sounds until his/her speech processor is programmed with one of the aforementioned coding strategies. We have covered the theoretical aspects of a speech coding strategy. In practice, each strategy has various adjustable parameters that need either to be measured objectively through psychoacoustic experiments or to be determined subjectively by a clinician. The careful adjustment of these parameters is required to ensure the safety, audibility, and efficacy of electric stimulation.

Taking the CIS strategy as an example, we can group the fitting parameters into 2 categories: acoustic and electric. For example, acoustic parameters include: volume and sensitivity settings for auditory inputs, automatic gain control, number of channels, frequency table, and mapping function; electric parameters include: pulse width and rate, electric threshold and comfortable levels, and stimulation mode. We will start with the discussion on the fundamental electric settings, followed by an in-depth discussion of acoustic signal adjustment.

Setting Stimulation Mode

To stimulate auditory neurons, at least 1 pair of electrodes should provide a start-to-end path for the current flow. Each pair of electrodes forms 1 stimulation channel. Depending on the configuration of the returning electrode, stimulation mode in cochlear implants can be monopolar (MP), bipolar (BP), or common ground (CG) (Figure 4).

No matter which mode is selected, the active electrode is always the intracochlear electrode. In the MP mode, the returning ground electrode can be either one or two remote extracochlear electrodes, or the metal shell of an implant stimulator at the temporal bone. Due to a large distance between the paired electrodes, the monopolar mode generates wide spread of current field. In the BP mode, the returning electrode is one of the neighboring intracochlear electrodes. When the number of electrodes between the bipolar pair is N (eg, 0 to 3), it is referred to as BP (N = 0) or BP + N (eg, BP + 1, BP + 2, or BP + 3). In the CG mode, all of the intracochlear electrodes are connected to ground except the active electrode(s).

In selecting the stimulation mode, current spread and its associated loudness perception should be taken into consideration. Some strategies only allow a certain stimulation mode setting. In general, the BP mode produces less current spread, and the MP mode generates wide current spread. The CG mode is intermediate.20 Most cochlear implant users prefer the MP stimulation mode. For certain coding strategies, the other 2 modes might provide benefits by focusing current stimulation.

Configuring Pulses

Biphasic pulse trains are the primary waveforms used in cochlear implants to keep charge-balance. A biphasic pulse consists of a leading negative pulse and a delayed positive pulse at equal amplitudes (see Figure 4). An interphase gap can be added between 2 phases. To define a pulse train, 3 parameters are needed: pulse width, interphase gap, and pulse rate. Pulse amplitude varies with the subband envelope as shown in a CIS strategy, and it is not a fitting parameter. The pulse width refers to the duration of 1 single phase, usually from 10 to 100 μs. The pulse gap can be 0 or up to several microseconds. Pulse or stimulation rate could affect temporal resolution. The higher the pulse rate is, the more temporal cues could possibly be encoded, but greater channel interaction may occur. The pulse rate can be as low as 100 Hz or as high as 10,000 Hz per channel among implant devices.

Measuring Threshold and Most Comfortable Level

Once the pulse pattern and stimulation mode are selected, the next step is to measure the minimal pulse amplitude that induces a just noticeable sound at the threshold (T) level, and the pulse amplitude that is at the most comfortable level (MCL). The T and MCL determine the dynamic range of electric stimulation. For some devices, the T and MCL are usually expressed in specific clinical units rather than the current units, microampere (μA).

Measuring the T and MCL is the main task in the clinical fitting of a cochlear implant, since these measurements are performed subjectively on each channel or on a set of preselected channels. Any change in the pulse configuration or stimulation mode setting could significantly affect T and MCL and they must be readjusted based on the new settings.

During measurement, bursts of a 300 to 500 ms long pulse train are presented to 1 selected channel and the subject is asked to rank its loudness. The ranking can be based on a loudness chart labeled as “off,” “just noticeable,” “soft,” “medium loud,” “loud,” “comfortable loud,” and “too loud,” or on a rating scale between 0 (“off”) and 10 (“too loud”). The T level is usually measured prior to the MCL. Starting from a level of no sound, the pulse train amplitude is gradually increased until the patient reports that a barely noticeable tone. Alternatively, the measurement can begin with the presentation of a pulse train at a suprathreshold level, and its amplitude is decreased until the subject reports no sound is heard. To avoid overestimation or underestimation, the T level should be set after several runs of decreasing or increasing pulse train presentations. To set the MCL levels, a medium loud pulse train is presented at the beginning, and its amplitude is thereafter increased slowly until the subject perceives a tone at the most comfortable level. One caveat for the MCL measurement is to avoid overstimulation because it could cause an extremely loud sound and hurt the patient.

After setting each individual channel’s T and MCL, loudness balancing across all channels is recommended. A tone burst at either T or MCL can be played to all enabled channels sequentially. The T or MCL profile is adjusted for balancing loudness. For further confirming the tentative MCL setting, a sound processor can be activated for allowing the patient to listen to live speech sounds and judge the MCL setting. This functionality is known as “going live.” To avoid sudden loud sounds, sound volume should be turned down before going to live speech. Final adjustments of MCL are made according to the patient’s feedback.

The T and MCL can vary over time, particularly soon after the activation of a patient’s speech processor. During this period, adjustments of T and MCL should be done regularly to maximize clinical benefit. Besides the behavioral measurement of T and MCL as discussed above, another way of setting them is by collecting neural response data via the BT. Such an approach can be useful for babies and young children. In data collection, 1 intracochlear electrode is activated, and 2 surrounding intracochlear electrodes are set as recording electrodes to collect evoked potentials. Neural responses are amplified, averaged and then sent back to the speech processor. The strength of stimulation current on the activating electrode is gradually increased, and the amplitude of neural responses on neighboring electrodes can be used to predict the T level.
Adjusting Acoustic Parameters

Normal human hearing has a wide dynamic range of about 120 dB, whereas the input dynamic range of a sound processor usually is only 40 to 60 dB. Thus, an AGC is normally utilized to compress acoustic sounds, avoiding clipping of loud sounds and soft sounds. An AGC can apply higher gains to soft sounds, intermediate gains to medium-loud sounds, and lower gains to loud sounds. The sound levels of initiating gain changes are referred to as knee points. In clinical fitting, varying the knee points can benefit a patient wearing the implant in a variety of listening environments.

In acoustic signal processing, the most frequently used fitting parameters are the number of channels and their associated frequency allocation table. The channel number depends on the number of electrodes enabled, stimulation mode and the choice of coding strategy. When some electrodes are ineffective or disabled, the number of channels will be less. A filter bank relies on the frequency table to analyze input sounds. Most cochlear implants use a frequency table equally distributed on a logarithmic scale. For example, the corner frequencies of a 6-channel CI strategy’s table are 300, 460, 800, 1,385, 2,057, 2,800, 3,900, 4,500, and 5,500 Hz. The change of frequency table settings might depend on a patient’s listening preference, for example, speech or music.

Changing Sensitivity and Volume

Sensitivity setting changes the minimal sound level that a patient can hear and volume sets the loudness of a sound. A patient might wear the speech processor in quiet or loud listening environments. Proper setting of sensitivity provides benefits to a patient when listening to speech at different background noise levels. Figure 5 shows how the sensitivity and volume settings can affect the acoustic input and the electric output dynamic range. In this example, the maximal acoustic input of 90 dB SPL is mapped to the electric MCL, and the minimal acoustic input of 20 dB SPL is mapped to the electric T level. When sensitivity is decreased, the acoustic input range is moved upward, thus, in this example the T level is mapped to 30 dB SPL. When the sound volume is decreased, the maximal acoustic input at 90 dB SPL is mapped to a fraction (1/n) of the MCL. The loudness of the input sound is reduced by decreasing the electric output.

Mapping from acoustic sounds to electric currents is implemented by a nonlinear function, such as a logarithmic mapping curve. Some devices allow the choice of the mapping curve shape by changing 1 parameter related to the compression function.

All parameters or settings associated with a specific coding strategy are assembled and stored into 1 map. It lists the designated value of each parameter, as well as the patient’s identity and implant information. A map can also be customized to different listening environments, such as quiet or noise. Finally, a map is loaded to the patient’s speech processor via a programming cable between a computer and the speech processor. A speech processor can hold at least 3 maps tailored for different coding strategies, stimulation modes, or listening environments. A patient can switch among maps to obtain optimal listening performance with a cochlear implant.

SUMMARY

Following the surgical placement of a cochlear implant, intensive programming of the auditory prosthetic device is required to optimally send electric sounds to the brain. Speech coding strategies have been developed over 40 years to map acoustic sounds to electric currents. This chapter reviews most coding strategies in clinical use along with the history of cochlear implant design, development, and manufacture. The chapter focuses on the strategies that are currently being programmed in commercial devices as well as on how to perform cochlear implant programming in a clinical setting. Even though there is no best solution to program an implant, fitting a patient with a suitable coding strategy and optimal parameters can usually maximize patient performance.

Facial Paralysis
P. Ashley Wackym, MD
John S. Rhee, MD, MPH

Facial nerve abnormalities represent a broad spectrum of lesions, including numerous congenital and acquired causes. The patient who suffers from facial paralysis experiences not only functional consequences but also the psychological impact of a change in self-image and impaired communicative ability. In fact, a 1991 poll revealed that the level of discomfort that Americans felt on meeting those with facial abnormalities was second only to that associated with interacting with the mentally ill, and this discomfort far exceeded anxiety about encountering the senile, mentally retarded, deaf, blind, and those confined to a wheelchair.

**FACIAL NERVE ABNORMALITIES**

Table 1 summarizes the various causes of facial paralysis.

**Congenital**

**MÖBIUS SYNDROME (CONGENITAL FACIAL DIPLEGIA).** Möbius syndrome is a rare congenital disorder, which usually includes bilateral seventh nerve paralysis and unilateral or bilateral sixth nerve paralysis. Since the disorder was described, many authors have studied families with the syndrome. It is considered to have an autosomal dominant inheritance pattern with variable expressivity. The inheritance pattern is thought to be no higher than 1 in 50 in families in whom myopathies or other extremity anomalies such as clubfoot, arthrogryposis, or digital anomalies are not present.

The etiology of Möbius syndrome is unclear. Neuropathologic studies have noted that the nuclei of cranial nerves (CNs) VI, VII, and XII are abnormal, with lesser abnormalities being found in the nuclei of CNs III and XI. Other authors have reported that the facial nerves are smaller or absent at autopsy. Pitner and colleagues advanced yet another hypothesis based on their observation that normal facial nuclei were present on postmortem analysis; they suggested that there was a primary failure of facial muscle development. More recently, Cattaneo and colleagues characterized 2 groups of patients with Möbius syndrome. The first group was characterized by increased facial distal motor latencies and poor recruitment of small and polyphasic motor unit action potentials. The second group

</table>
was characterized by normal facial distal motor latencies and neuropathic motor unit action potentials. They hypothesized that in the first group, the disorder is due to a rhombencephalic maldevelopment with selective sparing of small-size motor units, and in the second group, the disorder is related to an acquired nervous injury during intrauterine life, with subsequent neurogenic remodeling of motor units. The authors speculated that these 2 different neurophysiologically defined phenotypes could be used to distinguish sporadic from inherited Möbius syndrome.

The clinical observation of congenital extraocular muscle paralysis and facial paralysis is the typical presentation of this disorder (Figure 1). No mass lesions will be found on magnetic resonance imaging (MRI). Ophthalmologic consultation and management are mandatory. Reinnervation procedures such as crossfacial grafts or hypoglossal–facial nerve anastomosis yield poor results, either owing to the paucity of motor end plates or the atrophic seventh nerves. Significant improvements of resting tone and voluntary animation can result from temporalis muscle transposition, which brings in a new neuromuscular system.

**Hemifacial Microsomia.** The term hemifacial microsomia refers to patients with unilateral microtia, macrostomia, and mandibular hypoplasia. Goldenhar syndrome (oculoauriculovertebral dysplasia) is considered to be a variant of this complex and is characterized by vertebral anomalies and epibulbar dermoids. Although approximately 25% of patients with hemifacial microsomia have facial nerve weakness, 1 patient with Goldenhar syndrome has been reported to have aplasia of the facial nerve.8

**Osteopetrosis.** Osteopetrosis is a generalized dysplasia of bone that may have an autosomal dominant or recessive inheritance pattern. The recessive form is more rapidly progressive and causes hepatosplenomegaly and severe neural atrophy secondary to bony overgrowth at neural foramina. Optic atrophy, facial paralysis, sensorineural hearing loss, and mental retardation are common in the recessive form, and death usually occurs by the second decade. However, in these severe cases of osteopetrosis, which were previously fatal, bone marrow transplantation has been reported to be of value.9

The dominant form causes progressive enlargements of the cranium and mandible and clubbing of the long bones. Increased bone density is seen radiographically. Progressive optic atrophy, trigeminal hypesthesia, recurrent facial paralysis, and sensorineural hearing loss are common. Complete decompression of the intratemporal facial nerve should be performed in patients with recurrent facial paralysis and radiographic evidence of osteopetrosis.

**Acquired**

**Trauma.** Approximately 90% of all congenital peripheral facial nerve paralysis spontaneously improves, and most can be attributed to difficult deliveries, cephalopelvic disproportion, high forceps delivery, or intrauterine trauma. These types of congenital facial paralysis are often unilateral and partial, especially involving the lower division of the facial nerve. Since these causes involve extratemporal compression, surgical exploration or bony decompression is not indicated.10

Blunt trauma resulting in temporal bone fracture is best evaluated with high resolution temporal bone computed tomographic (CT) scans (Figures 2 and 3). Temporal and parietal blows to the head may occur anywhere along a coronal arc, from the vertex to the cranial base. When the vector of force is directed toward the base, it classically passes toward the external auditory canal, deflects off the otic capsule, and extends antero-
medially along the anterior edge of the petrous bone to the foramen lacerum and foramen ovale. The resulting fracture is described as a longitudinal temporal bone fracture. This is the most common type of temporal bone fracture (≈ 90%) and is also the most common type of fracture associated with facial nerve injury. The geniculate ganglion region of the facial nerve is most frequently injured. The indications for facial nerve decompression and exploration are the same as those discussed in detail under the Bell palsy section of this chapter.

Frontal and particularly occipital blows to the head tend to result in transverse fractures of the temporal bone. More severe head injury is usually required to cause these fractures. Since they often extend through the internal auditory canal (IAC) or across the otic capsule, hearing loss and vertigo commonly result. Although only 10 to 20% of temporal bone fractures are transverse in orientation, they cause facial nerve injury in approximately 50% of patients. The anatomic region of the facial nerve most commonly injured is the labyrinthine segment. Ishman and Friedland recently compared traditional temporal bone classification systems with an expanded classification scheme. They found that traditional temporal bone fracture descriptions correlate poorly with clinical findings. However, they found that distinguishing petrous from nonpetrous involvement demonstrated significant correlation with the occurrence of serious sequelae of temporal bone fractures. They also found that radiographically based subcategories of mastoid and middle ear involvement further refined this classification schema to correlate with minor complications and concluded that this scheme better focused clinical resources and attention toward more likely sequelae.

Penetrating injuries to the extratemporal facial nerve should be explored urgently to facilitate identification of the transected distal branches using a facial nerve stimulator. If primary repair is not possible, the principles of facial nerve repair using cable grafts, described later in this chapter, should be followed. In infected wounds, urgent exploration and tagging of identified distal branches should precede control of the infection and granulation. Subsequent repair usually requires the use of cable grafts.

Facial nerve injury may occur with otologic surgery. The risk of injury of the facial nerve is particularly high in children with congenital ear malformations. Additional groups at higher risk for injury to the facial nerve include infants who are undergoing mastoid surgery since the mastoid tip has not become pneumatized and the facial nerve exits the stylomastoid foramen laterally. In these young children, a semihorizontal, curvilinear skin incision should be used, and, as is the case with all otologic surgery, a facial nerve monitoring system should be used.

Infection

Bacterial. Facial paralysis as a complication of otitis media has become rare in children owing to the ready access to medical care and antibiotics. Takahashi and colleagues published their series of over 1,600 patients with facial paralysis and found that only 11 of these patients were younger than 20 years old and had facial paralysis owing to otitis media (0.67%). They described the facial paralysis in this group of patients to have a slower progression and less complete paralysis than that seen in Bell palsy. Temporal bone CT should be performed in all patients to eliminate the diagnosis of coalescent mastoiditis. Intravenous antibiotics in combination with myringotomy and tympanostomy tube placement remain our initial management algorithms for bacterial otitis media complicated by facial paralysis. Bacterial cultures should always be obtained at the time of myringotomy, and antibiotic selection should be tailored to the culture results.

Facial paralysis complicating mastoiditis or cholesteatoma is also rare. In Sheehy’s series of over 180 children undergoing surgery for cholesteatoma, only 1 patient (0.5%) had facial nerve weakness. The surgical management of these patients includes mastoidectomy, excision of the cholesteatoma, and appropriate antibiotic therapy.

Infection with the spirochete Borrelia burgdorferi (Lyme disease) can result in facial paralysis. This tick-borne infection is endemic to the northeastern United States and is named for the town of Lyme, Connecticut. Widespread infections have been reported from the west coast, midwest, and east coast, as well as throughout Europe and Australia. As is the case with other spirochete infections, the clinical manifestations of Lyme disease are protean. Facial palsy can be found in Lyme disease and should be considered in children presenting with facial paralysis. Serologic diagnosis should be followed by antibiotic therapy. Tetracycline is considered to be the agent of choice; however, erythromycin and penicillin have been successfully used.

Viral. Ramsay Hunt Syndrome (Herpes Zoster Oticus). James Ramsay Hunt (1872–1937), an American neurologist, published his seminal article associating the clinical syndrome that now bears his name with herpetic inflammation of the geniculate ganglion. Critical to the development of this hypothesis was the publication of the pathologic studies of Head and Campbell in 1900, which advanced a new hypothesis regarding the etiology of herpes zoster. This work inspired Hunt to first postulate that the etiology of herpes zoster oticus was recrudescence of herpes varicella-zoster virus (VZV) in the geniculate ganglion. Clinically, Ramsay Hunt syndrome may have a variety of manifestations. However, the original 4 classifications of the disease by Hunt included (1) disease affecting the sensory portion of the CN VII, (2) disease affecting the sensory and motor divisions of the CN VII, (3) disease affecting the sensory and motor divisions of the CN VII with auditory symptoms, and (4) disease affecting the sensory and motor divisions of the CN VII with both auditory and vestibular symptoms.

Herpes zoster oticus is the cause of 2 to 10% of all cases of facial paralysis, including 3 to 12% of adults and approximately 5% of children. Patients may experience paresis or complete paralysis, with the poorest prognosis for recovery in the latter group. Approximately half of patients with Ramsay Hunt syndrome retain some facial motor disturbance; only a few maintain a complete paralysis.

Based on the sensory distributions reflected by the VZV recrudescence observed by Hunt over his career, the most common site of vesicular eruption is in the concha of the auricle (Figure 4). In addition, he described 3 other areas where vesicles can be found during herpes zoster oticus: a small strip of skin on the posteroserial surface of the auricle, the mucosa on the palate, and the anterior two-thirds of the tongue. In his final publication, he detailed the sensory distributions of the facial nerve associated with the geniculate ganglion that subserved the axonal transport of the recrudescent VZV to form the vesicles visible during Ramsay Hunt syndrome.

With the advent of gadolinium diethyleneetriamine pentaacetic acid (Gd-DTPA)-enhanced MRI, acute imaging of the facial nerve is possible throughout the clinical course of Ramsay Hunt syndrome. Despite histopathologic reports of diffuse inflammation along the entire intratemporal facial nerve in the disorder, Korcz and colleagues found that in 3 of the 6 patients with Ramsay Hunt syndrome who were studied with Gd-DTPA MRI, enhancement of the involved nerve was localized to the geniculate ganglion, labyrinthine segment, and the premeatal regions of the affected facial nerve, whereas there was no enhancement at all in the remaining 3 patients. Likewise, in none of their 6 patients did they find enhancement of the vertical or tympanic segments of the facial nerve. These findings suggest that in the early stages of the clinical syndrome, the majority of the inflammation is found near the geniculate ganglion, whereas in the later stages, as examined postmortem, the inflammation has extended...
throughout the intratemporal facial nerve. However, the senior author has seen diffuse enhancement of the facial nerve on MRI examination of patients with Ramsay Hunt syndrome (Figure 5).

Blackley and colleagues reviewed the histopathology associated with Ramsay Hunt syndrome in their 1 case and 5 others.29 Aleksic and colleagues added another histologic case.33 Payten and Dawes reviewed the pathologic studies of herpes zoster oticus with facial paralysis for a 60-year interval.34 Wackym and colleagues used a molecular approach to demonstrate the presence of VZV deoxyribonucleic acid (DNA) combined with traditional histopathologic techniques to the study of the temporal bones from 2 patients with Ramsay Hunt syndrome.32,35 The most consistent observation was diffuse inflammatory infiltration throughout the involved facial nerve; in addition, several investigators have shown lymphocytic infiltration of the geniculate ganglion, alteration of the geniculate ganglion somata, or both conditions.20,29,31–33 Based on the models of VZV and herpes simplex virus (HSV) latency and reactivation,36 these findings are expected. Unlike HSV, which remains dormant directly within sensory neuronal somata, VZV remains latent within the nonneuronal satellite cells surrounding each sensory neuronal somata. With rerudescence, the replication VZV virions are released from satellite cells into the extracellular matrix, where some are taken up by the sensory cell body and transported via the axons back to the skin or mucosa. This release of VZV into the extracellular matrix within the geniculate ganglion would cause an immune response that could result in inflammatory infiltrates throughout the intratemporal facial nerve. Therefore, the diffuse lymphocytic infiltration of the entire facial nerve remains consistent with Hunt’s hypothesis.1,12,34 Furuta and colleagues reported the distribution of VZV DNA in 11 (79%) of 14 trigeminal ganglia and in 9 (69%) of 13 geniculate ganglia collected at autopsy of adults.35 These data suggest that latent VZV in the geniculate ganglion is a common biologic phenomenon; however, the small sample size and the lack of clinical history regarding whether the patients experienced herpes zoster oticus during their lifetime necessitated confirmation of these observations with a much larger sample size of well-characterized patients. They have expanded this series recently.38

Other authors have suggested that Ramsay Hunt syndrome represents a cranial polyneuropathy.39,40 Care must be taken in interpreting the histopathologic findings in each case as some may represent cephalic zoster with neuritis of multiple CNs.36,40 Severe central neurologic deficits or multiple cranial motor neuropathies are well recognized in cephalic zoster.41,42

Surgical management with decompression of the facial nerve in Ramsay Hunt syndrome has been advocated by some authors (reviewed by Crabtree).21 Although the advent of facial electroneuronography (ENoG) has resulted in a better idea about which patients with facial paralysis have severe facial nerve injuries requiring surgical decompression,43 the diffuse inflammatory edema common in Ramsay Hunt syndrome has led most clinicians to avoid undertaking facial nerve decompression.

Experience with the use of intravenous acyclovir (Zovirax) during the acute presentation of Ramsay Hunt syndrome suggests that antiviral medications may facilitate recovery and minimize the morbidity associated with facial paralysis.7,35,44–46 This intravenous route has more inherent expenses than an oral route of administration. However, tissue levels of acyclovir delivered by an oral route are not high enough to treat varicella-zoster infections. Alternate antiviral agents such as valacyclovir (Valtrex) (1 g orally 3 times a day for 10 to 14 days) or famciclovir (Famvir) (500 mg orally 3 times a day for 10 days), which achieve adequate levels by an oral route, are now available as an alternative to intravenous acyclovir for the treatment of patients with Ramsay Hunt syndrome.27 Because the oral route is much more cost effective, this route is preferred. Likewise, oral corticosteroids have been advocated in patients with Ramsay Hunt syndrome.48

Bell Palsy: Bell palsy is responsible for 60 to 75% of all cases of facial paralysis. In the past, Bell palsy was defined as an “idiopathic facial paralysis” or as a mononeuropathy of undetermined origin. Recent observations have linked the cause to HSV 1.49,50 Burgess and colleagues, using polymerase chain reaction amplification, identified HSV 1 DNA in paraffin-embedded sections of the geniculate ganglion from a patient who died 6 days after the onset of Bell palsy.49 Furuta and colleagues found HSV DNA in 71% of geniculate ganglia and in 81% of trigeminal ganglia in 8 random autopsy specimens taken from adult cadavers.51 These data suggest that latent HSV in the geniculate ganglion may be a common biologic phenomenon; however, the small sample size and the lack of clinical history regarding whether the patients experienced Bell palsy during their lifetime necessitate confirmation of these observations with a much larger sample size of well-characterized patients. However, genetic, immunologic, vascular, entrapment, and other infectious causes have all been advanced in the etiology of Bell palsy.52

Bell palsy is an acute, unilateral paresis or paralysis of the facial nerve in a pattern consistent with peripheral nerve dysfunction (Figure 6). The onset and evolution are typically rapid, less than 48 hours, and the onset of paralysis may be preceded by a viral prodrome. The symptoms during the early phase of facial paralysis include facial numbness, epiphora, pain, dysgeusia, hyperacusis (dyscussis), and decreased tearing. The pain is usually retroauricular and sometimes radiates to the face, pharynx, or shoulder. Physical findings of this subtle polyneuritis include hypesthesia or dysesthesia of the CNs V and IX and of the second cervical nerve.53 Motor paralysis of branches of the CN X is seen as a unilateral shift of the palate or vocal cord paresis/paralysis.

Recurrence of Bell palsy occurs in 7 to 12%4,31 of patients. In the series of 140 patients with recurrent Bell palsy reported by Pitts and colleagues, ipsilateral recurrences were as common as development of contralateral Bell palsy.54 Also of note in this series was the observation that the incidence of diabetes mellitus was 2.5-fold greater than nonrecurrent cases.

Gadolinium-enhanced MRI has been advocated as a diagnostic tool in assessing Bell palsy. Gadolinium enhancement of the normal facial nerve does not occur. Therefore, enhancement of this structure would be due to increased extracellular fluid from edema, inflammation, or neoplasm. Our observations with gadolinium-enhanced MRI in Bell palsy, as well as those of others,28 are supportive of Fisch’s hypothesis of axoplasmic damming at the mental segment with subsequent edema and nerve conduction impairment (Figure 7).35 However, 1 study demonstrated that there was no prognostic significance of gadolinium enhancement of the facial nerve on MRI in patients with Bell palsy.24 Therefore, gadolinium-enhanced MRI is not indicated in every patient with facial paralysis. In patients suspected of having a tumor from clinical or electrodiagnostic data, gadolinium-enhanced MRI, along with high resolution CT of the IAC, fallopian canal, skull base, and parotid, should be performed.

Adour and colleagues examined the outcome of treating patients with Bell palsy with both acyclovir and corticosteroids in a prospective, randomized, double-blind trial.56 Half of the patients received a 10-day course of
oral acyclovir (400 mg five times per day) and prednisone. The control group received prednisone and a placebo. All study patients began treatment within 3 days of the onset of facial paralysis. The placebo–prednisone group had lower facial function recovery scores (House-Brackmann grade III or IV in 23%) and was almost 3 times as likely to have an unsatisfactory result as the acyclovir–prednisone group (only 7% of the acyclovir–prednisone group had a House-Brackmann grade III or IV). A more contemporary review concluded that the current evidence favors the combination of acyclovir and prednisone, if commenced within the first 72 hours of symptom onset.\(^{57}\) ENoG provides a quantitative assessment of facial nerve function and allows a relative comparison between the normal and affected sides and will be discussed in more detail later in this chapter. Our criteria for surgical decompression include ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side, and the operation within 14 days of onset.\(^{33,38,59}\) Decompression is limited to the meatal and labyrinthine segments through a middle cranial fossa approach.\(^{59-61}\) Fisch and Esslen, in 1972, were the first to propose that the most likely site for neural compression and conduction block in Bell palsy was at the entrance to the meatal foramen, the narrowest bony point through which the facial nerve passes.\(^{62}\) Interestingly, intraoperative evoked EMG documented the conduction block at this area in 94% of decompressed cases, and marked swelling proximal to this point was the typical observation.\(^{62,63}\) Gantz and colleagues published a prospective study in which a well-defined surgical decompression of the facial nerve was performed in a population of patients with Bell palsy who exhibited the electrophysiologic features associated with poor outcomes (ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side).\(^{59}\) Subjects who did not reach 90% degeneration on ENoG within 14 days of paralysis all returned to House-Brackmann grade I (\(n = 48\)) or II (\(n = 6\)) at 7 months after onset of the paralysis. Control subjects self-selecting not to undergo surgical decompression when >90% degeneration on ENoG and no motor unit potentials on EMG were identified had a 58% chance of having a poor outcome at 7 months after onset of paralysis (House-Brackmann grade III or IV [\(n = 19\)]). A group with similar ENoG and EMG findings undergoing middle fossa facial nerve decompression exhibited House-Brackmann grade I (\(n = 14\)) or II (\(n = 17\)) in 91% of the cases. It is recommended that these criteria and this surgical algorithm be followed.

**Other Viral Infections.** Other viral infections such as primary chickenpox, mononucleosis, mumps, and poliomyelitis can result in facial paralysis that may or may not resolve spontaneously. For these specific viral infections, immunization, when available, is the most effective preventive measure, and supportive care is required during the active infection. Facial reanimation procedures are sometimes required after adequate follow-up suggests that spontaneous recovery will not occur.

**Benign or Malignant Neoplasms**

Tumor involvement of the facial nerve should be considered in facial paralysis if 1 or more of the following clinical features are present: facial paralysis that progresses slowly over 3 weeks, recurrent ipsilateral facial paralysis, facial weakness associated with muscle twitching, long-standing facial paralysis (greater than 6 months), facial paralysis associated with other CN deficits, or evidence of malignancy elsewhere in the body.

Several benign and malignant tumors can involve the facial nerve along its intracranial, intratemporal, or extracranial course (Table 1). Schwannoma is the most common primary tumor of the facial nerve. It is benign and usually involves the labyrinthine, tympanic, and mastoid segments of the facial nerve. Nerve resection and interpositional nerve grafting may initially
be necessary for restoration of continuity. However, decompression will often give patients many years of facial nerve function before resection and grafting must be completed.

The use of radiographic imaging is indicated if the characteristics of the facial paralysis are suggestive of a neoplasm. Radiographic studies should include visualization of the entire course of the facial nerve, from the brainstem to the facial musculature. Gadolinium-enhanced MRI (Figure 8) is extremely useful in imaging solid tumors involving the facial nerve, and high resolution CT scans are useful in identifying bony erosion of the fallopian canal. Tumors may arise in the vicinity of the facial nerve and cause facial weakness either by compression or direct invasion. When the tumor is benign, the continuity of the facial nerve should be preserved at all costs by sharp dissection and mobilization techniques. This is appropriate management, whether the nerve is compromised in the IAC by an acoustic neuroma or in the parotid gland by a pleomorphic adenoma. A malignant process with direct invasion of the nerve usually mandates resection of the involved portion of the nerve with immediate interpositional nerve grafting. If the management of the disorder involves chemotherapy or radiation therapy rather than surgical intervention, facial reanimation procedures may be indicated if there is persistent facial nerve dysfunction. As shown in Figure 8, there are many regions of the facial nerve from which facial neuromas may arise. Likewise, the phenotypes can vary between solid, cystic, and linear. These factors underscore the need for individualized treatment plans, which may include surgical decompression, partial resection, resection and nerve grafting, and/or stereotactic radiosurgery.

**Hemifacial Spasm**

Hemifacial spasm is typically a disorder of the fourth and fifth decades of life and occurs twice as often in women as it does in men. Electrophysiologic and surgical observations indicate that the facial nerve hyperactivity in hemifacial spasm is caused by vascular compression of the facial nerve. Trigeminal neuralgia, hemifacial spasm, glossopharyngeal neuralgia, tinnitus, and disabling positional vertigo have all been associated with vascular compression. Microvascular decompression operations involve separating the compressive vessel from its point of contact with the CN root entry or exit zone and interposition grafting must be completed. The use of radiographic imaging is indicated if the characteristics of the facial paralysis are suggestive of a neoplasm. Radiographic studies should include visualization of the entire course of the facial nerve, from the brainstem to the facial musculature. Gadolinium-enhanced MRI (Figure 8) is extremely useful in imaging solid tumors involving the facial nerve, and high resolution CT scans are useful in identifying bony erosion of the fallopian canal. Tumors may arise in the vicinity of the facial nerve and cause facial weakness either by compression or direct invasion. When the tumor is benign, the continuity of the facial nerve should be preserved at all costs by sharp dissection and mobilization techniques. This is appropriate management, whether the nerve is compromised in the IAC by an acoustic neuroma or in the parotid gland by a pleomorphic adenoma. A malignant process with direct invasion of the nerve usually mandates resection of the involved portion of the nerve with immediate interpositional nerve grafting. If the management of the disorder involves chemotherapy or radiation therapy rather than surgical intervention, facial reanimation procedures may be indicated if there is persistent facial nerve dysfunction. As shown in Figure 8, there are many regions of the facial nerve from which facial neuromas may arise. Likewise, the phenotypes can vary between solid, cystic, and linear. These factors underscore the need for individualized treatment plans, which may include surgical decompression, partial resection, resection and nerve grafting, and/or stereotactic radiosurgery.

**Hemifacial Spasm**

Hemifacial spasm is typically a disorder of the fourth and fifth decades of life and occurs twice as often in women as it does in men. Electrophysiologic and surgical observations indicate that the facial nerve hyperactivity in hemifacial spasm is caused by vascular compression of the facial nerve. Trigeminal neuralgia, hemifacial spasm, glossopharyngeal neuralgia, tinnitus, and disabling positional vertigo have all been associated with vascular compression. Microvascular decompression operations involve separating the compressive vessel from its point of contact with the CN root entry or exit zone and interposition grafting must be completed. The use of radiographic imaging is indicated if the characteristics of the facial paralysis are suggestive of a neoplasm. Radiographic studies should include visualization of the entire course of the facial nerve, from the brainstem to the facial musculature. Gadolinium-enhanced MRI (Figure 8) is extremely useful in imaging solid tumors involving the facial nerve, and high resolution CT scans are useful in identifying bony erosion of the fallopian canal. Tumors may arise in the vicinity of the facial nerve and cause facial weakness either by compression or direct invasion. When the tumor is benign, the continuity of the facial nerve should be preserved at all costs by sharp dissection and mobilization techniques. This is appropriate management, whether the nerve is compromised in the IAC by an acoustic neuroma or in the parotid gland by a pleomorphic adenoma. A malignant process with direct invasion of the nerve usually mandates resection of the involved portion of the nerve with immediate interpositional nerve grafting. If the management of the disorder involves chemotherapy or radiation therapy rather than surgical intervention, facial reanimation procedures may be indicated if there is persistent facial nerve dysfunction. As shown in Figure 8, there are many regions of the facial nerve from which facial neuromas may arise. Likewise, the phenotypes can vary between solid, cystic, and linear. These factors underscore the need for individualized treatment plans, which may include surgical decompression, partial resection, resection and nerve grafting, and/or stereotactic radiosurgery.
Similarly, in a series of 116 patients with microvascular compression syndrome reoperated on after failure, Wilkins reported the identification of previously unseen arterial compression in 65.5%. Liao and colleagues discovered persistent vascular compression in 3 of 5 patients undergoing repeat microvascular decompression.

Although some have doubted that microvascular compression of a CN can represent the cause of hemifacial spasm, the literature indicates that the identification of an arterial vessel compressing the facial nerve in hemifacial spasm and subsequent decompression results in higher cure rates and decreased recurrences than when a specific artery is not identified. We believe that some microvascular decompression procedures fail because the offending vessel has not been identified at the primary operation. Some of these failures occur because the microscope provides incomplete information about the anatomic relationship between the nerves and vessels. The zero-degree endoscope provides a panoramic view of the cerebellopontine angle, and with angled endoscopes, provision for “looking around corners” is made. Magnan and colleagues used an endoscope in 60 patients with hemifacial spasm and demonstrated that with the operating microscope the offending vessel could be visualized in 28% of patients, whereas the endoscope was effectively employed in 93% of the same patients. We have advocated the adjunctive use of the endoscope in microvascular decompression surgery and believe that this will improve surgical outcomes.

Miscellaneous Disorders

The onset of simultaneous bilateral facial paralysis suggests Guillain-Barré syndrome, sarcoidosis, sickle cell disease, or some other systemic disorder. Guillain-Barré syndrome is a relatively common neurologic disorder and is an acute inflammatory polyradiculoneuropathy that progresses to varying degrees of paralysis. The etiology remains unknown; however, autoimmune or viral mechanisms have been considered. Classic histopathologic features of the syndrome include a lymphocytic cellular infiltration of peripheral nerves and destruction of myelin. The facial paralysis is typically bilateral and often resolves spontaneously after a prolonged course of paralysis. Although there is no role for surgical decompression of the facial nerve in this disorder, reanimation is only considered late in the course of the disease.

Melkerson-Rosenthal Syndrome. Melkerson-Rosenthal syndrome is a neuromucocutaneous disease with a classic triad of recurrent facial (labial) edema and recurrent facial paralysis associated with a fissured tongue. Patients with Melkerson-Rosenthal syndrome may not present with the complete triad, and although facial paralysis is the most commonly recognized neurologic symptom, it is not mandatory for the diagnosis. Headache, granular cheilitis, trigeminal neuralgiform attacks, dysphagia, laryngospasm, and a variety of CN and cervical autonomic dysfunctions may also occur. The patient with Melkerson-Rosenthal syndrome may present at any age and with any variety of classic and associated features, which may wax and wane. Approximately one-third of the patients have recurrent facial paralysis as part of their syndrome. The underlying etiologic factor has been thought to be a neurotropic edema causing compression and paralysis of the facial nerve as it passes through the fallopian canal. Since the anatomically most constricted area of the fallopian canal is the meatal foramen and because most prior reports observed recurrence after transmastoid decompression, Graham and Kemink elected to decompress the proximal segment in addition to the mastoid segment of the facial nerve in all such cases by performing a combined transmastoid and middle cranial fossa facial nerve decompression and neurolysis of the nerve sheath. The preliminary data presented by Graham and Kemink suggest that edema-tous involvement of the facial nerve in recurrent facial paralysis does occur intratemporally and that the recurrent paralysis can be prevented by transmastoid and middle cranial fossa total facial nerve decompression with neurolysis of the facial nerve sheath. Recurrent paralysis over a prolonged period of time usually results in increasing residual dysfunction. If evidence of residual paresis exists, facial nerve decompression of the labyrinthine segment and geniculate ganglion through a middle cranial fossa exposure is recommended at the time of the next episode of paralysis.

Surgical Anatomy of the Facial Nerve

Detailed knowledge and familiarity with the complex course of the facial nerve and its anatomic relationship to other vital structures are essential to the surgeon who plans to operate in this area. The facial nerve (CN VII) exits the brainstem at the pontomedullary junction approximately 1.5 mm anterior to the vestibulocochlear nerve (CN VIII). The facial nerve is smaller in diameter (approximately 1.8 mm) than the oval CN VIII (approximately 3 mm in the largest diameter). A third smaller nerve, the nervus intermedius, emerges between CN VII and CN VIII and eventually becomes incorporated within the sheath of CN VII. After leaving the brainstem, CN VII follows a rostralateral course through the cerebellopontine cistern for 15 to 17 mm, entering the porus of the IAC of the temporal bone (Figure 9). Other important structures in the cerebellopontine cistern include the anterior inferior cerebellar artery (AICA) and the veins of the middle cerebellar peduncle. The AICA passes near or between CN VII and CN VIII; the veins are more variable in position and number. On entering the IAC, the facial nerve occupies the anterosuperior quadrant of this channel for 8 to 10 mm. Then it enters the fallopian canal at the fundus of the IAC. The IAC is anterior to the plane of the superior semicircular canal (SSC). Superiorly, the bone overlying the IAC is within a 60° angle, whose vertex is the SSC ampulla. At the entrance of the fallopian canal (meatal foramen), CN VII narrows to its smallest diameter, 0.61 to 0.68 mm. Only the pia and arachnoid membranes form a sheath around the nerve at this point since the dural investment terminates at the fundus of the IAC. Many authors believe that the small diameter of the meatal foramen is an important factor contributing to the etiology of facial paralysis in certain diseases such as Bell palsy and Ramsay Hunt syndrome.

The intratemporal course of the facial nerve has three distinct anatomic regions: the labyrinthine, tympanic, and mastoid segments. The labyrinthine segment is shortest (≈ 4 mm),
NERVE INJURY AND NEURODIAGNOSTIC TESTS

Facial Nerve Histology

A connective tissue layer, the endoneurium, surrounds each myelinated axon (Figure 10). This layer is closely adherent to the Schwann cell layer of each axon. The importance of the endoneurial sheath, in the context of nerve injury and repair, is that it provides a continuous tube through which a regenerating axon can grow. The second layer of the nerve sheath is the perineurium. The perineurium provides tensile strength to the nerve. The perineurium is also the primary barrier to the spread of infection. The outermost layer is the epineurium. This layer contains the vasa nervorum, providing the blood supply as well as the lymphatic vessels.

Facial Nerve Injury

It is necessary to review the types of nerve damage to understand better electrodiagnostic testing of the facial nerve, prognosis for recovery, and the development of synkinesis, as well as the rationale for facial nerve decompression. Table 2 summarizes the Sunderland and Seddon classifications of nerve injuries. A facial nerve grading system has been established by the American Academy of Otolaryngology–Head and Neck Surgery (Table 3). The House-Brackmann scoring system was developed as a means of reporting facial recovery after facial nerve paralysis caused by idiopathic facial nerve paralysis or recovery after removal of an acoustic neuroma when an injury to the facial nerve had been sustained. Although this scale is useful when measuring facial nerve function in patients who have suffered an incomplete nerve injury (Sunderland degree I to IV (see Table 2)), it is inappropriate for assessing patients who have suffered Sunderland degree V injury and have undergone facial nerve repair or grafting.

Electromyography. Facial nerve EMG is important to use as an adjunctive tool when making decisions regarding surgery. Early in the time course of recovery, regenerating nerve fibers conduct at differing rates, producing dysynchrony, and, therefore, overestimate the degree of wallerian degeneration based on ENoG testing. In fact, it is possible to record “100% degeneration” with ENoG in patients with early recovery from Bell palsy while voluntary movement is observed. It is for this reason that a voluntary EMG is performed when the ENoG shows greater than 90% degeneration within 14 days of injury and surgical decompression is being considered. Needle electrodes are placed into the orbicularis oculi and orbicularis oris muscles, and the patient is asked to make voluntary contractions. If voluntary contractions occur during the first 2 weeks after the onset of paralysis, early debocking of the neural conduction block has taken place, and a good recovery of facial function will most likely follow. It is also important to keep in mind that ENoG is useful only during the acute phase of the injury, between days 3 and 21, and after complete loss of voluntary function. EMG is the more useful single diagnostic study after 3 weeks of facial paralysis. As will be discussed later in this chapter, EMG testing is also important when deciding whether to perform nerve substitution procedures and other reanimation procedures.

**General Principles in Facial Nerve Surgery**

Whenever the facial nerve is to be surgically exposed, several technical points must be observed. First, a system for monitoring facial nerve function during the operation should be employed. Historically, visual observation during critical stages of the operation was performed. However, the standard practice for essentially all otologists is to use intraoperative facial nerve EMG with placement of needle electrodes into the orbicularis oculi and orbicularis oris muscles.

Instrumentation is crucial to successful exposure of the facial nerve. The largest diamond bur that the operative site can safely accommodate should be used when the surgeon is near the fallopian canal. Cutting burs have the potential to catch and skip in an unpredictable way and can consequently cause severe injury to the nerve. Continuous suction-irrigation keeps the burs clean and also dissipates heat, which can induce neural damage.

Blunt elevators, such as the Fisch raspatory (Leibinger, Dallas, Texas), should be used to remove the final layer of bone over the nerve. These instruments are thin but strong enough to remove a thin layer of bone. Stapes curettes are too large and can cause compression injury to the nerve. If a neurolysis is to be performed, disposable micro-blades are available (Beaver No. 5910, BD Medical—Ophthalmic Systems, New Jersey). Sharp dissection is less traumatic than blunt elevation when the nerve must be lifted out of the fallopian canal. The medial surface of the population of facial nerve fibers would be sampled by recording the evoked response from this group of muscles. Needle electrodes are not used because intramuscular needle electrodes would not sample a sufficient number of motor units to yield the representative maximal amplitude. A supramaximal bipolar stimulation (galvanic) is provided to saturate the nerve and produce a complete and synchronous depolarization. The galvanic stimulation is typically delivered as rectangular pulses, with a pulse duration of 200 μs and an interpulse interval of 1 second. The amplitude of the evoked response is plotted as a function of time after stimulation. Both the normal and affected sides are tested, and the amplitude of the responses is compared. The percentage of degenerated fibers is calculated arithmetically, as follows:

$$\text{Percentage of degenerated fibers} = 100 - \left( \frac{\text{Amplitude of evoked response (in } \mu\text{V}) \text{ Normal side}}{\text{Amplitude of evoked response (in } \mu\text{V}) \text{ Affected side}} \times 100 \right).$$

This electrodiagnostic test depends on the physiologic premise of neural injury proposed by both Seddon and Sunderland (see Table 2). Injuries that are limited to producing a conduction block within the nerve (neurapraxia) do not disrupt axoplasmic continuity and will continue to conduct a neural discharge if the electrical stimulus is presented distal to the conduction block. With more severe injuries, axoplasmic disruption (axonotmesis) or neural tubule disruption (neurotmesis) will result in wallerian degeneration distal to the site of injury. Nerve fibers that undergo wallerian degeneration cannot propagate electrically evoked potentials distal to the injury. Axonotmesis, in contrast to neurotmesis, has a better prognostic outcome. With resolution of the neural injury, in a nerve that has undergone axonotmesis, the axon will regenerate through the intact neural tubule, potentially allowing complete return of motor function to the muscle fiber innervated by that nerve fiber. The more severely disrupted neural tubule injury of neurotmesis has the potential to regenerate in an unsuccessful manner and can thereby result in misdirection of fibers, clinically causing synkinesis and incomplete return of motor function. ENoG can be used to differentiate nerve fibers that have minor conduction blocks (neurapraxia) from those that have undergone wallerian degeneration; however, ENoG cannot differentiate the type of wallerian degeneration (axonotmesis versus neurotmesis). The severity of the injury can be inferred from the rate of degeneration after injury. More rapid wallerian degeneration is associated with neurotmesis, whereas nerves that degenerate more slowly are more likely to exhibit axonotmesis.43,58,59

The timing for performing ENoG should take into consideration the time course of wallerian degeneration. With a known complete transection of the facial nerve (eg, traumatic injury), 100% wallerian degeneration occurs over 3 to 5 days as the distal axon slowly degenerates. Therefore, early testing, within 3 days of paralysis, may not be representative of the degree of injury, and as outlined above, the time course of degeneration may reflect the degree of injury. An important technical detail to be attentive to is the need to stimulate the nerve at the stylomastoid foramen 10 to 20 times before making an amplitude measurement. The initial stimulation will improve the synchronization within the nerve and therefore improve the reliability of the test.

As discussed earlier in this chapter, our criteria for surgical decompression include ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side, and the operation within 14 days of onset.43,58,59 Decompression is limited to the meatal and labyrinthine segments through a middle cranial fossa approach.59-61

Gantz and colleagues published a prospective study in which a well-defined surgical decompression of the facial nerve was performed in a population of patients with Bell palsy who exhibited the electrophysiologic features associated with poor outcomes (ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side). Subjects who did not reach 90% degeneration on ENoG within 14 days of paralysis all returned to House-Brackmann grade I (n = 48) or II (n = 6) at 7 months after onset of the paralysis. Control subjects self-selecting not to undergo surgical decompression when >90% degeneration on ENoG and no motor unit potentials on EMG were identified had a 58% chance of having a poor outcome at 7 months after onset of paralysis (House-Brackmann grade III or IV (n = 19)). A group with similar ENoG and EMG findings undergoing middle fossa facial nerve decompression exhibited House-Brackmann grade I (n = 14) or II (n = 17) in 91% of the cases. It is recommended that these criteria and this surgical algorithm be followed.
nerve usually adheres to the bone and contains a rich vascular supply. Cauterization near the nerve should be performed only with an irrigating bipolar electrocautery, low current, and insulated microforceps.

**Middle Cranial Fossa (Transtemporal) Approach: Internal Auditory Canal Porus to Tympanic Segment**

The middle cranial fossa exposure is used to expose the IAC and labyrinthine segment of the facial nerve when hearing preservation is a goal.61,87 The geniculate ganglion and tympanic portion of the nerve can also be decompressed from this approach.

**Technique.** The patient is placed supine on the operating table with the head turned so that the involved temporal bone is upward (Figure 11A). The hair is shaved 6 to 8 cm above and anterior to the ear and 2 cm posterior to it. The surgeon is seated at the head of the table with the instrument nurse at the anterior side of the patient’s head. A 6 cm × 8 cm posteriorly based trapdoor incision, or a preauricular incision, is marked in the hairline above the ear (Figure 11B). If exposure of the mastoid is necessary, the inferior limb of the incision above the ear is elevated (Figure 11A). If exposure of the mastoid is necessary, the inferior limb of the incision can be carried postauricularly (Figure 11B, dashed line). The skin flap is elevated to expose the temporalis muscle and fascia. A 4 cm × 4 cm temporals fascia graft is harvested for use during closure of the IAC dural defect. Alternatively, Alloderm (LifeCell Corp., Woodlands, TX) can be used. An anteriorly based trapdoor incision is used to elevate the temporals muscle and periosteum (see Figure 11B, thin line). Staggering the levels of the muscle and skin incisions provides for a double-layer, watertight closure at the completion of the procedure. If exposure of the mastoid is not necessary, a preauricular incision is often used (Figure 11C).

The temporal root of the zygoma is exposed during elevation of the temporals muscle. This landmark represents the level of the floor of the middle fossa. Dural fishhooks are placed in the skin and temporals muscle flaps for retraction. A 3 cm × 5 cm bone flap for facial nerve decompression, or a 4 cm × 5 cm bone flap for tumor excisions, centered above the temporal root of the zygoma is fashioned with a medium-cutting bur (3 mm). It is important to keep the anterior and posterior margins of the craniotomy parallel to facilitate placement of the self-retaining retractor.

Branches of the middle meningeal artery are occasionally embedded within the inner table of the skull; therefore, elevation of the bone flap must be performed in a controlled manner. Bipolar coagulation and bone wax may be necessary to control bleeding. Elevation of the dura from the floor of the middle fossa can be one of the most difficult steps. Blunt dissection and magnification greatly facilitate dural elevation. The dura is elevated from the posterior to anterior direction to prevent accidental injury to an exposed geniculate ganglion and greater superficial petrosal nerve. Bipolar coagulation is used to coagulate dural reflections within the petrosquamous suture before transection with scissors.

The elevation proceeds until the petrous ridge is identified medially and the arcuate eminence, mental plane, and greater superficial petrosal nerve are exposed anteriorly. No attempt is made to identify the middle meningeal artery and accompanying troublesome bleeding veins. The tip of a self-retaining retractor (Fisch, Leibinger) is placed at the petrous ridge anterior to the arcuate eminence and medial to the meatal plane (Figure 12). A medium diamond bur (2 to 3 mm) and a suction irrigation apparatus are used to identify the blue line of the SSC. A preoperative Stenvers projection radiograph helps to determine the level of the SSC in relation to the floor of the middle fossa and the degree of pneumatization above the SSC (Figure 13).

Drilling begins posterior to the arcuate eminence over the mastoid air cells until the dense yellow bone of the otic capsule is identified. Otic capsule bone is slowly removed until the blue outline of the SSC is seen. The IAC is located by removing bone with a 60° angle anterior to the blue line of the SSC and with the vertex based at the SSC ampulla. This dissection is continued until approximately 180° of the IAC are exposed for facial nerve decompressions (see Figure 12) or 270° of the IAC are exposed for schwannomas. Because of the close proximity of the SSC and the basal turn of the cochlea, only approximately 120° of the circumference of the IAC can be safely removed in its lateral 5 mm or so. The facial nerve occupies the anterosuperior portion of the IAC.

Laterally, the vertical crest (Bill bar) marks the division between the superior vestibular nerve and the meatal foramen containing the facial nerve. The entrance to the fallopian canal is the narrowest, most delicate portion of the facial nerve and consequently the most challenging portion of the dissection. At the meatal foramen, the facial nerve turns anterior and slightly superior. The basal turn of the cochlea can be within 1 mm inferiorly, and the ampulla of the SSC can be directly posterior to the nerve. The labyrinthine segment is followed to the geniculate ganglion. If the facial nerve needs to be exposed distal to the geniculate ganglion (eg, with facial neuromas or with some traumatic injuries to the facial nerve), the tegmen tympani is removed with care to avoid injury to the head of the malleus and incus. The tympanic segment is easily seen to turn abruptly posterior; it is followed to where it courses inferior to the lateral semicircular canal. It is advisable to leave a thin shell of bone covering the nerve until its entire course is identified. Small blunt elevators are used to remove the final layer of bone. The nerve is tightly confined within the labyrinthine segment of the fallopian canal; larger curettes should be avoided to prevent compression injury. If the nerve is to be decompressed, a neurolysis is the final step. A disposable microscalpel (Beaver No. 5910) is used to slit the periosteum and epineural sheath.

Alternative methods to locate the facial nerve may be necessary, especially in traumatic cases. The greater superficial petrosal nerve can be traced posteriorly to the geniculate ganglion, or the tegmen tympani may be fractured and the tympanic segment visible through the fracture. The tympanic segment is then used to locate the geniculate ganglion and labyrinthine segments.
At the end of the procedure, a free temporalis muscle graft is placed within the IAC and a corner piece of the bone flap is fashioned to cover the defects in the tegmen tympani and IAC (Figure 14). Alternatively, titanium mesh (Synthes Maxillofacial, Paoli, PA) between layers of Alloderm can be used. This prevents herniation of the temporal lobe into the middle ear or IAC. The temporalis fascia previously harvested is placed over the free bone graft to help seal the dural defect at the IAC. The craniotomy defect is then repaired using titanium mesh (Synthes Maxillofacial) and hydroxyapatite cement (Norian CRS, Synthes, Inc., West Chester, PA), and the temporalis muscle is closed with interrupted absorbable sutures. The skin is closed in layers with particular care in closing the galea. No drain is placed. A mastoid-type pressure dressing is applied.

**Advantages and Uses.** The middle cranial fossa route is the only method that can be used to expose the entire IAC and labyrinthine segment with preservation of hearing. This, in combination with the retrolabyrinthine and transmastoid approaches, enables visualization of the entire course of the facial nerve and still preserves function of the inner ear. The middle cranial fossa technique is the most commonly used for decompression of the facial nerve in Bell palsy55,61 and longitudinal temporal bone fractures. However, as described earlier in this chapter, this approach may be useful in the management of patients with schwannomas of CN VII or CN VIII, as well as with patients with Melkersson-Rosenthal syndrome.

**Postoperative Care/Complications and their Management.** The anatomy of the floor of the middle cranial fossa is quite variable and presents some difficulty in identification of landmarks. The Stenvers projection radiograph provides important anatomic information regarding the degree of pneumatization above the SSC and should be performed in all cases to minimize the risk of surgical injury to the SSC. In addition, the surgeon must have a precise knowledge of 3-dimensional anatomy of the temporal bone. Many hours in a temporal bone dissection laboratory are required to attain the delicate microsurgical skills that are necessary for this type of surgery.

Middle cranial fossa facial nerve decompression can result in conductive and/or sensorineural hearing loss. Conductive hearing loss can be secondary to temporal lobe herniation or ossicular disruption during dissection in the attic.

**Figure 12** Surgical view of the right middle cranial fossa exposure after craniotomy, temporal lobe retraction, and bony exposure are complete. (A) Placement of the retractor with exposure of the arcuate eminence and greater superficial petrosal nerve. (B) The facial nerve, cochlea, and labyrinth within the temporal bone are shown ghosted beneath the bone as viewed through the middle cranial fossa approach. (C) Drilling of the IAC for facial nerve decompression. (Reproduced with permission; copyright © 2007 P. A. Wackym.)

**Figure 13** Stenvers projection radiograph demonstrating the anatomic variation of pneumatized air cells beneath the floor of the middle cranial fossa and the superior semicircular canal (arrow). (Reproduced with permission; copyright © 1995 P. A. Wackym.)

**Figure 14** Reconstruction following right middle cranial fossa facial nerve decompression. Temporalis muscle is placed within the internal auditory canal (IAC) surgical defect to fill the dural and bony defect at the conclusion of the facial nerve surgical decompression. Temporalis fascia or Alloderm (LifeCell Corp., Woodlands, TX) is placed over the floor of the middle cranial fossa and muscle graft. A free bone graft or titanium mesh (Synthes Maxillofacial, Paoli, PA) is placed perpendicular to the axis of the IAC to prevent herniation of the temporal lobe onto the facial, cochlear, and vestibular nerves. Temporalis fascia or Alloderm is then used to seal the temporal lobe dura and cover the bone graft or titanium mesh. (Reproduced with permission; copyright © 2007 P. A. Wackym.)
A free bone graft, as already described, prevents temporal lobe herniation. Sensorineural hearing loss can result from direct injury to the inner ear by the drill exposing the cochlea or semicircular canals or from transtorial injury by the drill striking an ossicle. Should the SSC be entered during the surgical dissection, the fenestration should be immediately occluded with bone wax. Injury to the internal auditory vessels within the IAC can also result in loss of inner ear function. Loss of vestibular function can occur by the same mechanisms.

Postoperative intracranial complications including meningitis, temporal lobe edema, and epidural hematoma formation are possible. Perioperative antibiotics administered over 48 hours are recommended. Fluid restriction and dexamethasone (Decadron) are used for the first 3 days postoperatively to minimize temporal lobe edema following intraoperative retraction. In addition, our longer craniotomy flap decreases the amount of temporal lobe retraction required for complete exposure of the IAC and fallopian canal. With adequate intraoperative hemostasis using the bipolar cautery, oxidized cellulose (Oxycel or Surgicel, Ethicon, Inc., Somerville, NJ), and dural tacking sutures, we have never had a clinically significant postoperative epidural hematoma develop.

 Leakage of cerebrospinal fluid (CSF) must be avoided to prevent meningitis. All exposed mastoid air cells must be obstructed with bone wax. A temporalis muscle-free graft is placed into the superior aspect of the IAC to separate the posterior fossa from the extradural floor of the middle cranial fossa. Temporalis fascia or AlloDerm is then used to provide a second layer of closure between the posterior fossa and the extradural middle fossa. Meticulous care must be taken to ensure that there are no dural dehiscences overlaping the temporal lobe through which CSF may drain. If these are identified, a temporalis fascia, muscle, or AlloDerm patch must be used to repair the dural tears to prevent CSF leaks. After a three-layer watertight closure of the temporals muscle, galea, and scalp, a mastoid-type dressing is applied daily for 5 days postoperatively. Should CSF leakage persist, a temporary lumbar drain is placed, and the patient is kept at bed rest. If the CSF leakage does not resolve within 5 to 7 days after placement of the lumbar drain, reexploration of the surgical field is indicated to identify and seal the area of CSF egress.

Uncontrolled bleeding or injury to the AICA poses the most serious complication during the operation; however, this is extraordinarily rare. The middle cranial fossa approach does not provide adequate access to the entire cerebellopontine angle. The AICA and accompanying veins can loop into the IAC. Control of bleeding of these vessels may require a suboccipital exposure. Injury to the AICA results in brainstem and cerebellar infarction of a variable degree, depending on its size and the area of its terminal arterial supply.

NERVE REPAIR

Whenever the continuity of the facial nerve has been disrupted by trauma, iatrogenic injury, or tumor invasion, every effort should be made to restore its continuity. In some instances, an end-to-end reapproximation can be accomplished, but if any tension occurs at the anastomotic site, an interposition nerve graft has a better chance of providing facial movement. All nerve repair techniques produce synkinesis, but sphincteric function of the mouth and eye is usually restored. Newer microsuture techniques and instrumentation should be employed to enhance return of function.

In general, the injured ends of the nerve should be freshened at a 45° angle. Experimental evidence has shown that cutting the nerve at this angle exposes more neural tubules and improves regrowth of the nerve.85,88 In addition, a fresh razor blade induces less crush injury to the nerve than a scalpel blade or scissors does. We have found that the perineurium of CN VII does not hold 9-0 sutures, and attempting to suture it increases trauma to the neural tubules. Removing a portion of the epineurium before suturing prevents connective tissue growth at the anastomotic site. If the epineurium is cleaned from the end of the nerve for approximately only 0.5 mm, sutures can still be placed in the epineurium for reapproximating the nerve segments. Three or 4 9-0 nylon sutures are placed with jeweler’s forceps or longer instruments (19 cm microforceps) for anastomosis in the cerebellopontine angle. The epineurium, 2 or 3 sutures are placed (Figure 15).

When an interposition graft is required, the greater auricular and sural nerves are the preferred graft donor sources. The greater auricular nerve is readily available near the operative field and is a small area of sensation to the lateral lower leg and foot. The sural nerve has many branches that can be used to reconstruct the branching pattern of the facial nerve. There is little discomfort from removing the sural nerve since it provides only a small area of sensation to the lateral lower leg and foot. The sural nerve is found immediately posterior to the lateral malleolus, along the saphenous vein. The graft should be 10 to 20% larger in diameter than the facial nerve and long enough to ensure a tension-free anastomosis.

FACIAL REANIMATION PROCEDURES

Contemporary strategies for management of patients with facial paralysis have been a product of a gradual evolution of past clinical successes and failures over the past century. The surgeon must consider the functional and cosmetic goals of reconstructive surgery, as well as the patient’s desires, expectations, and motivations. Functional deficits include incomplete eye closure, speech difficulties, oral incompetence, and nasal airway obstruction. The cosmetic deficiencies of facial asymmetry and dysmorphism can be emotionally devastating for some patients. It is the achievement of facial balance and muscle coordination that continues to be the more challenging and elusive goal.

Management of Upper Third of the Face

Eye Care. Protection of the eye is paramount (Figure 16). It is necessary to protect the cornea from foreign bodies and drying. Dark glasses should be worn during the day, artificial tears instilled at the slightest evidence of drying, and a bland eye ointment used during sleep. Patients who demonstrate a poor Bell phenomenon or have trigeminal nerve deficits are particularly at risk for corneal damage. Taping of the eye closed is not usually recommended, but early-exposure keratitis may require patching or, rarely, a tarsorrhaphy. A formal ophthalmologic examination is recommended prior to any surgical intervention.

Eyebrow. Ptosis of the eyebrow can have functional and cosmetic consequences. In the elderly patient, the functional loss of the frontalis and orbicularis oculi muscles is compounded by the loss of tissue elasticity and decrease in the bulk of the subcutaneous tissue. This can lead to significant brow ptosis and hooding of the upper eyelid, which may cause lateral visual field compromise.

The 2 most commonly used procedures to correct brow ptosis are the midforehead lift and the direct brow lift. Both procedures require direct skin and subcutaneous tissue excision, followed by suspension of the orbicularis oculi muscle to the frontal bone periosteum. Slight overcorrection is needed as the brow position will settle during the next few weeks. The endoscopic approach for cosmetic browlifting is not commonly used owing to the severity of the brow ptosis associated with the complete loss of frontalis muscle function. However, there have been some recent reports of successful outcomes using a modified endoscopic browlift technique.1,89 These techniques are sometimes combined with the use of a biodegradable brow stabilization device (ENDOTINE Forehead; Coapt Systems Inc. Palo Alto, CA).90

Upper Eye Lid. Historically, tarsorrhaphy had been the standard of care in patients with facial paralysis. Today, this procedure should be reserved for only those patients with a severe risk for exposure keratitis or those who have failed upper eyelid reanimation procedures. The most commonly used procedure is the insertion of a prosthetic, specifically a gold weight implant or a palpebral wire spring.

In experienced hands, the palpebral wire spring can produce excellent results, affording the capability of mimicking, to some extent, the spontaneous blink. However, the insertion of the palpebral wire spring is technically more difficult, with a higher reported extrusion and infection rate. In addition, these springs often need postoperative adjustment for optimal function.1

Gold weight implantation is a relatively simple procedure that is highly successful, well tolerated by patients, and easily reversible if facial muscle function returns (Figure 17). The ideal candidates for gold weight placement are those with the following factors: some existing ability to lower the upper lid, good Bell phenomenon, normal corneal sensation and tearing, prominent supratarsal lid crease, and nonprotruding eyes.

Prefabricated gold weight implants come in weights ranging from 0.8 to 1.6 g. Custom weighting can be requested, if needed. All patients should be correctly sized by taping different size weights to the eyelid in an upright position. The largest weight allowing eyelid closure without causing more than slight lid ptosis should be chosen; the most common weights are 1.0 and 1.2 g. The patient should be informed that the weights are often not helpful when lying supine. In fact, eyelid closure may be worse in some cases owing to the weight of the implant pulling the eyelid open when supine. Eye care, as described above, should be continued following the reanimation procedure.

After selecting the proper size implant, the procedure is performed under local anesthesia. An incision is made along the supratarsal fold down to the orbicularis oculi muscle. Sharp scissors dissection is carried down through the muscle to the tarsal plate. Dissection is continued inferiorly over the surface of the tarsal plate to within 3 mm of the lash line. An exact pocket is made for the implant to be placed just slightly medial to the center of the pupil. The gold weight is then inserted and suture fixated to the tarsus using 6-0 clear prolene sutures. The incision is closed in layers, 6-0 chromic suture for the levator aponeurosis/orbicularis muscle layer and 6-0 fast gut suture for the skin.

The most common problems associated with gold weight implantation are lid underclosure, excessive lid ptosis, and implant extrusion. The reported extrusion rate in the literature is greatly varied, from as low as 1% to as high as 43%.1,91,92 The risk of implant extrusion can be minimized by meticulous surgical technique and proper patient selection. Removal of the implant is performed once facial nerve function has returned; however, the gold weight can also be used as a permanent means to achieve eye closure.

Lower Eye Lid. The goals for lower lid management are to improve lower lid margin approximation to the globe, correct ectropion, and maximize the efficiency of the tear drainage system. Lid-tightening procedures must not disturb the delicate inter-face between the lacrimal punctum and the globe. A lateral traction test, simulating a lid-tightening procedure, will demonstrate the effect of the procedure on lid position and the displacement of the punctum. As a general rule, up to one-eighth of the lid can be resected without disturbing the relationship of the inferior punctum to the globe. If the lateral traction test indicates excessive punctum displacement (greater than 2 mm) or does not provide proper lid support, then alternative or adjunctive surgical procedures are indicated. Excessive punctum lateralization indicates medial canthal tendon laxity, thus indicating the necessity for a medial canthoplasty. If further elevation of the lower lid is needed, then “spacer” grafts (palate mucosa, conchal cartilage) are used to provide vertical height to the eyelid.

Lower lid-tightening procedures include the Bick procedure, tarsal strip, and midlid wedge resection. The Bick procedure is our procedure of choice for lower lid tightening. The procedure involves resecting a lateral wedge of the lower lid, developing a tongue of tarsus, and resuturing the lateral edge of the lid to the lateral orbital rim (Figure 18). The procedure allows for fine adjustment of the tension on the lower lid by resecting a precise amount of tissue. Care must be taken not to overshorten the lower lid, creating a hammock effect, with the lower lid actually bowing down under the globe.

Management of Lower Two-Thirds of the Face

The ultimate goal in treatment of the lower two-thirds of the face is to create symmetric, mimetic movement of the facial musculature. The best chance for this outcome is with primary repair of the facial nerve, with or without nerve interposition grafting. However, primary nerve repair is
not always possible, and alternative procedures must be entertained. The choice of procedure is dictated by a number of factors including duration of paralysis, prognosis of the underlying illness, concomitant CN deficits, comorbid medical conditions, and the patient’s wishes and motivations.

Role of Electromyography in Planning Facial Reanimation Procedures. The degree of motor end-plate degeneration and prognosis for spontaneous recovery of the facial nerve can be assessed with EMG. The presence of normal or polyphasic action potentials at 1 year following facial nerve injury portends a favorable outcome, and no reanimation procedures are indicated. If fibrillation potentials are found, this indicates intact motor end plates but no evidence of reinnervation. This finding supports the use of a nerve substitution procedure to take advantage of the potential neurolized tone and movement of the intrinsic facial musculature. Electrical silence obtained from EMG indicates complete denervation and atrophy of the motor end plate. Neurotized reanimation procedures are contraindicated, and other reanimation procedures should be entertained.

Nerve Substitution Procedures. Nerve substitution procedures are indicated when primary facial nerve repair is not possible. In addition, the following conditions are required for these procedures: intact proximal donor nerve, intact distal facial nerve, and viable motor end-plate function. Although these procedures provide facial tone and resting symmetry, they do not restore involuntary, independent mimetic facial expression. However, the majority of patients do achieve some voluntary facial movement with rehabilitation. The most commonly described nerve substitution procedures are the XI–VII crossover, VII–VII crossed, VII–VII crossover, and XII–VII jump graft.

The XI–VII procedure (accessory to distal facial nerve) has largely been abandoned owing to the morbidity of loss of trapezius muscle function. The VII–VII crossed grafting involves linking a functional branch of the facial nerve on the nonparalyzed side to a division of the facial nerve on the paralyzed side by using a long interposition nerve graft (sural, medial antebrachial cutaneous) (Figure 19). The disadvantages of this procedure include the sacrifice of a portion of the normal facial function on the contralateral side, a long interval for innervation (9 to 12 months), and a lack of substantial neural “firepower” owing to the relatively few number of axons grafted. Theoretically, the advantage of this technique is the possibility of symmetric, mimetic movement. Disappointing results from several investigators have made this procedure less appealing.

Hypoglossal–facial (XI–VII) crossover is most appropriately performed for complete and permanent facial paralysis up to 2 years after injury (Figure 20). This situation may arise following radical parotidectomy, temporal bone resection, skull base surgery, severe temporal bone trauma, or cerebellopontine angle tumor resection. An EMG finding consistent with viable motor end plates of the facial muscles is a prerequisite for surgery. Poor candidates for the XII–VII crossover include patients with multiple lower CN deficits. Sacrifice of the hypoglossal nerve may not be well tolerated and compensated for in the presence of other cranial neuropathies.

Improved facial tone and symmetry occur in 90% of patients following XII–VII anastomosis.1 The results are more impressive in the midface and less in the frontal and lower portions of the face. The return of muscle tone is seen within 4 to 6 months following neurorrhaphy, with better results seen in earlier repairs.94 Voluntary facial movements follow with progressive improvements over the next 1 to 2 years. True spontaneous facial expressions are rare, although through motor sensory reeducation, patients may develop spontaneous animation with speech.

Pensak and colleagues, in their series of 61 cases of XII–VII crossover, rated their results as excellent in 3%, good in 39%, fair in 49%, and poor in 10% of patients.95 Conley and Baker, in their series of 122 cases, reported good or excellent results in 65%, fair in 18%, and poor in 17%.94 They also noted better results in those patients who underwent “immediate” repair (<2 years) than in those who were “delayed” (≥2 years).

Synkinesis, hypertonia, and hemilingual atrophy are all noted deficiencies of the classic XII–VII crossover. Most studies report minimal disabling sequelae owing to loss of unilateral hypoglossal function unless concomitant ipsilateral CN deficits exist.

The XII–VII jump graft technique was devised by May and colleagues to offset some of the above noted disadvantages of the classic XII–VII crossover.96 The procedure entails placing an interpositional nerve graft between a partially transected hypoglossal nerve trunk, distal to the hypoglossal ascendens, and the distal facial nerve trunk (Figure 21). Several authors have reported functional results comparable to the XII–VII crossover; however, the problems of hypertonia and mass facial movements have not been encountered.96,97 Kartush and Lundy further modified this approach with anastomosis to only the lower division of the facial nerve, thereby reducing potential synkinesis.98 Figure 22 represents an example of an excellent outcome of a patient who underwent a XII–VII jump graft technique 3 months after a large facial neuroma resection with facial nerve sacrifice at the skull base. The patient was able to obtain symmetric resting tone of the facial muscles with some voluntary motion of the lower two-thirds of the face with subtle tongue movement.

Muscle Transposition Procedures (Dynamic). Regional muscle transposition can provide dynamic reanimation of the mouth in patients with long-standing facial paralysis (over 2 years). It is indicated for patients with congenital facial paralysis (Möbius syndrome) or when facial nerve grafting or nerve substitution techniques are contraindicated. It can also be performed in conjunction with facial nerve grafting or nerve substitution procedure in select cases to augment results. The temporalis muscle is most commonly used because of its length, contractility, and favorable vector of pull. Masseter muscle transposition can be useful following radical parotid surgery or when the temporalis muscle is not available.
Temporalis Muscle Transposition. The temporalis is a fan-shaped muscle arising from the temporal fossa. The motor branch of the trigeminal nerve innervates it, and branches off the internal maxillary artery provide its blood supply. Preoperative evaluation includes the assessment of the function and strength of the temporalis muscle.

To perform a temporalis muscle transposition procedure, the temporalis muscle and fascia are both exposed by extending a modified facelift incision into the parietal region of the scalp (Figure 23). The pretragal incision is carried down to the subdermal region, above the superficial musculoaponeurotic system of the face. A tunnel is created from the zygomatic arch in a subdermal plane between the temporal fossa and the cheek-lip crease incision (adult) or the oral commissure incision (children). The lateral portions of the zygomatic arch can be burred down to reduce the bulging appearance of the muscle at this fulcrum incision into the parietal region of the scalp (Figure 23). The pretragal incision is carried down to the subdermal region, above the superficial musculoaponeurotic system of the face. A tunnel is created from the zygomatic arch in a subdermal plane between the temporal fossa and the cheek-lip crease incision (adult) or the oral commissure incision (children). The lateral portions of the zygomatic arch can be burred down to reduce the bulging appearance of the muscle at this fulcrum.

Figure 22 (Top left and right) Preoperative views of patient at rest and smiling with complete right facial nerve paralysis following skull base surgical resection of a large facial neuroma. (Bottom left and right) Two year postoperative views at rest and smiling following insertion of a 0.8 g gold weight to the right upper eyelid and a hypoglossal–facial interpositional nerve graft technique as shown in Figure 21. Approximately one-third of the hypoglossal nerve was sectioned, distal to the hypoglossal descendens. The nerve graft was sewn end to side with the hypoglossal nerve and end to end with the facial nerve. Patient has normal tongue movement and function. (Reproduced with permission; copyright © 2007 P. A. Wackym.)

Figure 23 Temporalsis muscle transfer for lower face reanimation. (A) Dotted lines indicate the lip–cheek and temporal incisions. (B) Midportion of the temporalis muscle is harvested. (C) Temporalis muscle pulled through subcutaneous cheek tunnel into the lip–cheek incision. (Reproduced with permission; copyright © 2007 P. A. Wackym.)
point. Only the midst portion of the temporalis muscle is used. A portion of the periorbitalis is dissected with the muscle and its fascia to create additional length. The muscle is then transposed over the zygomatic arch, through the subcutaneous tunnel, and into the lip–cheek incision. The muscle–fascia–periorbitalis complex is sutured to the orbicularis oris muscle near the submucous layer of the corner of the mouth. Additional sutures are placed from the muscle to the subdermal layer of the upper aspect of the lip–cheek incision to accentuate the lip–cheek crease. Overcorrection is necessary for an optimal final result. The depression in the temporal area is corrected by rotating the remainder of the temporalis muscle into the deficient area. The redundant facial skin is resected as in a facelift, and wounds are closed in layers. Two closed suction drains and a compressive dressing are used for 48 hours postoperatively.

Ideally, the overcorrection of the lateral oral commissure and lip–cheek crease will resolve by 3 to 6 weeks. The results of the transposition should be evident by 4 to 6 weeks, with the patient able to produce a broad smile by tensing the temporalis muscle. Complications include infection, hematoma, and seroma. The most common reasons for failure of the procedure are inadequate overcorrection and suture dehiscence at the orbicularis oris–temporalis muscle interface.99

Suspension Procedures (Static). Static suspension procedures are indicated for those patients who are not candidates for nerve substitution or dynamic reanimation procedures. These procedures can provide permanent support, or, in cases in which reinervation of the facial muscles is expected, static procedures can provide temporary or additional support until reinervation of the facial muscles is complete. A variety of materials are available for static suspension procedures, ranging from autografts (palmaris longus tendon, fascia lata tendon) to alloplastics, such as Gore-Tex (GORE S.A.M., WL Gore & Associates Inc., Flagstaff, AZ) and acellular human dermis (AlloDerm).100,101 The choice of material is dependent on patient factors and desires, as well as the surgeon’s preference and experience.

The static suspension procedure is most often used to lateralize the corner of the mouth and lip–cheek crease. The procedure is similar in approach to the temporalis muscle transposition. The autograft or allograft is placed in a subcutaneous tunnel from the lip–cheek crease to the zygomatic arch. In cases in which reinervation of the facial muscles is expected, it is important not to injure the deeper facial nerve branches when creating the tunnel. Sutures are used to secure the graft to the orbicularis oris muscle and lip–cheek incision, whereas wires or screws are used for anchoring at the zygomatic arch (Figure 24).

A separate local suspension can also be performed to lateralize the nose in cases of alar valve compromise. The nasal base is exposed with incisions along the alar–nasal and nasolabial creases. An allograft or autograft is then sutured to the deep aspect of the nasal base. The nasal base is then pulled laterally to its desired position. After the periosteum of zygomaticomaxillary buttress is exposed, the other end of the graft is fixated to the bone with a screw.

Innervated Free Muscle Transfer

The ideal indication for innervated free muscle transfer is in the patient with Möbius syndrome, for whom both facial nerve and musculature are not available. It is also indicated as an alternative to regional muscle transfers or static procedures in patients with long-standing facial paralysis (>2 years). It is usually performed as a two-stage procedure in which an initial cross-facial nerve graft is combined with a subsequent free muscle transfer (most commonly, gracilis or serratus anterior).102 Alternatively, the innervated free flap may be grafted to the hypoglossal nerve, performed as a single-stage procedure.103

In select patients, this procedure provides the possibility for dynamic, mimetic movement that cannot be achieved by static procedures. The disadvantages, however, are manifold, including donor site morbidity, risk of vascular thrombosis, lengthy operative time, long interval for reinnervation, and muscle bulkiness.

NEUROMUSCULAR FACIAL RETRAINING TECHNIQUES

For patients who have experienced some recovery of facial nerve function, and also for those patients who experience synkinesis, neuromuscular facial retraining therapy is an important treatment modality. These techniques can be applied before and after reanimation procedures to optimize outcome. In general, these techniques can be used to address loss of strength, loss of isolated motor control, muscle tension hypertonicity, and/or synkinesis. This method combines techniques such as patient education in basic facial anatomy, physiology, and kinesiology; relaxation training; sensory stimulation; EMG biofeedback; voluntary facial exercises with mirror feedback; and spontaneously elicited facial movements.104–106

CHEMODENERVATION

The use of botulinum toxin for chemodenervation of synkinesis muscles has greatly aided in the treatment of patients who suffer from hypertonicity, spasms, and symptomatic fasciculations due to facial nerve regeneration.107 The muscles that are most frequently injected are the obicularis oculi, zygomaticus major, mentalis, corrugator, and platysma. In some instances, the contralateral unaffected facial muscles are selectively weakened in order to achieve better facial symmetry. Dosages average 2.5 to 5 units per injection with Botulinum toxin Type A (Botox, Allergan, Irvine, CA).

SUMMARY

The etiology and pathogenesis of several disorders that produce facial paralysis have been reviewed. Likewise, the diagnostic methods and algorithms that are used to make decisions regarding medical versus surgical management in acute facial paralysis have been summarized. Anatomy
and surgical principles were highlighted and treatment alternatives for reanimation or neurovascular facial retraining outlined.

History of Neurotologic Skull Base Surgery

Skull base anatomy is complex and may be affected by a wide variety of pathology. Historically, surgical access posed a challenge; and, therefore, the earliest surgical efforts did not take place until the later part of the nineteenth century, after the introduction of anesthesia. It became obvious that the most direct approach to certain inaccessible intracranial tumors was through the skull base rather than through the calvarium. The transtemporal approach to the cerebellopontine angle (CPA) was initially proposed by Panse in 1904; and attempted by Borchardt in 1905 and Quix in 1911. At the time, the absence of effective imaging modalities allowed considerable growth of the lesions prior to diagnosis, rendering initial surgical approaches too deep and narrow to resect large tumors effectively. In addition, effective closure against cerebrospinal fluid (CSF) leakage and atraumatic removal of bone surrounding neural and vascular structures had yet to be achieved. Therefore, in the first half of the twentieth century, surgeons avoided the complexity of the skull base and preferred the simpler solution of working through the thin calvaria, despite the fact that injurious degrees of brain retraction were often required.

In the 1960s, William House and others utilized modern operating microscopes and high-speed drills to resurrect a number of skull-base approaches that had previously been abandoned as impractical. Contemporary skull-base surgery defined itself during the 1980s, with the advent of high-resolution multiplanar imaging (computed tomography (CT) and magnetic resonance imaging (MRI)), improved microsurgical instruments and optical systems, and neurophysiologic monitoring.

The term skull base surgery is somewhat of a misnomer, as very few surgical procedures are presented. An overview of other, less common skull base neoplasms will also be achieved. Therefore, in the first half of the twentieth century, surgeons avoided the complexity of the skull base and preferred the simpler solution of working through the thin calvaria, despite the fact that injurious degrees of brain retraction were often required.

In the 1960s, William House and others utilized modern operating microscopes and high-speed drills to resurrect a number of skull-base approaches that had previously been abandoned as impractical. Contemporary skull-base surgery defined itself during the 1980s, with the advent of high-resolution multiplanar imaging (computed tomography (CT) and magnetic resonance imaging (MRI)), improved microsurgical instruments and optical systems, and neurophysiologic monitoring.

The term skull base surgery is somewhat of a misnomer, as very few surgical procedures are actually carried out to treat pathology intrinsic to the skull base. In reality, the majority of neurotologic skull base procedures are performed for lesions located beneath the cerebral cortex or adjacent to the brainstem, and the removal of bone allows exposure while minimizing cerebral and cerebellar retraction.

RELEVANT ANATOMY

The skull base refers to the floor of the cranial cavity and is composed of the ethmoid, sphenoid, and occipital bones, as well as the paired frontal and temporal bones. It is divided into anterior, middle, and posterior fossae. This chapter will focus on the posterior fossa which is bordered by the clivus anteriorly, the posterior surface of the petrous portion of the temporal bone laterally, and the occipital bone posteriorly. An axial view of the skull identifying the mastoid, petrous apex, CPA, and clivus is shown in Figure 1.

The CPA is a fluid-filled space of the lateral cistern. It is bordered by the posterior surface of the temporal bone anteriorly, the anterior surface of the cerebellum posteriorly, the inferior olive medially, the inferior border of the pons and cerebellum superiorly, and the cerebellar tonsil inferiorly. The facial (VII) and vestibulocochlear (VIII) nerves course laterally through the CPA toward the porus acusticus and internal auditory canal (IAC). The trigeminal nerve (V) is located superiorly and the lower cranial nerves (IX, X, XI) are located inferiorly (Figure 2). The vascular anatomy in the area includes the anterior inferior cerebellar artery (AICA), posterior inferior cerebellar artery (PICA), internal auditory artery, and superior cerebellar artery (Figure 3). The IAC contains the facial nerve anterosuperiorly, cochlear nerve anteroinferiorly, and the vestibular nerves posteriorly. These are separated by the vertical crest and transverse crest as shown in Figure 4.

The petrous portion of the temporal bone is pyramidal in shape, with anterior, posterior, and inferior surfaces. The petrous apex is the most medially located portion of the temporal bone. The anterior surface forms a portion of the middle cranial fossa, and the posterior surface marks...
the anterolateral extent of the posterior fossa. The lateral extent of the petrous portion is demar-
cated by the inner ear and intratemporal carotid
artery. Medially, the posterior surface ends at
the petroclival and petrooccipital synchondroses,
where it abuts the clivus. The clivus is located in
the midline and is formed from the basal portion
of the occipital bone (basioocciput) and the basi-
sphenoid (Figure 5).

The jugular foramen lies inferiorly at the junc-
tion of the petrous portion and the occipital bone.
Traditionally, the jugular foramen is described as
having a posterior vascular compartment, pars
venosa, and an anterior neural compartment, pars
nervosa, which are separated by a fibrous or bony
bridge connected to the jugular spine. In reality,
each of these compartments has both neural and
vascular elements. The pars venosa contains the
glossopharyngeal nerve (IX) and the inferior petrosal
sinus (Figures 6 and 7).6

DIFFERENTIAL DIAGNOSIS

Skull base tumors may be classified either
by pathology or according to anatomic loca-
tion. These tumors involve the skull base either
through primary growth, direct extension from
adjacent sites, or by metastatic spread. They may
be derived from endoderm, ectoderm, mesoderm,
or neuroectoderm. Table 1 lists the most common
skull base lesions by anatomic location.

EVALUATION

Signs and Symptoms

Skull base neoplasms may affect numerous ana-
tomic subsites resulting in diverse clinical pre-
sentations. A general overview of symptoms and
signs are presented in Table 2. These clinical
signs can be organized based upon cranial nerves
affected, brainstem and cerebellar compression,
hydrocephalus, and direct invasion of structures.
Symptoms specific to each disorder will be dis-
{

Audiologic and Vestibular Testing

All patients with a suspected skull base lesion
should undergo pure tone and speech audiom-
etry to establish the level of auditory function.
Audiometry is a cost-effective screening tool
to guide the acquisition of further studies, such as
auditory brainstem responses (ABR) or imaging.
Preoperative hearing levels are useful in guiding
surgical approach (hearing conservation versus
nonconservation) and can have prognostic value
when a hearing conservation approach is being
considered. ABR testing can also be used as a
screening tool to facilitate a diagnosis and to esti-
mate the probability of hearing preservation.

Vestibular testing, including electronystag-
mography (ENG) test battery, rotary chair test-
ing, and dynamic posturography, may be useful
in evaluating patients with balance disturbance.
However, such testing does not have the specific-
ty to diagnose skull base lesions, therefore it is
of all intracranial tumors arise in the CPA. In a series of 1,354 CPA tumors treated in a neurotologic practice, the following accounted for 98% of lesions: vestibular schwannomas (91.3%), meningiomas (3.1%), epidermoids (2.4%), nonvestibular schwannomas (1.4%), and arachnoid cysts (0.5%). Vestibular schwannomas (VS) usually arise within the IAC and appear as ovoid or cylindrical structures filling the canal. These lesions enlarge into the CPA as rounded masses giving a typical “ice-cream cone” appearance, where the ice cream represents the CPA component and the cone the IAC and enlarged porus acusticus. As the VS enlarges, the CPA component often takes an ovoid configuration with the long axis parallel to the posterior petrous wall.

Schwannomas are typically isointense to brain on T1-weighted images, display intense enhancement with gadolinium, and constitute a “filling defect” in surrounding hyperintense CSF on T2-weighted images (Figure 8). These lesions may have heterogeneous enhancement secondary to nonenhancing microcystic and macrocystic components within the tumor. They are occasionally associated with adjacent arachnoid cysts (0.5%). They may also rarely exhibit enhancement of immediately surrounding dura, a finding termed a “dural tail,” or pseudomeningeal sign. Meningioma is the lesion most likely to be mistaken for a VS (Table 4). Other relatively common lesions of the CPA that can mimic VS include epidermoid cysts, arachnoid cysts, and facial nerve schwannomas (FNS). Epidermoid and arachnoid cysts can easily be differentiated from VS as they do not demonstrate solid enhancement. FNS confined to the CPA and IAC may be indistinguishable from VS. However, tumor extension into the labyrinthine segment of the Fallopian canal, as manifested by enlargement or enhancement, can be a helpful distinguishing factor between the two entities.

Meningiomas have 3 morphological growth patterns: (1) hemispherical or “mushroom cap” appearance, with a broad-base parallel to the petrous bone (75%); (2) plaque-like (en plaque) with bone invasion or hyperostosis (20%); and (3) ovoid or globular, mimicking VS (5%). Meningiomas are usually eccentric to the porus acusticus, rarely penetrate or erode the IAC, and often extend superiorly into the middle cranial fossa. On MRI, they are typically isointense to gray matter on T1W and T2W images; however, relative hypo- or hyperintensity of the lesion to gray matter on T2 may signify internal fibrous or vascular composition, respectively.

Meningiomas demonstrate avid enhancement with gadolinium (Figure 9). A dajcent dural thickening, known as the dural tail or meningeal sign, is found in 60% of cases and usually represents reactive thickening rather than neoplastic change. CT may reveal internal calcifications in 25% of cases. Hyperostosis of adjacent osseous structures, although rare, can be a reliable indicator of meningioma.

Epidermoid cysts commonly occur in the posterior fossa and tend to expand into areas of low resistance. Therefore, they often insinuate into various cisterns and have irregular margins that are scalloped or “cauliflower-like.” They tend to engulf cranial nerves and cisternal vessels. On M R, they tend to be hypointense on T-1-weighted and hyperintense on T2-weighted images (usually isointense to CSF). Rarely, “white epidermoids” may display reversed signal characteristics with a high T1 and low T2 signal. Epidermoids do not demonstrate solid enhancement; slight rim-enhancement can occasionally be seen. A rachnoid cysts are similar to epidermoids in terms of their T1 and T2 signal characteristics, however they have smooth borders, do not insinuate, and tend to displace surrounding nerves and vessels rather than engulf them. Diffusion-weighted MR imaging is beneficial in the differentiation of epidermoid cysts (high signal) from arachnoid cysts (low signal).

Mastoid and Petrous Apex. Petrous pyramid effusions, mucocelles, and cholesterol granulomas are the most commonly encountered radiographic abnormalities in the petrous apex and are thought to represent points along a continuum of pathology. Incidental petrous apex effusions are...
often mistaken for disease with a variable T1-weighted signal and a high T2-weighted signal. They are easily distinguished from pathology on CT scan as the air-cell opacification is nonexpansile and lacks bone destruction. Mucoceles are typically dark on T1-weighted images, bright on T2-weighted images, and have peripheral rim enhancement. Due to their predominantly high T2-weighted signal and a high T2-weighted signal. Mucoceles are typically dark on T1-weighted images, bright on T2-weighted images, and have peripheral rim enhancement. Due to their predominantly hemorrhagic content, cholesterol granulomas are typically bright on both T1-weighted and T2-weighted images. Mucoceles or cholesterol granulomas should be differentiated from solid tumors, which demonstrate central enhancement. Less common lesions of the petrous apex include solid neoplasms, infectious processes, and osseous entities. Solid lesions of the petrous apex include metastasis, plasmacytoma, and endolymphatic sac tumors. These lesions often cause bone destruction and demonstrate variable degrees of central enhancement on postcontrast imaging. A unique feature of endolymphatic sac tumors is the presence of intralobational calcifications in the retrolabyrinthine area along the posterior semicircular canal. Petrous apicitis is also destructive and reveals coalescence of the air cells on CT scan; on gadolinium-enhanced MRI, there is often enhancement of the petrous apex, surrounding dura, Meckel cave, and affected cranial nerves. Bony lesions including fibrous dysplasia, Paget disease, and osteoradionecrosis should also be considered in the differential diagnosis of temporal bone lesions.

discussed above. Pituitary macroadenomas can have plaque configuration or have an en plaque growth pattern; their imaging characteristics have been described above. Pituitary macroadenomas can cause expansion of the sella with typically smooth bony expansion. However, once the tumor has transgressed the bone, the lesion may mimic a clival malignancy. Nasopharyngeal carcinomas can also invade the clivus via the petroclival and petrosphenoidal fissures, and evidence of radiologic abnormalities of the nasopharynx must be diligently sought when evaluating a lesion involving the clivus.

**Jugular Foramen.** Paragangliomas (glomus tumors) are common lesions affecting the jugular foramen (glomus jugulare) and the middle ear (glomus tympanicum). The radiographic differentiation of these subtypes is straightforward when the lesions are small and remain confined to their site of origin. However, differentiation can be more complex in larger tumors. Erosion of the lateral bony plate of the jugular fossa favors the diagnosis of a glomus jugulare. CT imaging of glomus jugulare tumors reveals destructive changes to the lateral part of the jugular foramen, with possible involvement of the carotid artery and descending facial nerve. The vascular nature of these tumors results in a “salt and pepper” appearance on T1-weighted MRI images: bright foci represent slow blood flow and dark foci represent high velocity flow voids (Figure 11). There is intense enhancement with contrast on both CT and MRI scans. Magnetic resonance venography (MRV) is useful to determine the patency and involvement of the sigmoid sinus.

Adapted from reference 7.
Jugular foramen schwannomas (JFS) arise from cranial nerves IX, X, and XI. These lesions involve the medial portion of the jugular foramen, grow vertically along the course of the affected cranial nerves, and assume a fusiform or dumbbell shape. In contrast to paragangliomas, there is a smooth, sharply margined enlargement of the jugular foramen on CT scan. These lesions are hypointense on T1-weighted images and bright on T2-weighted images and enhance homogenously with gadolinium.

Jugular foramen meningiomas have imaging characteristics discussed above. They may be differentiated from paragangliomas by the presence of calcifications, hyperostosis, and dural tails.

Facial Nerve. FNS commonly affect the geniculate ganglion and may affect multiple segments of the nerve. They are typically fusiform, tubular masses with smooth bony margins on CT. On MRI, they are hypointense on T1-weighted images, hyperintense on T2-weighted images, and display homogeneous enhancement. Facial nerve hemangiomas, also known as ossifying hemangiomas, most commonly occur at the geniculate ganglion. In contrast to schwannomas, they have irregular bony margins on CT and display a “honeycomb” bone matrix. The MRI signal characteristics are similar between these two lesions, however hemangiomas tend to be more heterogeneous with low signal foci secondary to the ossified matrix. Further discussion regarding facial nerve tumors is found in Chapter 34, “Facial Paralysis.”

CEREBELLOPONTINE ANGLE

Vestibular Schwannoma

Introduction. In neurotologic practice, VS represents the most common skull base neoplasm and a substantial amount of time is spent in both its diagnosis and treatment. These tumors have a wide range of clinical presentations and may be managed with a diverse array of treatment options. As the care for VS has evolved, patients may expect increasingly favorable outcomes.

Epidemiology. Vestibular schwannomas represent approximately 6% of all intracranial tumors and up to 90% of all lesions in the CPA.21 There is no significant racial or gender predilection. The overall incidence of VS based on population studies from Denmark, Canada, and a US HMO appears to be between 10 and 13 per million people.22-24 Occult VS has also been a topic of interest, with an autopsy series in 1936 suggesting that the prevalence may be as high as 2.5% in the general population.25 Further studies, however, have revealed that this estimate is likely several orders of magnitude too high, as this prevalence would suggest that millions of Americans have occult VS, and the incidental finding of a VS on MRI would be quite common. In the era of gadolinium-enhanced MRI scans, less than 2% of VS patients were found to be completely asymptomatic26 and a retrospective review of 46,414 patients found only nine with incidentally discovered VS.27 The prevalence of occult VS is, therefore, approximately 2 in 10,000 adults.
and myelin production. As it exits the brainstem, which may be related to eighth nerve anatomy.

It is recommended that vestibular schwannoma be adopted as standard terminology.

In 1992, an NIH Consensus Development conference recommended that vestibular schwannoma be adopted as standard terminology.

The vast majority of VS arise within the IAC, which may be related to eighth nerve anatomy and myelin production. As it exits the brainstem, the proximal eighth nerve is histologically more similar to central rather than peripheral nervous tissue. Therefore, its myelin is produced by oligodendroglial cells. Distally, its composition is more typical of peripheral nerves, with its myelin being produced by Schwann cells. The transition zone between this “central” and “peripheral” myelin, or the glial-schwannian junction, is known as the Obersteiner-Redlich zone. Traditionally, it has been proposed that VS arise from this region, possibly due to a higher density of Schwann cells in this location. Recent literature, however, has suggested that VS actually occur lateral to this transition zone and not from Schwann cells at the transition zone itself. The location of this transition zone varies considerably, but it is thought to occur in the vicinity of the vestibular (Scarpa) ganglion. There have been contradicting studies as to whether the superior or inferior vestibular nerve is more commonly the nerve of origin. Current opinion favors equal incidence from the superior and inferior divisions of the vestibular nerve.

The genetic basis of VS has been derived from NF2 patients and the specific defect has been mapped to chromosome 22. This gene is believed to be a tumor-suppressor gene, and both copies of the gene are required to be dysfunctional to develop a tumor. NF2 patients are born with 1 defective copy and only require 1 more mutation for tumorigenesis. Sporadic cases, however, require 2 spontaneous mutations which is a rare event; this is also known as the “double hit” mechanism for tumor production. The role of the gene product, known as merlin, is unclear, but recent studies indicate that it may exert its activity by inhibiting phosphatidylinositol 3-kinase.

Tumor Pathology. Grossly, the surface of a VS is typically smooth, regular, and has pronounced vascularity. The color ranges from yellow-tan to pale gray (particularly when cystic components are present). Internally, the tumor is quite heterogeneous with textures that range from soft and friable to firm and rubbery. Traditionally, these tumors have been described as encapsulated, but recent evidence reveals that they are surrounded by a very thin layer of connective tissue rather than a true capsule and that neoplastic Schwann cells extend to the tumor’s margin.

The histopathology of VS reveals 2 distinct morphologic patterns. Antoni type A describes densely packed cells with small, spindle-shaped, densely staining nuclei. Antoni type B refers to a loose arrangement of vacuolated, pleomorphic cells, which seem to occur predominantly in larger tumors with cyst formation. A whorled or palisading appearance of Antoni A cells is known as a Verocay body. A summary of the key pathologic features of VS are given in Table 5.

Nearly all VS are benign, and although malignant degeneration of benign VS has been described, it is exceedingly rare.

Growth Characteristics. VS are benign slow-growing tumors. They enlarge primarily through...
cellular proliferation although cellular hypertrophy may play a small role. Rapid expansion can occasionally occur secondary to cystic degeneration or intratumoral hemorrhage and lead to acute neurological deterioration. Tumor involution can also be seen when cystic areas spontaneously decompress or tumors outgrow their blood supply. Caution should be taken when comparing lesion size on serial imaging studies, as apparent tumor involution may be due to variations in technique and quality.

The growth of VS may be considered to occur in 4 anatomic stages: intracanalicular, cisternal, brainstem compressive, and hydrocephalic (Figure 12). VS typically originate in the IAC and are considered to be intracanalicular until they protrude into the CPA cistern. At this point, they enter the cisternal stage, in which they progressively displace CSF, AICA, and cranial nerves VII and VIII. The brainstem compressive stage begins when the tumor contacts the lateral pontine surface. At this point, cranial nerve V can become affected. The hydrocephalic stage begins when the fourth ventricle is effaced secondary to brainstem compression. Table 6 summarizes the various stages and their associated symptoms.

Improved measurement of the growth rate of VS has recently been made possible with the advent of serial imaging with high-resolution MRI and CT scans. In a meta-analysis of 13 studies and 571 tumors, the mean growth rate was found to be 0.18 cm per year, with 54% of patients showing radiologic growth over an average of 3 years.37 In the patients with growing tumors, the average growth rate was 0.4 cm per year, and in those requiring intervention, the rate was 0.59 cm per year. Approximately 10 to 15% of lesions are considered fast-growing with a growth rate greater than 1 cm per year.38,39 One must be cautious before assuming that a large percentage of VS will remain stable over the long term. First, the patients being chosen for observation in these studies may represent those with a more indolent course, thereby introducing a selection bias. Second, these slow-growing tumors may not show significant growth when followed for only 3 years, whereas their growth may become apparent if they were followed over the long term, for example, 10 or 20 years. Finally, methods used to measure tumor size remain somewhat inexact, making comparison difficult.

Unfortunately, there is still no universally accepted method of measuring VS. Most authors advocate measuring the maximal CPA component of the tumor in 3 axes: (1) parallel to the petrous ridge on an axial image, (2) perpendicular to the petrous ridge on an axial image, and (3) vertically on a coronal image. Many have simplified this to the single largest measurement in the axial plane. Unfortunately, due to the irregular geometry of VS, these measurements do not necessarily reflect tumor size, and computerized volumetric measurements are likely to replace diameter-based measurements in the future.

**Clinical Presentation.** Although the classic presentation of VS includes progressive unilateral sensorineural hearing loss, tinnitus, and disequilibrium, clinicians must be aware that these lesions can present with a variable array of symptoms. The natural progression of these symptoms based on tumor size is summarized in Table 6. Historically, the relative frequencies of various symptoms have changed with the evolution of improved imaging modalities, which has allowed earlier diagnosis. This evolution of symptom frequencies is outlined in Table 7.

**Hearing Loss.** Hearing loss is the most common symptom of VS, occurring in over 85% in cases, and is also the most frequent initial symptoms for which patients seek medical attention.26 It is typically unilateral and, in its initial stages, involves the high frequencies. Patients will often complain of poor clarity as word recognition is affected out

From reference 7.
of proportion to pure tone hearing loss. Clinicians must be aware that in the MRI era, recent series have reported up to 15% of patients had subjectively normal hearing, although only 4% were audiometrically normal. In addition, asymmetry was not always present as 7% of patients had an audiometrically symmetric hearing loss.

Complicating the clinical diagnosis even further, up to 26% of patients with VS complain of one or more episodes of sudden hearing loss which is typically ascribed to different causes. As 1 to 2% of patients with sudden hearing loss will ultimately have a VS, we recommend imaging in all patients with a sudden hearing loss to rule out this possibility.

Tinnitus. Tinnitus is a frequent symptom of VS occurring in over half of patients. The tinnitus is typically constant, high pitched, and localized to the affected ear, however it may have variable qualities and be nonlocalizing. Patients with VS may also have unilateral tinnitus in the absence of subjective hearing loss, therefore further evaluation for VS should be considered in these individuals.

Vertigo, Disequilibrium, or Dysmetria. VS can affect both the peripheral and central vestibular system, therefore patients may present with a variety of complaints relating to their balance. Vertigo, defined as the illusion of motion, is surprisingly infrequent in VS. This is likely due to the slow destruction of vestibular function, which allows central adaptation to occur. When present, vertigo typically occurs from small tumors, affecting ears in which considerable vestibular function remains. The sensation of motion often resolves within several days to weeks. Disequilibrium is the continuous sense of instability, which is often secondary to an uncompensated peripheral vestibular disturbance and/or cerebellar compression. Unlike vertigo, this symptom is quite common in VS, often progressive, and associated with larger tumors (>3 cm) in the brainstem compression stage. Large tumors can present with dysmetria and truncal ataxia from brainstem compression stage. Large tumors can present with dysmetria and truncal ataxia from brainstem compression, clinically manifested by ipsilateral hypertensive deep tendon reflexes, hemiplegia, or hemiparesis.

Trigeminal Nerve Dysfunction. Trigeminal dysfunction typically presents as midface hypesthesia or parathesia and eventually progresses to involve other divisions of the face. As the tumor enlarges, anesthesia also occurs. Trigeminal symptoms typically occur in the brainstem compressive stage when the trigeminal nerve becomes stretched and compressed superiorly. The corneal reflex is nearly always decreased or absent in these patients, and this sign may precede any sensory facial disturbance. Facial pain from VS has been described in larger tumors and is treated in the same manner as its idiopathic form (tic dououreux).

The motor portions of the trigeminal nerve are much more resistant to compressive effects, therefore motor dysfunction is limited to a small percentage of advanced cases of VS. When present, it often manifests as unilateral temporal wasting, masseter atrophy, and secondary malocclusion.

Facial Nerve Dysfunction. The facial nerve is resistant to gradual compression and stretching from VS, therefore dysfunction of this nerve is quite rare. Facial nerve dysfunction may present as either hypofunction (weakness or paralysis) or hyperfunction (twich, spasm). Clinically detectable weakness of the nerve may occur in large tumors, but the incidence is less than 2%. Facial hyperfunction is independent of tumor size and can coexist with facial weakness. Minor twitching of the face, commonly seen in the orbicularis oculi muscle, can occur in up to 10% of patients. It is important to consider the diagnosis of facial nerve schwannoma in these patients.

The facial nerve has a sensory component distributed over the posterior ear canal and conchal bowl. Sensory dysfunction in this area secondary to VS, known as Hitseberger sign, is of little clinical significance.

Ophthalmologic Manifestations. The most common ophthalmologic findings in VS are (a) horizontal nystagmus from vestibular hypofunction, and (b) decreased corneal reflex from trigeminal dysfunction. The nystagmus in the horizontal plane typically beats away from the tumor side indicative of ipsilateral vestibular hypofunction. However, with larger tumors, a vertical plane nystagmus may be seen due to brainstem compression. Hydrocephalus is rarely seen today, however this can lead to papilledema and secondary visual loss. Chronic elevated intracranial pressure may also cause optic atrophy which is characterized by a progressive loss of peripheral vision and eventual blindness.

Lower Cranial Nerves. Lower cranial nerve dysfunction (IX through XII) clinically presents with hoarseness, aspiration, dysphagia, and/or ipsilateral shoulder and tongue weakness. These findings are extremely rare in VS regardless of tumor size. When present, such dysfunction should prompt the reevaluation of the diagnosis, and a jugular foramen schwannoma should be considered to be more likely.

Investigations

Audiometry. Conventional pure tone and speech audiometry are the most cost-effective screening tools to determine which patients should
have further testing such as ABR or imaging. Patients with VS typically present with an asymmetric, high frequency, down-sloping hearing loss with a word recognition score (WRS) lower than expected based upon the pure-tone thresholds. The audiogram configurations are variable, and one study revealed a down-slope in 68%, a trough in 9%, flat in 9%, low frequency in 8%, a peak shape in 5%, and normal in 1%.44 Historically, a battery of special audiologic tests was used to diagnose VS. However, these have largely been abandoned and only performance intensity function for phonetically balanced words test for rollover and acoustic reflex decay remain in widespread use. Although the sensitivity and specificity of these tests is poor, abnormal results may be an indication for further investigations.

In addition to screening for VS, audiometry can help determine the utility and prognosis for a hearing conservation microsurgical approach. In 1995, the Committee on Hearing and Equilibrium of the American Academy of Otolaryngology—Head and Neck Surgery established a classification system based upon the pure tone average (PTA) and WRS (Figure 13).52 This classification is currently used for reporting the preoperative and postoperative hearing results when hearing conservation surgery is being considered. In general, better preoperative hearing is associated with higher rates of hearing preservation. A meta-analysis of 16 studies with 1,993 patients revealed preserved hearing (postoperative AAO-HNS Class A, B, or C) in 56.1% of patients with preoperative Class A, 43.4% with Class B, and 32.2% with Class C.46

Auditory Brainstem Responses. ABRs are the most sensitive and specific of all the audiologic tests for VS diagnosis. Prior to the advent of enhanced MRI scanning, ABR testing was used as a key diagnostic tool, and its diagnostic efficiency has been extensively studied. Among patients with documented VS, approximately 20 to 30% have no waves, 10 to 20% have only wave I and nothing thereafter, 40 to 60% have all waves but a wave V latency delay, and 10 to 15% have normal traces.47 Although the rate of false-negatives (normal ABR without an acoustic neuroma) is the literature is approximately 15%, it ranges from 33% for intracanalicular tumors to 4% for larger lesions. False-positive rates (abnormal ABR without an acoustic neuroma) are much higher and exceed 80% in a number of series.50-52 Because of these limitations and the narrowing cost differential of ABR compared to MRI, the indication for ABR as part of the diagnosis of VS has diminished significantly. ABR testing may be considered in patients clinically at low risk for VS with a minimal pure-tone asymmetry, those with a decades-long history of stable asymmetric loss, or those with unilateral tinnitus and symmetric hearing. Any patient considered to be at high risk for VS based upon history, physical examination, or audiometry should proceed directly to a gadolinium-enhanced MRI scan.

ABR may also provide prognostic information for hearing preservation after microsurgical management. Good ABR morphology, lower wave V latencies, and the preservation of wave III have all been associated with an increased rate of hearing preservation.53-55

Vestibular Testing. The ENG test battery is abnormal in up to 90% of VS patients, and typically a reduced ipsilateral response with horizontal nystagmus is seen. Unfortunately, ENG has poor specificity for the diagnosis of VS, therefore it is not routinely ordered in our practice. However, arguments for ENG testing in patients with VS surround its potential prognostic value in predicting postoperative vertigo and the potential for hearing conservation. Patients with absent caloric responses tend to have less disabling vertigo in the postoperative period because they have already had the opportunity to compensate to the vestibular loss. This information may be used to counsel patients, but does not ultimately affect the choice in management.

In hearing conservation, it has been suggested that a VS originating from the superior vestibular nerve carries a favorable prognosis, since such tumors are farther away from the cochlear nerve and internal auditory artery.56 The caloric response results from stimulation of the lateral semicircular canal which is innervated by the superior vestibular nerve. Therefore, an absent caloric response indicates injury to the superior vestibular nerve and occurs more frequently from tumors originating from the superior vestibular nerve itself. Three recent studies, however, have failed to demonstrate ENG as a significant prognostic factor in hearing conservation.57,58

Imaging. The imaging of VS has been discussed in the CPA imaging section of this chapter above.

Management. There are 3 treatment options for patients with VS: (1) observation with serial imaging, (2) microsurgery, and (3) stereotactic radiation. The goals in management are: first, the preservation of life, second, the preservation of facial function, and third, the preservation of hearing. Of course, the risks and benefits of each of the treatment options should be discussed with the patient in this collaborative decision-making process.

Observation. The decision to choose observation with serial imaging is based upon the probability of needing treatment within the predicted lifespan of the patient. Therefore, unfavorable patient lifespan factors (advanced age, infrum health) and favorable tumor factors (small size, stable, or slow-growing) are considered indications for conservative management. Patients who are poor surgical candidates can be treated expectantly at first, with subsequent stereotactic radiotherapy as warranted by progressive tumor growth or clinical symptoms.

Since the growth rate cannot be established on the initial imaging study, the second study should be performed at 6 months with yearly studies thereafter if no significant growth is seen. VS will often fall into 2 categories based upon their growth rate. Patients with tumors growing at rates >0.2 cm/yr or with progressive clinical symptoms will likely require additional therapy in the form of stereotactic radiotherapy or microsurgery. Patients with tumors with slower growth rates over 3 years often do not require treatment and can be followed for extended periods with serial imaging.

Disadvantages to choosing observation include (1) patients may require treatment at a more advanced age thereby raising the risk of complications; (2) some patients may require treatment for larger tumors thereby compromising results; (3) the opportunity for hearing conservation may be lost with tumor growth or hearing deterioration; (4) tumor growth could exceed the limits amenable to stereotactic radiation (>3 cm); (5) some patients may have significant anxiety about having an “untreated” tumor; and (6) the time and expense associated with periodic radiologic follow-up.59

Microsurgical Management. There are 3 primary surgical approaches used in VS microsurgery: (1) translabyrinthine (TL), (2) retrosigmoid (RS), and (3) middle fossa (MF). The exposure afforded by each of these approaches is illustrated in Figure 14 (TL), Figure 15 (MF), and Figure 2 (RS). The advantages and disadvantages of these 3 approaches have been summarized in Table 8.

The amount of tumor removal can be classified as total removal, near-total removal, or subtotal removal. Near-total removal refers to a small thin capsule (<2 mm thick) being left behind, typically along the facial nerve in the CPA.59 In a subtotal removal, larger amounts of tumor are left behind (>2 mm), and the residual can be quantified as a percentage of the total tumor volume.59 Although total removal is normally achieved, partial resection can be considered for neural preservation, advanced patient age, decreased hearing status...
in the contralateral ear, or intraoperative events necessitating premature termination of the procedure. Although VS surgery can be performed by either a neurotologist or neurosurgeon alone, a team approach minimizes surgeon fatigue and allows specialized skills to be combined. The experience and skill of the surgeon and perioperative team play a significant role in the choice of surgical approach. Ideally, the surgical team should be comfortable with all approaches so that the choice can be based upon the attributes of the specific patient and tumor.

**Factors Influencing Operative Approach**

1. **Hearing.** In patients with nonserviceable hearing (AAO-HNS Class D) or in patients where the chance of hearing conservation is quite small, we advocate the TL approach regardless of tumor size, location, or nerve of origin. If hearing conservation is a viable option, either MF or RS is chosen based on the factors listed below.

2. **Tumor Size.** Tumor size is a major consideration in the choice of surgical approach. Intracanalicular tumors can be managed via either the MF or RS approaches. The MF approach probably provides the best chance of hearing conservation, but there is a greater need to manipulate the facial nerve as it often lies between the surgeon and the tumor. In tumors with a CPA component of less than 10 mm in diameter, the MF approach has been shown to have higher transient facial nerve dysfunction, but similar long-terms results compared to the RS approach. In tumors with CPA components 10 to 18 mm in diameter, long-term facial nerve outcomes are worse with the MF approach than with a TL approach. Even in the MF approach, dissection in the lateral 25% of the IAC is often blinded by the overhang of the transverse crest. Even in the MF approach, dissection in the lateral 25% of the IAC is often blinded by the overhang of the transverse crest. Even in the MF approach, dissection in the lateral 25% of the IAC is often blinded by the overhang of the transverse crest.

3. **Tumor Extension and Erosion.** The depth of lateral extension in the IAC on gadolinium-enhanced MRI scans helps guide the selection of surgical approach. In the RS approach, only the medial two-thirds of the IAC can be directly exposed without sacrificing a portion of the otic capsule, thereby reducing the chances at hearing preservation. Even in the MF approach, dissection in the lateral 25% of the IAC is often blinded by the overhang of the transverse crest. In our experience, the presence of a “modiolar spike” of the lateral part of the tumor inferior to the transverse crest and deep into the fundus is a particularly poor prognostic sign for hearing conservation.

4. **Nerve of Origin.** The origin of the tumor from either the superior or inferior vestibular nerve is of significance for preservation of both hearing and the facial nerve. Inferior vestibular nerve tumors tend to a more intimate relationship with the cochlear nerve and internal auditory artery, resulting in less hearing conservation. They also deflect the facial nerve superiorly, leaving it in a less favorable position for an MF approach. The utility of caloric vestibular testing to determine the nerve of origin has been discussed above. Instead, we routinely use coronal MRI scans to determine the tumor’s location in relation to the transverse crest since this has practical implications in selecting a surgical approach.

5. **Complications.** Facial nerve transection is uncommon in modern acoustic neuroma surgery, and overall rates of permanent severe or total paralysis are well under 10%. Facial nerve outcomes are similar between TL and RS approaches, but the MF approach has a higher...
incidence of transient weakness in tumors with <10 mm CPA extension and of permanent weakness in tumors with 10 to 18 mm CPA extension. Therefore, if a hearing conservation approach is being considered, we prefer the RS approach for all tumors with greater than 10 mm CPA extension.

Persistent postoperative headaches can cause significant morbidity. This is particularly problematic with the RS approach, although its incidence can be reduced by limiting spillage of bone dust in the CPA during drilling of the IAC, which can incite aseptic meningitis. In addition, repositioning the bone plate at the conclusion of the resection can assist in reducing headaches, presumably by limiting traction of cerebral musculature on the dura. Nonetheless, the risk of postoperative headaches is 3.8 times greater with an RS than a TL approach even if the bone plate is replaced, and this difference has been shown to remain significant up to 6 months postoperatively.

Retraction injuries can occur to the cerebellum during the RS approach and to the temporal lobe during the MF approach. After an RS approach, encephalomalacia involving the lateral 1 to 2 cm of the cerebellar hemisphere is sometimes seen on T2-weighted MRI scans. Most patients recover uneventfully; but, on occasion, the injury may extend deeply toward the midline, and prolonged ataxia may result. Retraction of the dominant temporal lobe during an MF approach can cause dysphasia, but this is quite rare. Rarely, transient short-term memory loss, seizure, and odd dreams can occur. Postoperative encephalomalacia is less common with the MF approach than with the RS approach because the retraction of the temporal lobe is extradural rather than intradural.

In a recent study, the incidence of CSF leak was equal (approximately 10%) following the TL, MF, and RS approaches. However, some have maintained the CSF leak may be more common following RS craniotomy and may be more difficult to manage with conservative measures.

In our experience, efforts to preserve the cochlear nerve in hearing conservation approaches lead to prolonged operative time, increased postoperative vestibular dysfunction, and a slightly greater risk of tumor recurrence. These observations have yet to be studied formally. The vestibular disturbance likely reflects abnormal signals from preserved vestibular nerve remnants which may slow vestibular compensation. Tumors can recur from a small fragment left in the fundus. The chances of this are higher in the MF and RS approaches than in the TL approach because dissection of the lateral one-third of the IAC is often blinded by the preserved otic capsule. Some have advocated the use of endoscopes to visualize the fundus for any residual tumor. However, in our experience, it is often difficult to use angled endoscopes in such a small area, avoid injury to the facial nerve, and discern tumor from surrounding tissue.

| | Requires small abdominal fat graft | Higher risk of persistent postoperative headache |
| | Occasional transient memory disturbance or aphasia | Bone removal completed after dural opening |
| | Risk of recurrence similar to RS approach | Higher risk of recurrence compared to TL |

Hearing Results. Hearing results from a number of major centers are presented in Table 9. The success rates in the literature vary widely, and one must consider the numerous variables that have not been controlled among series. Relevant confounding factors include tumor size, tumor location, preoperative hearing levels, surgical approach, reporting of hearing results, and the definition of success.

The highest rates of hearing preservation have been reported with small tumors treated via the MF approach. In these most favorable conditions, the rate of preservation of “useful” hearing surpasses 50%. The MF approach, however, has 3 disadvantages: exposure of the CPA component of the tumor is limited; in contrast to the TL approach, the lateral IAC may require blind dissection; and in comparison with the other approaches, the facial nerve is at increased risk of permanent palsy if the cisternal component is >1.0 cm.

Overall hearing preservation rates via the RS approach tend to be lower than for the MF approach, but direct comparison controlling for tumor size and preoperative hearing status is difficult. In our series, up to 25% of patients retained serviceable hearing after the RS approach for tumors less than 2 cm in CPA diameter. Hearing preservation rates are diminished when the cisternal component is greater than 2 cm in diameter.

When choosing a hearing conservation approach for a particular patient, overall success rates are not as important as individual prognostic factors. For example, a patient with a small tumor, minimal IAC involvement, excellent preoperative hearing, and a normal ABR will likely have a

Stereotactic Radiosurgery and Radiotherapy. Stereotactic radiosurgery and radiotherapy are discussed in Chapter 36, “Stereotactic Radiosurgery and Radiotherapy.” There has been significant controversy regarding the relative roles of microsurgery and stereotactic radiotherapy in the primary treatment of VS. As these tumors are slow-growing, intervention can be typically with- held until tumor growth can be shown on serial imaging. In general, radiotherapy is recommended for smaller tumors in older individuals, whereas younger individuals are recommended microsur-
gery regardless of tumor size. The rationale is that younger patients will have more time to develop the potential adverse long-term complications of radiation such as secondary neoplasms. Microsurgery is recommended for patients with larger tumors (>3 cm) as radiotherapy carries the risk of edema and secondary brainstem compressive symptoms. Finally, tumors treated with radiotherapy require indefinite monitoring with MRI scans which can be cumbersome for patients and create difficulties when seeking to change health insurance plans.

Stereotactic radiosurgery or radiotherapy is commonly used for VS recurrence following microsurgery. In our experience, the recurrence rate following near-total removal is only 3%, however the rate rises to over 30% following subtotal resection. In all cases of partial resection, the tumor should be carefully monitored for recurrence with serial imaging. Outcome for stereotactic radiation of tumor recurrence is simi-

Meningioma

Epidemiology. Meningiomas are the second most common tumor found in the CPA (<10%), the second most common intracranial tumor (<20%), and the second most common central nervous system tumor after gliomas. Unlike vestibular schwannoma, there is a 2:1 female sex predilection, with the tumor being diagnosed most commonly in the fifth to sixth decades of life.

Pathogenesis. Risk factors for meningioma include NF2, and it has been estimated that one-fifth of adolescents with meningioma have NF2. Radiation has been shown to increase the risk of meningioma fourfold. There is also an association between meningioma and sex hormones; the tumor is more common in women, has been associated with breast cancer, and has been shown to have binding sites for estrogen and progesterone.

The genetics of meningioma have revealed that monosomy 22 is a common early molecular event in tumorigenesis and cytogenetic losses in chromosomes 1, 7, 10, and 14 and telomerase activation are observed in clinically aggressive meningiomas. Genes associated with meningiomas include S6-kinase, p53/MDM2, protein 4.1B, merlin (NF2 gene), and TSLC1.

Pathology. The gross and microscopic characteristics of meningiomas have been summarized in Table 10. Meningiomas arise from arachnoidal cap cells, pial cells, and dural fibroblasts. Histologically, meningiomas have been classified into 4 categories: syncytial or meningotheliomatosus lesions (55%), fibroblastic lesions (15%), transitional lesions (30%), and angioblastic lesions (5%). In 2000, the World Health Organization (WHO) updated the classification for meningiomas based upon aggressiveness, risk of recurrence, grade, and histologic subtype (Table 11).

Meningiomas have a proclivity to arise either along the course of venous sinuses or in relation to neural foramina (Figure 17). Extratemporal meningiomas are the most common and usually originate at the CPA attached to the posterior surface of the petrous pyramid or adjacent to the superior petrosal sinus. Other locations, in decreasing frequency, include the tentorium, clivus, cerebellar convexity, and foramen magnum. Although invasion of the temporal bone is usually secondary from extratemporal meningiomas, primary involvement can occur from the IAC, the jugular foramen, the geniculate ganglion, and the sulcus of the greater and lesser superficial petrosal nerves.

Rarely, a meningioma can be entirely within the IAC and mimic an intracanalicular VS.

Diagnosis. Clinically, the symptoms at presenta-
tion in decreasing frequency are progressive hearing loss, headaches, vertigo, tinnitus, otorrhea, otalgia, facial weakness or loss of taste, diplo-
ia or visual disturbance, dysphagia, dysarthria, dysphonias, nausea and vomiting, facial pain or
and lower cranial nerve dysfunction.

Present with pulsatile tinnitus, a middle ear mass, membrane, conductive hearing loss, and facial nerve may present with a hyperemic tympanic membrane.

Treatment discussed in the imaging section previously.

Their differentiation from those of VS have been

The imaging characteristics of meningiomas and MRI with gadolinium is the most effective imaging modality for the diagnosis of meningioma. The imaging characteristics of meningiomas and their differentiation from those of VS have been discussed in the imaging section previously.

Treatment Meningiomas are benign tumors, but are locally destructive with the ability to invade cranial nerves. The treatment options are similar to those of VS, but the variations in tumor location and symptoms make it difficult to create a standardized management algorithm. In general, the patient’s age and estimated life expectancy, the morbidity of tumor removal, and the natural history of an untreated tumor must be taken into consideration. Conservative management with serial imaging should be considered in tumors unlikely to cause symptoms within the patients expected life and tumors where excision would result in unacceptable morbidity.

Surgical excision is the treatment of choice when possible. In general, patients have better outcomes when surgery is performed prior to the onset to neurological signs. Therefore, tumors being followed conservatively should be carefully monitored for growth and symptoms. Young patients with large tumors or progressive neurological signs should be treated surgically. The surgical approach is dictated by the tumor size, location relative to neural and vascular structures, and the status of hearing. A distant bone involved with tumor should be resected due to the propensity of meningiomas to spread within osseous haversian canals. A wide variety of surgical approaches can be used based upon the tumor characteristics; these include middle fossa, retrosigmoid, transtentorial, transcoclear, and combined translabyrinthine-suboccipital approaches. Hearing preservation is much more likely with meningiomas than with VS, therefore labyrinth-sparing approaches are used whenever possible regardless of tumor size. Simpson classified the extent of tumor removal (Grades I to IV), and this classification has been correlated to outcome following surgery.

Complete tumor resection can often be difficult due to location and involvement of neural and vascular structures, therefore recurrence rates have been reported to be as high as 30% even following apparently complete removal. As clinical recurrence rates have been shown to increase over time, long-term follow-up with radiologic examination is recommended.

The role of stereotactic radiosurgery or radiotherapy in meningiomas is controversial. Although stereotactic radiosurgery or radiotherapy can be used primarily for inaccessible tumors or patients unfit for surgery, it is being used increasingly as an adjunct following subtotal resection.

MIDDLE EAR AND MASTOID

Squamous Cell Carcinoma

Squamous cell carcinoma is the most common primary malignant tumor of the temporal bone and represents 60 to 80% of all malignancies from the skin of the external auditory canal (EAC) and middle ear cleft. Squamous cell carcinoma of the EAC is discussed in Chapter 14, “Diseases of the External Ear.”

Adenomatous Tumors

A adenomatous tumors involving the middle ear and temporal bone are rare. Historically, it became clear that these “adenomas” could have either a benign or aggressive clinical course. It was not until 1990, however, that these tumors were classified into two distinct subtypes based upon clinical course and histopathology: mixed pleomorphic cell pattern and papillary pattern. The mixed pleomorphic cell pattern will be discussed in this section on tumors of the middle ear and mastoid, however the papillary pattern will be discussed in the following section on inner ear tumors due to their origin from the endolymphatic sac.
**Mixed Pleomorphic Adenoma.** Mixed pleomorphic cell tumors (mucosal adenomas) are the more common of the two subtypes, remain localized to the middle ear and mastoid cavity, and rarely involve the facial nerve or otic capsule. They are believed to arise from poorly differentiated basement membrane cells within the normal middle ear mucosa. These tumors have a male sex predilection and usually present between the ages of 20 and 60 years. The most common presenting symptom is conductive hearing loss, however otorrhea, tinnitus, and facial nerve weakness may be present. Physical examination reveals a middle ear mass, and CT scans often confirm a soft tissue mass confined to the middle ear and mastoid in the absence of bone destruction.

Because of the tumor location, presenting symptoms, and imaging characteristics, these lesions are commonly mistaken for chronic otitis media with cholesteatoma, and the diagnosis is often made during mastoidectomy. Mixed pleomorphic tumors are benign and less aggressive than their papillary counterpart, however there is still a high recurrence rate after excision. Therefore, complete resection with long-term follow-up is recommended as the treatment of choice.113

**INNER EAR**

**Papillary Adenoma (Endolymphatic Sac Tumor)**

In contrast to mixed pleomorphic adenomas, papillary tumors occur less frequently, often extend to the petrous apex and intracranially, and occur more commonly in women. These tumors have historically been termed Heffner tumors, low-grade papillary adenocarcinoma, and aggressive papillary middle ear tumors. Histologically, these tumors demonstrate papillary and cystic components, a single- to double-layered epithelial lining, and adjacent bone infiltration. The glandular features suggest that the origin of these tumors is the endolymphatic sac.112,113 There is an association with von-Hippel-Lindau disease (VHL) and approximately 11% of patients with this disease have endolymphatic sac tumors.114 Clinically, these tumors usually present with hearing loss, vertigo, tinnitus, and facial nerve paralysis. CT scans typically reveal a mass located near the vestibular aqueduct (between the sigmoid sinus and IAC), bony destruction, and erosion toward the vestibule (Figure 18).

Treatment for these tumors is surgical excision with adequate margins. Resection is often accomplished via the TL approach, however more extensive approaches may be necessary for medial or intracranial extension. These tumors are quite vascular, therefore preoperative angiography and embolization may play a role in larger tumors. There is a 90% cure rate after gross total surgical removal, and radiation therapy has been used after incomplete removal. It has been estimated that 50% of tumors respond favorably to radiation, however the small number of patients makes interpretation of the results difficult.112,113,115,116

**Intralabyrinthine Schwannoma**

Intralabyrinthine schwannomas originate within the inner ear and are differentiated from the more common VS which can secondarily invade the labyrinth. They can occur in a wide variety of locations within the labyrinth including the scala tympani within the basal turn of the cochlea, modiolus, ampulla of the lateral semicircular canal, and utricle.117 Clinical manifestations depend on the location of the tumor and can include cochlear symptoms (hearing loss, tinnitus) or vestibular symptoms (vertigo, disequilibrium). Physical examination is often normal, but may reveal nystagmus during a vertiginous episode or a middle ear mass in large lesions. CT scans are usually normal, but MRI may reveal the absence of fluid density on T2-weighted sequences and an enhancing lesion postgadolinium within the cochlea and/or vestibule. Symptomatic patients are often monitored with serial imaging as operative management universally results in a complete hearing loss. Surgical approaches include a standard TL approach for lesions within the vestibule and a transotic approach for lesions involving the cochlea.

**JUGULAR FORAMEN**

**Paragangliomas (Glomus Tumor)**

Paragangliomas, also known as glomus tumors, are the most common tumor of the middle ear and the second most common tumor of the temporal bone. Jugulotympanic paragangliomas have a clear female predilection, and they typically occur in the fifth decade of life.

**Pathogenesis.** Paraganglia are a part of the neuroendocrine system, and they migrate in association with the ganglia of the autonomic nervous system.118 Extra-adrenal paraganglia, with the exception of the carotid bodies which serve a chemoreceptive function, normally undergo progressive involution until puberty. Tumors of these paraganglia are divided into 2 groups: (1) adrenal paragangliomas known as pheochromocytomas and (2) extra-adrenal paragangliomas located in the abdomen, chest, and head and neck regions. Head and neck paragangliomas are classified based on anatomic location and include the carotid body, jugulotympanic, vagal, laryngeal, nasal, and orbital paragangliomas.119 Interestingly, the terms glomus was mistakenly attached to these tumors when it was believed their origin was similar to true glomus (arteriovenous) complexes.

The majority of glomus tumors appear sporadically, but a small proportion of these tumors (<10%) may be hereditary and associated with tumor syndromes including multiple endocrine neoplasia type II (MEN2), von Hippel-Lindau, neurofibromatosis type 1 (NF1), and familial paraganglioma.120 Familial paraganglioma is linked to 3 of the 4 mitochondrial complex II peptides namely the succinate dehydrogenase subunit B (SDHB), subunit C (SDHC) and subunit D (SDHD), and may have either maternal or paternal modes of mitochondrial inheritance.121 Multicentricity occurs in approximately 10% of spontaneous tumors and increases to 30% in familial tumors.122 Glomus tumors contain chief cells, which are part of the diffuse neuroendocrine system (DNES), and have the potential to produce catecholamines creating a physiologic response similar to pheochromocytomas. This is quite rare in head and neck paragangliomas (<3%) but may occur more frequently in familial syndromes. Finally, these tumors are histologically benign, although up to 4% may become metastatic.122

**Pathology.** Glomus tumors are typically reddish-purple, vascular, and lobulated masses. Histologically, a characteristic zellballen pattern in which nests of chief cells (type I) are surrounded...
by sustentacular cells (type II or supporting cells) in a highly vascular stroma. The pattern can be enhanced with silver staining.

**Classification.** Paragangliomas in the temporal bone can be divided into glomus tympanicum and glomus jugulare (Figure 19). Glomus tympanicum primarily involve the tympanic stroma and arise along the course of Jacobson nerve. Glomus jugulare arise from the dome of the jugular bulb and involve structures of the jugular foramen. These tumors are further characterized according to either the Fisch\textsuperscript{123} or Glasscock-Jackson\textsuperscript{124} classification systems (Table 12). Glomus tumors typically have slow, progressive growth spreading via paths of least resistance; however, advanced lesions have the ability to invade cranial nerves. The clinical presentation and operative management of these 2 lesions is quite different, therefore they will be discussed individually below. A nother variant, the glomus vagale, arises beneath the skull base in proxim-

Investigations. The imaging characteristics of both glomus tympanicum and glomus jugulare on CT, MRI, and angiography have been discussed above. Angiography is used in glomus jugulare and should be deferred until the preoperative period so that both diagnostic and therapeutic (embolization) measures can occur in the single study. Angiography can reveal arterial supply, degree of vascularity, degree of arteriovenous shunting, evidence of major venous sinus occlusion, and identify multicentric lesions. Magnetic resonance angiography (MRA) and MRV are flow-sensitive MRI scans that can also be used. MRV in particular can reveal occlusion of the venous system and identify involvement of the jugular bulb.

Patients presenting at a young age, family history of paragangliomas, multicentric tumors, secreting tumors (symptoms of catecholamine release), or malignant tumors are all suggestive of possible hereditary disease.\textsuperscript{125} In these cases, a detailed physical examination including fundoscopic examination for retinal angiomas (seen in VHL) and skin examination for café au lait spots (associated with NF1) should be performed. Urinalysis for hematuria, urine catecholamines, serum calcium, and serum calcitonin can also be measured for occult functioning tumors, VHL, and MEN2. M. ult centricity can be screened with a CT scan (extending from mandible to bladder) and I\textsuperscript{23} meta-iodobenzylguanidine (MIBG) scintigraphy.\textsuperscript{121} Finally, specific genetic testing can also be ordered for the various familial syndromes.

**Glomus Tympanicum** The clinical presentation of glomus tympanicum includes pulsatile tinnitus (76%), hearing loss (conductive 52%, mixed 17%, sensorineural 5%), aural pressure/fullness (18%), vertigo/dizziness (9%), external canal bleeding (7%), and headache (4%).\textsuperscript{123} Brown sign is seen clinically when a pulsatile, purple-red middle ear mass blanches with positive pneumatic otos-
it in situ, can often be used to provide sufficient exposure to the tumor and adjacent structures in these cases. New postoperative cranial nerve deficits occur in 25 to 50% of cases, with larger lesions having a higher incidence of neuropathy. Rehabilitation with speech therapy, vocal cord medialization, and facial nerve reanimation are often effective. Patients must be counseled on the risks of surgery as well as the risks of functional deficits if the tumor is left untreated. Using contemporary techniques, surgical resection has a low recurrence rate, a low disability rate, and good functional outcomes.125,128–130

Stereotactic radiosurgery or radiotherapy is indicated in incompletely resected tumors or those with positive surgical margins. Certain centers also advocate radiation therapy as first-line therapy for advanced tumors or for elderly patients. Two large review articles found similar control rates, recurrence rates, and morbidity between surgery and radiation.131,132 However, the lack of long-term follow-up and the tendency to include unresectable tumors in the radiation group may bias these results. The risk of radiation-induced malignancies must be considered, especially when treating younger patients with a longer expected lifespan.133

Jugular Foramen Schwannoma

JFS are the second most common jugular foramen tumor, but are relatively rare with only 200 cases in the world’s literature.134 JFS represent 3% of all intracranial schwannomas and 1 of the largest series in the literature only had 14 patients.135 JFS can arise from cranial nerves IX to XI and determining the nerve of origin is often quite difficult. The anatomy of the surrounding structures in the jugular foramen region can vary, as is represented in Figure 20. Three growth patterns of JFS have been described: (1) distal jugular foramen tumors can expand inferiorly out of the skull base, (2) proximal jugular foramen tumors can expand into the posterior fossa, and (3) middle jugular foramen tumors can expand into bone or become bilobed.136 Symptoms and signs related to lower cranial neuropathies predominate with cranial nerve X (63%), IX (55%), XI (41%), and XII (36%) being most commonly affected.6 Other less common and signs symptoms include cranial nerve V and VII dysfunction, hemifacial spasm, nystagmus, ataxia, and papilledema.135

The imaging characteristics of schwannomas have been discussed, and JFS can be differentiated from paragangliomas by the absence of irregular bony destruction and flow voids. The treatment options include surgery and radiation. The surgical approaches, complications, and rationale are similar to those used for glomus jugulare tumors.

FACIAL NERVE

Facial Nerve Schwannoma

FNS are rare and can occur along the entire course of the facial nerve. Intratemporal FNS are more common than either intracranial or extratemporal (parotid) FNS. The presenting symptoms for intracranial FNS are similar to VS and include sensorineural hearing loss (100%), tinnitus (80%), and vestibular dysfunction (60%).137 Extratemporal FNS typically present as a parotid mass.

Intratemporal FNS can originate from the geniculate ganglion and horizontal and vertical segments, in the IAC, and from the labyrinthine segment in descending frequency (Figure 21). Contiguous portions can be involved and, uncommonly, FNS may display multicentricity described as a “string of pearls.”138 In a large review of over 200 cases, the most common presenting symptoms and signs were facial paralysis (73%), hearing loss (50%), tinnitus (13%), ear canal mass (13%), and pain (11%).139 Facial paralysis most commonly presents as a slow, progressive palsy with accompanying hyperfunction (facial twitch or hemifacial spasm). Although 14% of FNS can mimic Bell palsy and present with a sudden paralysis, patients with FNS will usually have progressively more severe episodes of palsy that is characteristic of these tumors.139 Any patient with a suspected Bell palsy without functional recovery after 3 months should undergo an MRI scan to rule out a tumor. Hearing loss resulting from FNS is often conductive due to prolapse of the tumor onto the ossicles. These tumors can be seen on otoscopy in one-third of cases and may be found incidentally during an exploratory tympanotomy for conductive hearing loss. A
biopsy of FNS often results in facial paralysis, imaging should be undertaken in suspected cases to establish the diagnosis. Sensorineural hearing loss can also occur secondary to cochlear invasion, and vertigo can result from a labyrinthine fistula. The imaging characteristics of FNS have been discussed above.

The treatment of FNS focuses on preserving or restoring facial function. The best outcome after excision and replacement with an interposition graft is a House-Brackmann Grade 3 or 4, with good eye closure, but severe synkinesis. Therefore, with normal or near-normal facial function, observation with serial physical examination, MRI scans, and electroneuronography (ENOG) is recommended. There is no consensus as to when operative management should be undertaken. Some authors feel that if significant degeneration occurs (>50%), further observation may result in the inability to recover useful function with an interposition graft, and surgical intervention should be performed. In our practice, we routinely wait until the facial function is worse than would be expected with an interposition graft (House-Brackmann Grade III) before operating. In small series, wide decompression of the FNS in certain cases may achieve a postoperative House-Brackmann Grade I or II with lasting preservation over time, however further data are needed to evaluate this procedure.

It is rarely possible to resect an intratemporal FNS while preserving the facial nerve. More commonly, an interposition graft from either the greater auricular nerve or sural nerve is needed. A tympanomastoid approach is used to access FNS while preserving the facial nerve intact and rec-

IA C.  There are approximately 50 case reports of geniculate ganglion hemangioma to date in the world’s literature. On gross examination, hemangiomas are rubbery red or purple masses with vascular spaces. The histologic appearance of geniculate hemangiomas is not characteristic of the more common hemangiomas found elsewhere in the body. In 1 report, geniculate ganglion hemangiomas with thin-walled vascular spaces were classified as hemangiommas and those with thick-walled vascular spaces as hamartomas or vascular malformations. Osseous hemangiomas contain spicules of bone, and this has been variably seen within geniculate hemangio-

CLIVUS

Chordoma

Chordomas are neoplasms that arise from the primitive notochord, which is formed from ectoderm during the third week of development. Remnants from both the cranial and sacral end of the notochord frequently persist after the period of regression; however, they rarely become a true neoplasm. The 3 major sites for chordomas are sphenoid (35%), vertebral (15%), and sacrococcygeal (50%). Pathologically, they are divided into 3 types: conventional (classic), chordoid, and dedifferentiated (atypical). Grossly, these tumors are gray and gelatinous with no obvious capsule. On microscopic examination, the primary cell types are stellate, intermediate, and physaliphorous. Immunohistochemistry reveals that these tumors are reactive to vimentin, cytokeratin, and S-100 protein.

Chordomas are rare, occur in the fourth to fifth decades of life, preferentially affect males, and have a slow, insidious growth pattern. Diplopia and headache are the most common presenting symptoms, and abducens nerve (VI) palsy was the most common deficit. A number of other symptoms including lower cranial nerve dysfunction, cerebellar symptoms, and nasopharyngeal obstruction can occur. Imaging characteristics of chordomas have been discussed, however conventional angiography and MRA can be useful for preoperative planning and embolization.

The treatment of choice for chordoma is total or near-total surgical resection, although this is difficult given the tumor’s location and surrounding neurovascular anatomy (Figure 22). Radical removal is associated with better long-term survival and decreased recurrence rates. The surgical approach is chosen based on the particular tumor and often several different approaches may be necessary. Midline approaches can be used for lesions located medial to both hypoglossal canals and options include transoral-transpalatal, transmaxillary-transnasal, transtemporal, and endo- 

Radiation is typically used for palliation or recurrence, however some have advocated high-dose irradiation immediately following radical surgery. Recent reports examining both conventional radiotherapy and photon-beam radiotherapy as adjuvant treatment have shown palliation of pain, but no significant increase in survival. Long-term prognosis is poor with 10-year progression-free survival rates of 15 to 55%, despite the manner of treatment.

Chondrosarcoma

Chondrosarcoma is a rare primary malignancy of bone, potentially arising from any bone
Chondrosarcomas can be divided into 5 histologic subtypes: conventional, myxoid, mesenchymal, clear cell, and dedifferentiated. The expected natural history is correlated with histologic grade and well-differentiated tumors have better overall prognosis than poorly differentiated ones. Immunohistochemistry is important to differentiate chordoma from chondrosarcoma; whereas both lesions test positive for S100 and vimentin staining, only chordomas test positive for cytokeratin and epithelial membrane antigen.

Grossly, chondrosarcomas tend to be gray, avascular, and gelatinous similar to chordomas. Chondrosarcomas can be divided into 5 histologic types: conventional, myxoid, mesenchymal, clear cell, and dedifferentiated. The expected natural history is correlated with histologic grade and well-differentiated tumors have better overall prognosis than poorly differentiated ones. Immunohistochemistry is important to differentiate chordoma from chondrosarcoma; whereas both lesions test positive for S100 and vimentin staining, only chordomas test positive for cytokeratin and epithelial membrane antigen. These tumors are slow growing, have an insidious onset, occur in the fourth to fifth decades of life, and have no sex predilection. The most common symptoms include diplopia, headache, hearing loss, imbalance, visual field loss, and facial numbness. The overall incidence of metastases is approximately 15%, with the rate increasing to 70% for poorly differentiated (Grade III) tumors. The imaging characteristics of chondrosarcoma and the differentiation from chordoma have already been discussed above.

Surgical excision is the cornerstone of treatment. A variety of skull base approaches outlined above can be used to gain access to the petrous apex and clivus for tumor resection, depending on the size of the lesion, its location, and the existence of preexisting cranial nerve deficits. Although the soft nature of these tumors facilitates dissection, complete resection is still difficult due to vital neural and vascular structures in the vicinity. Tumor recurrence has been associated with larger tumors, residual disease on postoperative imaging, younger patients, and lack of adjuvant radiotherapy. The role of radiotherapy in chondrosarcoma remains to be fully defined, but it appears to be beneficial in many cases. When surgical resection is not possible, stereotactic radiation has been advocated as the sole treatment in patients with small tumors. The overall expected 5-year control rate with multimodality therapy is approximately 95%.

CONCLUSIONS

The differential diagnosis of skull base neoplasms is broad, and a systematic approach is needed for the accurate diagnosis and management of patients with these tumors. Modern imaging modalities have allowed early identification of these tumors that may produce minimal signs until they are far advanced. A multidisciplinary skull base team is needed to manage patients with these tumors effectively with various microsurgical approaches. A thorough knowledge of alternate treatment options is essential to counsel these patients effectively.

REFERENCES

It was in 1951 that Dr. Lars Leksell first conceived of what is now known as gamma knife radiosurgery. As articulated, he envisioned “the delivery of a single, high dose of radiation to a small and critically located intracranial volume through the intact skull.” He first thought that this would be accomplished via a center of arc principle; and, in fact, the early attempts at accomplishing this utilized a single arc across which radiation was delivered to the intracranial target. The first gamma knife unit (Elekta Instrument AB, Stockholm, Sweden) was installed in Stockholm, Sweden in 1968, and it was not until 1987 that the first gamma knife (model U) was installed at the University of Pittsburgh. The gamma knife model B was first introduced in 1996, and this is the unit which is most used throughout the United States. The gamma knife model C was introduced in 1999, and the biggest change associated with this unit was that there is an automatic positioning system (APS). Other than this, the unit is quite similar to the model B, and both contain 201 radioactive isotope cobalt 60 (60Co) sources and beam channels. When the collimator helmet is locked into position, the 201 openings of the collimator helmet coincide with the cobalt sources. There is a shielded chamber within which the 60Co sources are contained, and stainless steel shielding doors protect the treatment room from the 60Co sources. There is a treatment couch with an adjustable mattress that slides into the gamma knife unit together with the collimator helmet and the patient. Figure 1 schematically shows the orientation of the components of the gamma knife model 4C, while Figure 2 shows the overall appearance of the gamma knife model 4C unit. During 2008, a completely redesigned gamma knife unit, named Perfexion, is being introduced (Figure 3). It uses 192 60Co sources, has a single collimator helmet with variable diameters, and can treat lesions within the entire head and neck, down to the level of the clavicles (Figure 4).

Whereas stereotactic radiosurgery can be applied to a wide range of skull base diseases, patients with vestibular schwannomas are most frequently treated with this modality. This form of treatment, just as is the case with microsurgery, has advantages and disadvantages, which must be thoroughly discussed with the patient. For the patient, it is appealing to undergo an outpatient procedure rather than microsurgical management that requires a much longer period of care (Figure 5). As an example, with a typical vestibular schwannoma managed via microsurgery, surgery takes place on the day of admission, and an overnight stay in the intensive care unit is customary. This is subsequently followed by 5 to 7 days of hospitalization and a post discharge recovery of 2 to 4 weeks. This is in sharp contrast to gamma knife radiosurgery, which is performed on an outpatient basis. Clear demonstration of tumor control and, with current methods, low cranial nerve morbidity have been published. Unfortunately, there are sometimes advertised claims that are misleading to patients. It should be noted that magnetic resonance images (MRIs) at different levels artificially change the apparent size of a tumor. There is a critical need for accurate measurement and reporting of tumor volume over time. Competing therapeutic systems have made available to the public images in which the size of the tumor following treatments has been misrepresented. In fact, the MRI used to illustrate...
“tumor shrinkage” in the New England Journal of Medicine article reporting outcomes of a cohort of patients treated with gamma knife radiosurgery suffers from the same problem of comparing different levels.1 Several medical institutions throughout the world offer training courses for physicians and radiation physicists at centers that have invested in the Leksell Stereotactic System or Leksell Gamma Knife. During the last decade and one-half, more than 1,500 neurosurgeons, neuroradiologists, physicists, and radiation oncologists have attended these educational programs. Elekta Instrument AB (Stockholm, Sweden) offers basic training courses as well as advanced technical workshops. The courses consist of didactic lectures, observation of patient treatment, and practical hands-on training. Additionally, all new installations of Leksell Gamma Knife are accompanied by a 1-week on-site start-up training, in which the neurosurgeons, neurosurgeons, radiation oncologists, and physicists constituting the gamma knife treatment team are responsible to participate.

FRAME ATTACHMENT

General Principles

The procedure used for the attachment of the stereotactic head frame is in stereotactic radiosurgery flows from the point of comparing the different levels. Gamma Knife treatment team are responsible to

![Gamma Knife 4C](image)

![Gamma Knife Perfexion](image)

**Figure 4** Comparison of the collimator helmets used with the gamma knife model 4C and the Perfexion. attachment should be stable. These principles should be addressed from the beginning of the frame attachment. In lateral targets, such as vestibular schwannomas, there is a potential risk for collisions between the collimator helmet of the gamma knife unit and the opposite lateral side of the frame, the posts, or the fixation screws. Similarly, other targets that are located in the posterior fossa can result in frame collisions with the anterior post. It is due to these factors that the target should ideally be located in the center of the frame.

The method of anesthesia used during frame placement is surgeon and patient dependent. In our program, either sedation with versed and fentanyl or monitored anesthesia with propofol, followed by injection of local anesthetic at the pin sites, is used.

Tools and Orientation

A bsolute stability of the frame is required, including the necessity of avoiding screw fixation in bone flaps, cranioplasty materials, burr holes, or skull defects, since treatment accuracy is based upon the geometry of the stereotactic frame coordinates. Figure 6A shows the usual array of tools used for the frame attachment, including a variety of screw lengths, to be able to choose those ideally suited for the individual location of the post along with a pair of screwdrivers and generally 20 mL of local anesthesia. The placement of the frame should begin with an accurate orientation of the location of the target within the patient’s head. Ideally, the target should be located within the fiducial range and placed centrally within the frame, thereby avoiding later collisions with the collimator helmet and granting sufficient accuracy for the stereotactic target definition.

Localization and Placement

After the surgeon is oriented regarding the location of the target, the stereotactic frame is preliminarily attached by using external auditory canal support pins, a Velcro band, or a stereotactic fiducial box. When using a fiducial box to facilitate frame placement, it is important to use the MRL fiducial box, rather than the CT or angiography fiducial box, since this is the smallest of the three plexiglass fiducial boxes (Figure 6B). Complete asymmetric frame placements are possible and do not impair the accuracy of imaging. The frame can either be shifted from side to side or can be moved as far as possible to the front or back. When the frame is successfully placed,

**Figure 5** Schematic outline of treatment timelines of microsurgical resection compared to gamma knife radiosurgery of a vestibular schwannoma. (Published with permission, copyright © 2007, P.A. Wackym, M.D.)

meaning that the position of the target is as close as possible to the center of the frame, the nurse or assistant holds and stabilizes the stereotactic frame with two hands. The frame is stabilized against the patient, thereby providing a constant position in the optimal localization. The surgeon can now adjust the length of the posts to suit the patient’s head as well as to give stability to the frame while being careful to avoid bone flaps, cranioplasty materials, burr holes, or skull defects.

Post and Screw Attachment and Measurements

For targets in the posterior fossa, a low position of the anterior posts can sometimes help avoid anterior collisions with the collimator helmet, particularly if the patient has a large head. After the posts are adjusted and firmly fixed to the frame, local anesthesia is injected by inserting the needles through the holes provided for the screws. The screws can now be inserted. The goal of this step is to attain a preliminary frame fixation in the desired position. Fixation with diagonally opposing screws provides the best stability without changing the desired frame position. If the frame has to be shifted to 1 side, apply the longest screws first, thereby defining the desired distance of the target to the frame. The frame is now preliminarily stabilized with the screws on the patient’s head (Figure 6C). The length of the screws is considered to be ideal if the tips do not extend more than 8 to 10 mm off the posts; however, this surgeon prefers to limit this projection to 4 to 6 mm. If the screw extends further, exchange the existing screw with a screw that has the ideal length for the position of the head. The length of the 4 posts is determined by measuring from the base of the frame to the tip of each post. In addition to that, the length of the screws that extend over the posts is measured. These measurements are required for the frame and skull section in Leksell GammaPlan treatment planning software. The stereotactic frame attachment is completed once the volume of the head has been measured using the plastic bubble, simulating the relationship of the frame to the collimator helmet (Figure 6D). In critical positions, collisions can sometimes be avoided by using the curved posts in the anterior position in certain patients with posterior fossa tumors.

RADIATION PHYSICS

Introduction

Small and well-delineated cerebral targets can under certain circumstances be treated selectively with narrow, high energy radiation beams. In the Leksell Gamma Knife, this radiation is emitted by 201 sources of 60Co. Healthy brain tissue located between skull and target can be relatively spared provided that a suitable irradiation technique has been chosen and the target is small. Depending on the histologic type of target and...
the size, a single maximum dose of 20 to 160 gray (Gy) is prescribed (10 to 80 Gy delivered to the 50% isodose line). Currently, for vestibular schwannomas, the routine prescription is 12 to 14 Gy delivered to the 50% isodose line, which will be defined later. The actual irradiation procedure is carefully planned for each individual patient by means of calculated dose distributions overlaid on images of the brain, cranial nerves, and surrounding structures. The quality of the resultant treatment plan, which is tailored using virtual planning software, must then be assessed using tools described later.

**Basic Concepts of Radiation Physics**

“Radiation” is defined as the emission and propagation of energy through matter or space by means of electromagnetic disturbances that display both wave-like and particle-like behavior.3 The particles are known as “photons.” “Radiactivity” is a property of all unstable elements that regularly decay to an altered state by releasing energy in the form of photons or particles, such as electrons. In essence, then, radiation and radioactivity describe the release of energy to a medium. In addition, for clarification purposes, “X-ray” is the term used to describe energy that is emitted from a machine such as a linear accelerator; “gamma ray” is the term used to describe energy emitted from a radioactive source. Essentially, X-ray and gamma rays have the same properties; the only difference is that gamma rays have a much narrower range of energies, for example, 10 kilo-electron volts (keV) to 10 mega-electron volts (MeV), than X-rays.5

In the case of gamma knife, the source of radioactivity is cobalt 60. Cobalt 60 decays to a more stable element, nickel (Ni 60) when 1 of the neutrons of the 60Co nucleus transforms spontaneously into a proton and an electron (Figure 7). The proton stays in the nucleus, but the electron, which is of low energy, is emitted, but is of such low energy that it has no biologic effect. Also during this process, gamma rays of 2 different energies are emitted by the nucleus: 1.17 and 1.33 MeV. The gamma rays are of high energy and are highly penetrating; this energy is absorbed in tissue and can cause a biologic effect. Thus the name is “gamma knife.” The half-life of a radioactive sample is the time required for half of the atoms in the sample to decay to its stable form.5 The half-life of cobalt 60 is 5.27 years. In practice, this means that after little more than 5 years, the treatment time for the same prescribed dose is doubled because there are only half as many atoms decaying now, and therefore half as many gamma rays are being given off in a given period of time. In turn, it takes more time to get the prescribed dose to the target. Finally, the treatment time becomes too long, and the sources must be replaced.

Radiation can be ionizing or nonionizing. Types of nonionizing radiation include heat, microwaves, visible light, and radio waves. These types of energy have longer wavelengths than X- and gamma rays and therefore are of lower energy; usually the nonionizing types of energy are absorbed more uniformly and evenly and much greater amounts of energy in these forms are needed to produce damage in living things. On the other hand, ionizing radiation, such as X- and gamma rays, are of high energy; the important characteristic of ionizing radiation is the localized release of large amounts of energy, for example, enough energy to break chemical bonds and produce biologic effects. The biologic effects of radiation are caused mainly from damage to DNA. The process whereby this happens is described below.

The gamma rays from 60Co are absorbed in tissue via the Compton effect. In this process, the gamma ray photon interacts with a loosely bound electron of an atom in the tissue. Part of the energy of the photon is given to the electron as kinetic energy. The photon, in turn, is deflected in its path, and has a reduced energy. The electron, now called a “fast” electron, is freed from its bond to the atom (therefore, the atom has been “ionized”) and can go on to ionize other atoms of the tissue or break chemical bonds. The net result is the production of a large number of fast electrons in the tissue. These fast electrons, then, can cause damage to tissue in 2 ways: indirect action and direct action.

Direct action results when a fast electron interacts directly with DNA to cause damage, such as a single or double strand break. Indirect action occurs when a fast electron interacts with a water molecule to produce a hydroxyl radical, which is
highly reactive; the hydroxyl radical can then produce DNA damage by breaking chemical bonds in the DNA. Eighty percent of a cell is composed of water; and, for gamma rays, indirect action dominates. Once the damage to DNA has been done; however, a cell does not die until it tries to reproduce. This is called mitotic cell death. The most common form of cell death is mitotic death: cells die attempting to divide because of damage to chromosomes. Therefore, it may take days, months or even years for a biologic effect, such as tumor shrinkage, to be seen from radiation, depending on how fast the cells are replicating. There is, however, another type of cell death: apoptosis. Apoptosis is programmed cell death and is common in embryonic development as certain cells become obsolete, for example, when tadpoles lose their tails. However, radiation can induce apoptosis in certain cell types, such as lymphoid cells. Therefore, although mitotic death is the predominant mechanism of cell killing, apoptosis can also contribute, especially in lymphoid and hematopoietic cells.

A absorbed dose, or "dose," of radiation is the energy imparted per unit mass by ionizing radiation to matter at a specific point. The international System of Units (SI) unit of absorbed dose is joules per kilogram, otherwise known as Gy. The previously used special unit of absorbed dose, the rad, was defined to be an energy absorption of 100 erg/g. Rad, however, is an older, outdated term and has been replaced by Gy; 1 Gy is equivalent to 100 rad.

Therapeutic radiation can be prescribed in many different ways. For example, it is frequently prescribed to a point, for example, "isocenter," the point at which the gantry of a linear accelerator rotates around, which ideally corresponds to somewhere inside the target, and sometimes to an "isodose line." Isodose lines are a way of describing the dose distribution: for example, the 100% isodose line shows the distribution of 100% of the prescribed dose, which is usually overlaid on the computed tomography (CT) or magnetic resonance (M.R.) images so one can visualize how much dose the target and surrounding tissue would be receiving from a particular treatment plan; the 90% isodose line shows the distribution of 90% of the prescribed dose, and so forth. The 50% isodose line shows where 50% of the prescribed dose lies. In the case of gamma knife treatments, the dose is frequently prescribed to the 50% isodose line, which ideally conforms tightly around the tumor. Therefore, this ensures that the periphery of the tumor will receive at least the prescribed dose, but the dose will be higher than the prescribed dose inside the tumor as discussed below.

There are 2 reasons for prescribing the dose in this way. The first reason is that for stereotactic treatments, 1 of the goals is to minimize the dose to the normal, surrounding tissue. If the dose is prescribed to the 50% isodose line, the fall-off of dose outside the target area is the most rapid. Therefore, the surrounding tissues are spared the most, when the treatment is prescribed in this way. The second reason is that there are many clinicians who believe that a large hot spot of dose in the center of the tumor is critical for successfully treating with the gamma knife. When one prescribes to the 50% isodose line, the maximum dose in the tumor is actually double the prescribed dose; for instance, if one prescribes 12 Gy to the 50% isodose line, there is a hot spot of 24 Gy inside the tumor. Care is also taken in the treatment planning phase to avoid overlap of the hot spot with the course of the facial nerve or the cochlea. Traditionally, this is the way gamma knife treatments have been prescribed and good results have been obtained. With linear accelerator stereotactic treatments, a hot spot in the center of the tumor is not necessarily obtained, and good results have also occurred with this type of treatment. Therefore, whether or not the hot spot in the center of the tumor is critical to the treatment is unknown, but there are many ardent believers that this is the reason why gamma knife is so effective.

The radiation dose decreases with depth in tissue due to 2 phenomena. First, the number of energy transporting photons decreases with depth as they are absorbed by the tissue. Second, the dose decreases with depth due to the inverse square law, which states that when the distance to the radiation source is doubled, the dose is decreased by a factor of 4. This effect dominates in the case of Leksell Gamma Knife as the distance from source to target is short; however, a single beam delivers most of its radiation dose to the region of its entrance. In the following section, the strategy developed by the gamma knife system to overcome this issue is outlined.

Irradiation Technique

To overcome the problem that single photon beams deliver most of their energy at the beam entrance, we need to cross fire the target with radiation from many directions. A large number of beams can be directed so that they converge toward 1 single region where the target resides during treatment. At the beam intersection, energy from all beams is delivered to the cells. Outside that region, the radiation dose decreases rapidly so that tissue between the beam entrance and target is spared of significant amounts of radiation.

There are several technical solutions for achieving a convergent beam irradiation technique. A single radiation source can be moved relative to the patient’s head or vice versa. Naturally, a combination of patient and source movements can also be used. The safest and most reliable converging irradiation technique is the 1 with irradiation emitting sources moving and the patient remains stationary during treatment. This stationary procedure requires that the patient’s head is surrounded by a large number of sources during treatment and all the beams are aiming at a common region where the radiosurgical target resides. This is the technique utilized in the Leksell Gamma Knife. Radiophysical and technical tolerances of all components that affect dose delivery are so narrow that all 201 beams of 1 unit are identical from a radiophysical perspective. This fact holds true not only for each unit but also for all units of the same design, facilitating comparison of clinical results published by different Leksell Gamma Knife centers. As the beam characteristics are identical, they do not need to be measured at each individual Leksell Gamma Knife installation. They are therefore prestored in the treatment planning software, Leksell GammaPlan, greatly simplifying commissioning of the entire Leksell Gamma Knife.

When treatment is initiated, the treatment couch is automatically moved from its idie position into the treatment unit together with patient and helmet. Once the couch is docked in its treatment position, the helmet collimator and corresponding collimators in the unit form a beam channel, allowing the radiation that is continuously emitted by the sources to reach the patient (see Figure 1). At the end of each irradiation “shot,” the couch is automatically withdrawn, either to its idie position or to a position outside the radiation focus to reposition the patient for the next irradiation “shot.” There are 4 interchangeable helmets by means of which the size of the collimator (that part of the treatment unit that shapes the beam) can be changed between 4, 8, 14, and 18 mm (Figure 8). The combination of 4 different sized collimators and repositioning the patient in the 3-dimensional (3D) space defined by the stereotactic headframe are effective to deliver the radiation dose selectively and conformally to radiosurgical targets of any shape (Figure 9).

The use of convergent, narrow beams poses some strict technical and radiophysical requirements on the radiation delivering apparatus. The axis of all beams must intersect at a single point, and its exact location and spatial must be known precisely. The radiophysical character of the radiation beams must be well known, stable in time, and optimize to the sharp beam edges. Figure 10 illustrates these basic requirements in principle, which are important for selective and reproducible dose delivery. Four beams are shown intersecting the center of a 2-dimensional (2D) target. It is important that the beam axes are precisely aligned. Any intersection of the beam axes that deviates from the ideal will affect the dose distribution. Imperfections inherent in all equipment, regardless of manufacturer, must be kept small enough not to have any clinical significance during the lifetime of the treatment unit. Consequently, technical and radiophysical characteristics of the system and their consistency limit the smallest collimator that safely and reproducibly can be used. Figure 11 illustrates the real narrow beam situation of Leksell Gamma Knife discussed previously on a hypothetical level with the combined dose distribution of all 201 beams. This also illustrates the beam size effect and the penumbra (the region near the edge of the field where the dose falls rapidly) associated with each of the 4 collimator helmet sizes. With wider beams, alignment is less critical. On the other hand, their edges begin to overlap farther from the target periphery (Figures 10 and 11). The distance at which the beams begin to overlap depends on beam size for a given irradiation technique, meaning that the dose outside the
target periphery depends on the beam size. Figures 10 and 11 also show that an increasing number of beam edges overlap with the beams approach the target periphery. This theoretically means that a relatively high dose can be delivered outside the target to a large volume of normal tissue. Thus, as the beam size increases, at some point one can no longer claim that the treatment is selective, and one must find an alternative irradiation technique. The dose absorbed in normal tissue adjacent to the target periphery is the most significant factor limiting the largest volume that can be treated radiosurgically. The widest beam of Leksell Gamma Knife is 18 mm in diameter at isocenter, here shown as an off-axis distance (Figure 11).

Quality Assurance

When the radiophysical characteristics of a Leksell Gamma Knife are investigated for quality assurance purposes, measured and calculated dose profiles are compared. At present, experimental profiles are obtained by means of chromatographic film dosimetry. The special dose distribution is verified by means of 2 films. The films are consecutively exposed in Elekta's spherical head phantom and rotated 90° relative to each other. The calculated profile is used as a template. Optical density (OD) profiles are measured from the films along the 3 main axes of the stereotactic coordinate system. The OD profiles are converted into dose profiles by means of an OD dose calibration procedure. The measured profiles are compared with corresponding profiles that are calculated using the Leksell GammaPlan software. The calculations are made assuming the same irradiation conditions as the experimental ones. These hypothetical profiles are used as reference. The distribution of the dose in a volume surrounding the radiation focus is investigated in this way. The stereotactic spherical volume used to expose films for evaluating dose distribution of Leksell Gamma Knife does not have the narrow geometrical tolerances required to determine the location of the radiation focus in the irradiation unit. For this purpose, an aluminum bar that is machined to narrow tolerances is used. It has a spring-loaded needle and a space for a small film. When the tool is aligned exactly between the trunnions of the helmet, the sharp tip of the needle is located in the exact mechanical isocenter. Just prior to the exposure of the film, it is pierced by the needle. The location of the OD distribution is compared with the location of the narrow hole in the film. The two films are exposed consecutively with their planes rotated 90°. The deviation between the center of the OD and the needle hole is measured in the direction of the three main axes of the stereotactic coordinate system. The deviation between the mechanically defined isocenter and the location of the radiation focus is measured in this way.

Biologic Effects of Radiation

Radiation dose is the single most important factor that determines the outcome of a radiosurgical procedure, but it is far from being the only factor. The type of radiation is important. Earlier the treatment with gamma (photon) irradiation was described; however, protons, neutrons, and electrons are also used to treat certain tumors. This is called "particle radiation," and the different particles interact with tissue in different ways; however, the end result is still DNA damage that causes a biologic effect.

Fractionation is extremely important in radiation therapy. In stereotactic radiosurgery, there is typically 1 fraction; however, with traditional external beam radiation therapy, the fraction size (number of treatments) can be anywhere from 2 to 40 or more. Fractionation is important in terms of reducing normal tissue complications; and, in certain situations (such as optic nerve tumors), fractionated stereotactic radiotherapy (rather than radiosurgery) is preferred. The concept behind this is sublethal damage repair. Radiation causes a variety of injuries to DNA, the majority of which are repaired by cells. However, the capacity for DNA repair is diminished in cancer cells. Therefore, by breaking up the radiation into relatively small dose fractions (usually 1.8 to 2.0 Gy per day), normal cells tend to be marginally spared from permanent damage as compared to cancer cells after a given day of treatment. This increment in benefit is cumulative over a 30 to 40 day course of therapy that results in the net sparing of normal tissue. Note that this effect is lost if all the radiation is given in 1 day. Absence of sublethal damage repair is also the reason why lower doses are needed with radiosurgery to control the disease.

Radiosurgery does have the potential to cause significant toxicity. Therefore, it is important in radiosurgery to keep the high dose areas away...
The Beam Size Effect

Helmet | Penumbra
--- | ---
4 mm | 2.8 mm
8 mm | 5.0 mm
14 mm | 8.1 mm
18 mm | 10.1 mm

Figure 11. Gamma knife radiosurgery. The beam size effect is shown graphically and numerically. The right-hand side of the figure shows the isodose curves for the 4, 8, 14, and 18 mm collimator helmets. (Published with permission, copyright © 2007, P.A. Wackym, M.D.)

from normal tissue, especially radiation sensitive tissue, such as the optic nerves, optic chiasm, brainstem, and spinal cord. As an example, it has been found that approximately 8 Gy is the maximum tolerated dose of the optic chiasm when using a single fraction of radiation, such as in radiosurgery. However, if using fractionated treatment, the normal tissue tolerance of the chiasm is approximately 54 Gy. This same concept holds true for tumor control doses: higher total doses are needed in fractionated treatment to get the same tumor control as a lower dose in 1, single treatment, due to sublethal damage repair by the tumor cells between fractions. Therefore, considering the patient with a meningioma encasing the optic nerve, if the tumor was treated with stereotactic radiosurgery, a dose of approximately 12 Gy would be needed; however, the optic nerve can only tolerate approximately 8 Gy without risking serious vision compromise. With fractionated treatment, a dose of 54 Gy to the tumor would be adequate to control the tumor, and the optic nerve can tolerate 54 Gy if given in 1.8 Gy daily fractions; for this patient, then, one could treat the tumor adequately with fractionated radiotherapy while still respecting the tolerance of the optic nerve. However, the accuracy of radiation delivery via a fixed headframe in a single session compared to multiple sessions without a fixed headframe also should be considered. Therefore, each patient should be evaluated to determine whether radiosurgery or fractionated radiotherapy is the most appropriate treatment. The radiation tolerance of the cochlea is unknown.

Dose rate is also important in radiation therapy. Dose rate is defined as the radiation dose delivered per unit time; it is measured in Gy/h.10 In general, as the dose rate decreases, the biologic effect of a given dose is reduced. This is because sublethal damage repair can occur during a long radiation exposure, if the dose rate is low enough. There has been some concern regarding the aging sources in gamma knife units, and whether the lower dose rate affects tumor control rates. Kondziolka and colleagues, reviewing the University of Pittsburgh treatment outcomes, found no clinical difference in tumor control rates during the first 9 years of use of their first gamma knife unit, prior to reloading.11 However, they did notice that cranial-nerve morbidity was higher than expected during the first year. It was felt that this may have been due to the higher dose rate during the first year of operation of their gamma knife unit. However, there has been no study to date to show a detrimental effect on tumor control due to decreasing dose rate from aging gamma knife sources. If there is an effect, it is most likely small and not clinically important.

In addition to dose, dose rate and fractionation, the volume of the radiated field is important. With vestibular schwannomas, treating with a plan in which the dose tightly conforms around the tumor is important, as the goal is also to spare as much normal tissue as possible. However, for brain metastases, for example, the actual borders of the target may be difficult to define and treating the target with some margin of surrounding normal tissue may be more effective in eradicating the tumor than a tight dose around the target. Also, certain tumors may be located in more critical areas, and it may be more important to have a rapid dose fall-off to spare normal tissues (such as the brainstem) rather than a high dose to the tumor. In certain patients, compromises may be made. In addition, the clinical result of the treatment (including late side effects) may not occur for months or even years following the irradiation. The time interval between irradiating and observation is, therefore, important.

The biological response to radiation is also dependent on the type of cells that are irradiated. Some cell types are more radiosensitive than others; and, therefore, a lower dose may be needed to control 1 type of tumor versus another. Also, with the example of benign skull base tumors such as vestibular schwannomas, meningiomas, or paragangliomas, few cells are actively dividing at the time of treatment. Therefore, the primary effect may not be in destroying these more radiosensitive dividing cells, but rather a longer-term decrease in the vascular supply to the tumor.

Radiosurgery appears to cause endothelial cell injury in the blood vessels; in turn, the vessels become hyalinized and thickened and eventually close. This takes many months to occur. Eventually, fibroblasts replace much of the vessel. In addition, it is believed that the blood vessels in tumors are abnormal and, therefore, are more sensitive to radiation injury than blood vessels outside of the tumor. Therefore, this may also explain, in part, why the tumor is destroyed while the surrounding tissue is spared. As will be discussed later, this was a hard lesson learned in the initial application of gamma knife radiosurgery to these types of benign tumors. The use of radiation doses appropriate for malignancy resulted in excellent tumor control; however, unacceptably high levels of hearing loss and trigeminal and nerve dysfunction occurred.1 It has been pointed out by Pitts and Jackler,12 however, that there has been no evidence presented that decreased vascularity occurs after gamma knife therapy and in the animal studies performed by Linskey and colleagues13 there was no reduction of vascularity in xenograft vestibular schwannomas after treatment with 10 Gy. Using regional cerebral blood flow studies in patients with vestibular schwannomas before and after gamma knife radiosurgery, we have found a reduction in blood flow with the tumors. Figure 12 shows the pretreatment M R1 and the typical appearance 6 months after gamma knife radiosurgery. This patient received 12 Gy at the 50% isodose line, which means that the maximum tumor dose was 24 Gy focused where the reduced gadolinium enhancement within the center of the tumor was found. It is thought that higher central doses in addition to a delayed decreased vascularity at the tumor periphery are most likely the reasons for the loss of contrast in the center of the tumor after radiosurgery.11 In summary, although the radiation dose is a critical factor in tumor control, it is not the only factor that should be considered.

TREATMENT PLANNING

Placing Shots

Leksell GammaPlan is the dedicated software treatment planning system for Leksell Gamma Knife. Dose planning for gamma knife surgery means precisely conforming the isodose
distribution to the target. The isodose distribution is built-up by a number of individual shots or isocenters. The Leksell GammaPlan software is designed to help the operator as much as possible to perform this procedure and is quite straightforward to use (Figures 13 and 19).

Dose planning using Leksell GammaPlan involves composing shots to develop a conformal isodose. By definition, this includes the whole target but spares the surrounding healthy tissue. Figure 13 shows an example of vestibular schwannoma. The target is well positioned on the screen and magnified for good visibility. When the shot menu is opened, one can select the size of the collimators. Selecting 14 mm would be too large for the target and would not give an effective treatment plan. The shots are placed sequentially, and the size of the collimator is selected based on the tumor shape and the gaps in coverage of the 50% isodose line displayed over the tumor. Shots are placed to cover the target as effectively as possible. Changing the position of the shots and additional shots with low weight quickly lead to a conformal dose plan. The dose plan can be checked using Leksell GammaPlan with the 3D image or the measurement tools, such as dose volume histograms. While the subject of conformity index is beyond the scope of this chapter, an excellent review of available methods has been published.14 Leksell GammaPlan indicates the point in the stereotactic space where a global maximal dose can be found. Leksell GammaPlan also calculates the individual shot times. Once the treatment plan has been determined to be appropriate by the team (surgeon, radiation oncologist, and radiation physicist), the stereotactic coordinates and irradiation times are printed and used during the gamma knife treatment.

**Wizard**

An automated approach to initial treatment planning has been developed by Elekta Instruments AB. This software assists the treatment planner in generating a good initial dose plan quickly and is termed “the Wizard.” This is an interactive tool that helps the operator develop the dose plan. The operator first selects the shot size and the degree of density with which the Wizard should fill the target. A mouse click instructs the Wizard to fill the target with shots. If the initial dose distribution is not sufficient, a mouse click on the run button instructs the Wizard to optimize the plan by moving and weighting the shots. This interaction results in a better dose plan, and after a few more changes a satisfactory dose plan can be created. However, in this surgeon’s experience, manual placement of the shots, particularly for vestibular schwannomas, has always resulted in a better treatment plan.

**Fine-Tuning**

Fine-tuning is made with small adjustments, allowing optimization of the dose plan. Leksell GammaPlan simplifies this. For example, if the 3D image shows missed dose to part or parts of the target, shots can be moved, weighted, or added to produce a more conformal plan. As shown in Figure 14, high isodose lines show the dose distribution inside the target, making homogeneity and hot spots easily visible. Low isodose lines show the dose in the surroundings of the target. The purpose of this step is to show the dose distribution at risk structures, such as the facial nerve, to minimize the risk of complications after treatment. Leksell GammaPlan also allows the creation of different plans for the same target. This allows the operator to follow different strategies and later compare plans and select the best plan for the actual treatment. Treatment plans can utilize as few as 1 or 2 shots, such as when treating trigeminal neuralgia, or as many as 10 to 12 shots when treating a 2 cm vestibular schwannoma (maximum axial dimension within the cerebellopontine angle) plus filling the internal auditory canal. With the enhanced capabilities of Leksell Gamma Knife C, plans with 20 shots or more can easily be implemented.
in a timely manner, since the model C does not require manual adjustments of the \(X\), \(Y\), and \(Z\) coordinates by the gamma knife treatment team. This allows improved conformity and selectivity of gamma knife surgery, potentially reducing the risk of complications.

**Plugging**

To shape the dose distribution for the low isodose lines in one direction in particular, one or more of the 201 collimators can be replaced with a closed shield, called a plug. One can select spherical areas called shields with different diameters and place them over risk centers in the brain, cranial nerves, or lens of the eyes. Once the shields are put in place, within the software, Leksell GammaPlan closes off all beams that would irradiate through the shielded area. The result is a modified dose plan in the low isodose lines with only little affect on the target peripheral isodose. The beam channels that need to be plugged can be seen in the plug pattern (Figure 15). The plug patterns can be merged for all shots of the same size so that the operator only has to plug the helmets for the treatment once.

**Peripheral Isodose**

In the final plan, the peripheral dose is set to a value, which is assessed as optimal for a particular patient. Indication, size, and location of the target are taken into account, as well as clinical experience. The peripheral isodose is usually set to the 50% isodose line. This is exactly half the maximum dose in the target, referred to as the hot spot (see Figures 12 and 14). Along the 50% isodose line the dose gradient is usually the steepest ensuring sufficient dose within the target, while the dose level outside falls steeply, sparing the surrounding healthy tissue. Leksell GammaPlan can also display the absolute dose values if desired. It will show the point in the stereotactic space where the global maximum dose can be found. With vestibular schwannoma it is valuable to complete this exercise, as the maximal dose at the “hot spot” should be positioned well away from the facial nerve and cochlea. In addition, plotting the absolute dose lines will help in determining the actual level of radiation delivered to surrounding structures.

**Grouping Shots**

When the dose planning is completed, Leksell GammaPlan has to check and sort the shots. Assume for example, that the treatment consists of two shots with 8 mm collimators and five shots with 4 mm collimators. Leksell GammaPlan will group all shots and use the same collimators during each series of shots of a given size. For the model C unit, the operator does not have to enter the treatment room during a run. However, with the model B the treatment team reenters the treatment room after each shot is delivered and manually adjusts the \(X\), \(Y\), and \(Z\) coordinates, as well as the gamma angle, that is, the pitch of the...
head, if necessary. With both the model B and model C, the team has to change the collimator helmet manually when necessary, as dictated by the treatment plan.

Protocols

Detailed treatment and physics protocols can be viewed and printed out. All relevant data can be documented including details of the treatment plan, targets, dose volume histograms, snap shots, and images.

Export

When the treatment setup has been completed, the treatment protocol has to be exported to Leksell Gamma Knife. This is via a special secured direct serial connection. Leksell GammaPlan only accepts valid and verified treatment plans for export. A n addition, a protective design limits the transfer of a treatment plan to the Leksell Gamma Knife to 1 patient at a time. Once the data have been transferred to the operator’s console, it is verified, and the patient can be treated.

**TREATMENT PROCEDURE**

**Manually Setting Coordinates**

Treatment can be performed automatically using the APS or manually using trunnions. As described above, for the model B, manual setting of the X, Y, and Z coordinates as well as the gamma angle if necessary is accomplished by the treatment team. The Y and Z coordinates are set with the Y, Z slides on the coordinate frame, whereas the X coordinate and the gamma angle are set with the trunnions. A nother check and balance that is in place is the visual verification of each coordinate by a different team member.

**Automatic Positioning System**

With the APS, the treatment is controlled from the operator console. Once the treatment starts, the selected run is carried out automatically. Before repositioning, the couch will move out a short distance to bring the patient out of treatment focus. At this point, the APS will move the patient’s head to the next target position. When the first run is completed, the remaining runs, with different sized collimator helmets, are selected and performed in the same manner after manually changing the collimator helmet.

**NEW GAMMA KNIFE TECHNOLOGY: PERFEXION**

In 2002, a group of international experts were asked by Elekta Instrument AB to define the requirement specifications for a new gamma knife. The group concluded that the basic principle of multiple converging fixed beams and patient immobilization with the stereotactic frame provided the most reliably precise and accurate radiosurgical solution. The group agreed on 5 critical features: best dosimetry performance, best radiation protection for patient and staff, unlimited cranial reach, full automation and outstanding patient, and staff comfort. Based on these specifications, Elekta Instrument AB developed a completely new radiosurgical instrument which they named the Leksell Gamma Knife Perfexion. Interestingly, this instrument is capable of treating lesions of the head and neck using radiosurgery. Consequently, it is likely that this technology will play a much greater role in the practice of otolaryngology—head and neck surgery.

In contrast to earlier gamma knife units, the Perfexion has a single integrated permanent collimator system that incorporates openings for collimators of 3 different diameters. The new collimator design incorporates computer-controlled movements that vary the size and position of the openings, and these can be individually varied among 4, 8, and 16 mm or be blocked off. This provides a virtually unlimited ability for sculpting the dose distribution, enabling dynamic shaping with the same degree of accuracy inherent in a framed-based system.

Although the new Leksell GammaPlan PFX treatment planning software is more sophisticated than the current GammaPlan software, it was designed to have full backward compatibility to existing gamma knife radiosurgery protocols and methods. One major new feature is that the institution-based treatment planning system can be accessed remotely, providing access to all patient data in the online database. To increase the seamless access, Leksell GammaPlan PFX is now hosted on a personal computer platform with a Linux operating system rather than the dedicated proprietary workstation used in the past.

The first Perfexion unit was installed atTimone University Hospital of Marseille in July 2006. To evaluate the capabilities, advantages, disadvantages, and limits of this new technology, 83 patients were included in a prospective trial. Among these, 59 patients were eligible for the comparative prospective study based on inclusion criteria of informed consent signed, tumor or vascular indication, and no previous radiosurgery or radiotherapy. In accordance with the blinded, randomization process, 29 patients were treated with Leksell Gamma Knife 4C, and 30 patients with Leksell Gamma Knife Perfexion. Dose planning parameters, dosimetry measurements on the patients’ bodies, workflow, patient comfort, quality assurance procedure, and a series of other treatment-related parameters were prospectively evaluated in both arms. The analysis of their data indicated that procedures with Perfexion were collision-free even with extreme location of the lesion, for example, multiple metastases. The duration of the radiosurgical procedure, duration of nurse, physicist and physician intervention on the unit, and the duration of the quality assurance procedure were all reduced with the Perfexion unit. Radiation protection, already good with the Leksell Gamma Knife 4C, was improved with the Perfexion unit.

**APPLICATIONS AND OUTCOMES**

In this section, attention will be focused on remaining questions that should be answered as well as examples of good and poor outcome with hearing following gamma knife radiosurgery. Comparison to surgical outcomes is addressed in Chapter 35, “Vestibular Schwannomas and Other Skull Base Neoplasms.” A plication of the technology in areas which are inappropriate will be discussed.

Just as is the case with other forms of medical and surgical therapy, the techniques and outcomes of gamma knife radiosurgery for vestibular schwannomas have evolved and improved over time. These changes in methodology have been based on patient outcome. However, now that the tumor control and facial nerve preservation (motor function) occurs with virtually all patients treated with gamma knife, it is appropriate to focus attention on further improving the techniques so that optimal hearing and balance preservation can be achieved. In addition, better assessment of hearing and balance outcomes are necessary to provide adequate informed consent to patients deciding among expectant management, microsurgery, and stereotactic radiosurgery.

In the Medical College of Wisconsin Acoustic Neuroma and Skull Base Surgery Program, we have established a clinical pathway for all of our patients undergoing gamma knife radiosurgery for primary or secondary treatment of their tumors. Following completion of their stereotactic radiosurgery, at 6-month intervals, each
patient undergoes a gadolinium-enhanced MRI as well as an audiologic test battery and caloric testing to assess peripheral vestibular function. Pretreatment they undergo a complete electr

ography. We have published data regarding the early outcomes of a cohort of patients undergoing primary \( n = 24 \) and secondary \( n = 8 \) treatment of sporadic unilateral vestibular schwannomas using gamma knife radiosurgery, and the data to be presented next extend this series both in number of patients undergoing primary \( n = 35 \) and secondary \( n = 8 \) treatment, as well as in duration, with some patients having more than 5-year follow-up data. First, the objective auditory thresholds (Figures 16 and 17), speech discrimination ability (Figure 18), and degree of vestibular paresis (Figure 19) are presented longitudinally, as are the classification of hearing using the AAO-HNS18 (Table 1 and Figure 20) and Gardner-Robertson19 (Table 2 and Figure 21) systems.

According to the subsection termed “Healthcare Professionals, Treatment Statistics” on the Elekta AB web site, there have been 32,482 vestibular schwannomas treated with gamma knife radiosurgery as of December 2005.20 Numerous reports of the treatment outcomes of cohorts of these patients have been published in the literature; however, the literature has been relatively silent regarding the reporting of balance function before and after gamma knife radiosurgery. A recent technology assessment report from the Alberta Heritage Foundation for Medical Research focused on reviewing the efficacy and costs of radiosurgery.21 Similarly, the Acoustic Neuroma Patient Archive has a summary of patient outcomes and treatment methods for 3 series of patients treated with gamma knife radiosurgery, 4 series of patients treated with fractionated stereotactic radiosurgery, and 1 series of patients treated with proton beam radiation.22 However, because the University of Pittsburgh group has the longest and largest clinical experience in treating vestibular schwannomas with gamma knife radiosurgery, their hearing outcomes will be outlined in this portion of the discussion. There have been several reports of this large series; however, the Unsworth and colleagues publication from 2005 summarizes their experience with 829 vestibular schwannomas treated between 1987 and 2002.23 The evolution of treatment dose based on patient outcome is well described; however, there are several points regarding the reporting of hearing outcomes which deserve discussion.

This extensive clinical experience included an average tumor volume of 2.5 cm³ and a median margin dose to tumor of 13 Gy. They reported what is currently felt to be the standard of tumor control in 97% of patients at 10 years, and facial nerve (motor) dysfunction in <1% of patients. Trigeminal nerve symptoms occurred in <3% of patients, and they reported that, in general, these post-gamma knife symptoms occurred when the tumors reached the level of the trigeminal nerve. No reporting of balance function has been included in the analysis of their series. Unfortunately, the reporting of their hearing preservation has limited representation of the entire 829 patients. Although the 15-year experience included 829 patients, “5-year actuarial rates of hearing level preservation and speech preservation” were reported in 103 patients, and hearing outcomes data were presented in only 267 patients. They reported “unchanged hearing preservation” in 50 to 77% of these patients, and this method of reporting auditory performance points to the difficulty in interpreting the outcome of most of the studies reporting hearing outcome in patients with vestibular schwannoma who have been treated with gamma knife radiosurgery. They also stated that “for patients with intracanalicular tumors, hearing preservation rates in those treated with 12.5 to 14 Gy at the margin showed 90% preservation of servicable hearing.”24 Unfortunately, these data are not available in these reports.

In an earlier series of 190 patients with vestibular schwannomas, Flickinger and colleagues, reviewed the University of Pittsburgh experience from 1992 to 1997.25 The average dose to the tumor margin was reduced to 13 Gy, and excellent tumor control was achieved at 97.1%. In this study, issues highlighted earlier with reporting of hearing outcome are equally apparent. They reported “hearing-level preservation” in 71 ± 4.7% of patients. They also reported a “preservation of testable speech discrimination ability” in 91 ± 2.6% of subjects. Obviously, testable speech discrimination ability is far different than useful hearing, and it is unfortunate that these authors did not report the actual auditory thresholds or speech discrimination ability. Most importantly, these were not reported as a function of time post-gamma knife radiosurgery. In addition, they reported that “hearing levels improved” in 10 (7%) of 141 patients who exhibited decreased hearing defined as Gardner-Robertson grades II to V before undergoing gamma knife radiosurgery. Based on our clinical observations and those of other centers, this picture is far more complex over time than is represented in these publications.

Prasad and colleagues from the University of Virginia reported their series of 200 vestibular schwannomas treated with gamma knife radiosurgery over a 10-year interval in 2000.26 Of these patients, 153 patients had follow-up data including 96 with primary treatment and 57 with secondary treatment. They reported no hearing pre-gamma knife in 105 patients, including 53 of 96 primary treatment and 52 of 57 secondary treatment patients. The Gardner-Robertson grading system and subjective assessment of hearing was used; however, no pure-tone average (PTA) or speech discrimination data were reported. Unfortunately, their data set included audiometric data from
Based on the unpublished data of 43 patients with vestibular schwannomas treated with gamma knife radiosurgery and hypotheses of the mechanisms of injury, it may be possible to intervene to avoid the large changes in hearing and balance function found at the 6-month assessment. One potential method to optimize hearing and balance outcomes would include the use of oral corticosteroids. Critical questions would include dosage, duration of use, and when should the corticosteroids be started relative to the radiotherapy? The use of intratympanic steroids or intratympanic antioxidant compounds may be an alternative therapeutic strategy that would minimize systemic effects of high-dose corticosteroids, provided that the primary mechanism of hearing and balance functional loss was due to hair-cell injury rather than vascular
compromise of the labyrinthine artery during the initial tumor swelling within the internal auditory canal. Until a detailed understanding of the pathophysiologic basis of late hearing loss and disequilibrium, such as the development of labyrinthine fistulas, progressive inner ear devascularization, or progressive loss of outer versus inner cochlear and vestibular hair cells, appropriate clinical interventions that will allow maximal preservation of hearing and balance function while maintaining the excellent tumor control and motor facial nerve function outcomes that our patients currently experience after gamma knife radiosurgery for vestibular schwannomas.

**Anecdotal Cases**

There are also anecdotal cases that are worthy of discussion to illustrate a few specific points about stereotactic radiosurgery and the outcomes associated with fractionated stereotactic radiosurgery or gamma knife radiosurgery. First, we have found that there is a distortion in the MRI data set produced by the stereotactic headframe used in gammaknife radiosurgery. As shown in Figure 22, the treatment plan and outline of the tumor, based on MRI treatment planning, is approximately 1 mm more anterior than the position of the internal auditory canal as visualized with CT imaging. It is especially important to recognize that several gamma knife centers utilize MRI exclusively to build the 3D work space and complete the treatment planning, raising questions about long-term treatment outcomes if regions of the tumor are undertreated, and adjacent structures, such as the facial nerve, are overtreated.

Another anecdotal case that points out the need to assess critically terms such as “tumor control” is a woman from my practice who decided to travel to a large center with a strong experience with fractionated stereotactic radiosurgery for treatment of a small vestibular schwannoma. As seen in Figure 23, the patient has had excellent tumor control when considering the medial portion of the tumor. However, it can be seen that she had progressive growth of the tumor laterally, until her fundus was completely filled with tumor. Office notes and direct conversations with the treating radiosurgeon indicated that he considered this complete tumor control. Unfortunately, as shown in Figures 24 and 25, her thresholds and speech recognition continued to worsen until she was ultimately left with no useful hearing on the side of the tumor. At 3.5 years postfractionated stereotactic radiotherapy, her PTA fell to 84 dB from 15 dB, and her speech discrimination fell from 92% clearly a poor hearing outcome.

While also anecdotal, another case illustrates a dilemma that arises when counseling a patient about management options and is, therefore, worthy of brief discussion. A young woman was referred to us for evaluation and discussion of management options for her small vestibular schwannoma (Figure 26). She had poor auditory function with a PTA of 52 dB and speech discrimination of 60%. The advantages and disadvantages of observation, microsurgery, and gamma knife radiosurgery were discussed with her at length over several office visits. Based on her age as well as the position and size of her tumor, a plan evolved for observation and ultimately microsurgical removal via a translabyrinthine approach or, alternatively, with microsurgical removal via a translabyrinthine or middle cranial fossa approach as soon as she would want to this. It was anticipated that it would likely take at least 5 or more years for the tumor to fill the internal auditory canal and, with that, still not to change the facial nerve outcome during translabyrinthine resection of the tumor. Despite this, she decided to undergo gamma knife radiosurgery. As shown in Figure 26, the tumor initially increased and later decreased in size. There was also a surprising improvement in both her auditory thresholds and speech recognition ability (Figures 27 and 28). At 3.5 years post gamma knife radiosurgery, her PTA had increased to 25 dB and her speech discrimination had improved to 90%. Longer-term follow-up is certainly necessary and will be completed; however, this outcome was not anticipated, and she continues to be extremely pleased with her management decision.

One statistic, which is particularly alarming to patients considering gamma knife radiosurgery for their vestibular schwannoma, and also often quoted by individuals who are biased against gamma knife radiosurgery, is that there have been 8 cases of malignancy within vestibular schwannomas reported to date. These have been summarized by Bari and colleagues in 2002.28 Four of these patients had been previously treated with radiosurgery and 4 others cases did not receive radiation. Whereas it remains possible that these 4 malignancies developed after the radiation treatment, it is more likely that these malignant tumors were misdiagnosed as benign at the outset of evaluation and treatment. The concept of delayed development of radiation-induced neoplasms was addressed by Pollock and colleagues in 1998.39 They reviewed the 26-year experience with radiosurgery in more than 20,000 patients worldwide, and they found no increased incidence of new neoplasm development. They defined neoplasm as a new growth of tissue serving no physiologic function, and this would include both benign and malignant disease. Rowe and colleagues recently published a retrospective cohort study comparing the Sheffield, England radiosurgery patient database with their national mortality and cancer registries.39 These data comprised approximately 5,000 patients and 30,000 patient-years of follow-up, with more than 1,200 patients having a follow-up period longer than 10 years. Among all these patients treated with radiosurgery, a single new
Astrocytoma was diagnosed, whereas, based on their national incidence figures, 2.47 cases would have been predicted. Finally, to assess the risk of radiosurgery inducing malignancy in patients with neurofibromatosis type 2 (NF2) and von Hippel-Lindau disease, Rowe and colleagues completed a retrospective cohort study of 118 NF2 and 19 von Hippel-Lindau disease patients, totaling 906 and 62 patient-years of follow-up data, respectively. They reported 2 cases of intracranial malignancy, both of which occurred in NF2 patients. One of these was thought to have arisen before the radiosurgery; the other was a glioblastoma diagnosed 3 years after radiosurgery. They concluded that gliomas may occur in as many as 4% of NF2 patients, the single case may not represent an increased risk. Furthermore, they suggested that the late risk of malignancy arising after irradiation must be put in the context of the condition being treated, the treatment options available to these individuals, and their life expectancy.

Despite the limitations of the studies just reviewed, it is important to counsel patients about this possibility. It is likewise appropriate to counsel them about the possible causes of these malignant schwannomas. Considering the possibility of radiation-induced malignancies, it is important to examine 4 major points: (1) the second neoplasm must arise in the irradiated field; (2) a latent period of at least several years must have elapsed between the radiation exposure and the development of the second neoplasm; (3) there must be histologic and radiographic evidence of the preexisting condition, in addition to microscopic proof of the second neoplasm; and (4) the second neoplasm must be of a different histologic type from that previously irradiated, to eliminate the possibility of recurrence of the original tumor or a missed diagnosis of the original tumor. With these criteria in mind, Lustig and colleagues in 1997 reported the development of a squamous cell carcinoma following radiation treatment of vestibular schwannoma. In addition, Hanabusa and colleagues reported the malignant transformation of a vestibular schwannoma following gamma knife radiosurgery. There was histologic evidence of vestibular schwannoma following a retrosigmoid resection. Four years after this resection, recidivistic tumor was identified, and the patient was subsequently treated with gamma knife radiosurgery. Six months posttreatment, the tumor had grown, and the patient underwent a combined retrosigmoid-translabyrinthine approach. Abnormal mitotic figures were observed on histologic sections, and the diagnosis of malignancy was assigned. The patient subsequently died 6.5 years after the initial treatment of the malignant disease.

A concerning early trend in stereotactic radiosurgery was the concept of “debulking” the tumor and subsequently radiating the tumor for treatment.
the purpose of “hearing preservation” and “facial nerve preservation.” The single most important variable during this process is how much tumor is resected prior to radiation. In the absence of applying intraoperative MRI to visualize the remaining tumor volume, it is a difficult task to be certain when or if the preoperative goal for debulking has been achieved. This approach is not being used in high volume vestibular schwannoma programs nationally, and the traditional neurotologist/neurosurgeon team is not involved with this “innovative” approach. Figure 29 shows an example of a patient in whom a surgeon completed a “debulking procedure” which as shown in Figure 29B was essentially a biopsy. Aside from the unnecessary expense of completing both the craniotomy and gamma knife radiosurgery, the ethical and moral questions presented by this example are troubling. In light of the current outcomes in microsurgery or stereotactic radiosurgery, there is no justification for this type of management algorithm. Figure 30 shows the treatment plan that the patient described above received. This is also an excellent example of a poor conformation to the tumor volume. As shown, the brightest (yellow) line seen outside of the tumor outline (best seen in the axial section) represents the 50% isodose line to which a prescription of 13 Gy was given. It should be noted that there is a significant amount of radiation that was delivered to the brainstem based on this plan. In contrast, Iwai and colleagues applied this concept in a more appropriate way. They reported a series of 14 patients managed over a 6-year interval with vestibular schwannomas too large (range 3.0 to 5.8 cm) to treat primarily with radiosurgery. Subtotal resection was achieved in 13 and partial resection due to hypervascularity was performed in one patient. After recovery, radiosurgery was performed to treat the persistent tumor.

One final issue to consider is tumor growth after radiosurgery. It is important to appreciate that there is an increased size of the tumor after radiosurgery. In fact, we observed a statistically significant increase in tumor size for patients whose tumors extended outside of the internal auditory canal 6 months after gamma knife radiosurgery and a statistically significant decrease at 1 year posttreatment. Typically, posttreatment edema persists for 6 months; however, this may remain for up to 1 year. Consequently pretreatment counseling should include this information. There have been anecdotal cases discussed and occasionally reported that describe increased tumor size early after radiosurgery. The challenge is in making a decision about whether to resect these tumors and when. Pollock and colleagues emphasized the need to demonstrate sustained tumor growth by serial MRI before making the decision to operate and also to review the case with the surgeon who performed the radiosurgery before a surgical decision is made. The other related controversy is whether the facial nerve dissection and preservation are more difficult during microsurgical resection.
Facial nerve. They found microvasculitis of the facial nerve, axonal degeneration, loss of axons, and proliferation of Schwann cells. In light of the radiation effects will be observed. For this reason, it should be expected that greater damage to the tumor target without as much damage to the surrounding healthy tissue as conventional radiation therapy. Thus with conventional radiation therapy, some healthy tissue is always irradiated and the target area receives a homogeneous or even dose of radiation across the entire target area. Conformal radiation treatments have the ability to deliver a higher dose within the tumor and thus can cause more damage to the tumor target without as much damage to the surrounding healthy tissue as conventional external beam radiation treatment.

With the various methods of accomplishing fractionated stereotactic radiosurgery, the patient will be fitted with some type of reusable localization device, which may be a mask or a body frame. This assists in targeting with reproducibility and consequently greater accuracy. Typically, with skull base tumors including vestibular schwannomas, the localization device is molded to fit the precise contours of the individual patient. This molded device is placed on the patient each time they receive a treatment. Multiple treatments are usually required with conformal radiation as with conventional radiation therapy. These treatments may range from 1 to 28 treatments, which is lesser than usual conventional radiation treatments. Treatment time itself for each session is typically longer than with conventional radiation therapy because of the complexity of the treatment.
The outcomes after treatment of vestibular schwannomas with fractionated stereotactic radiotherapy are being reported; however, fewer patients to date have been treated with these types of modalities than have been treated with gamma knife radiosurgery.39–41

Intensity Modulated Radiation Therapy

Intensity modulated radiation therapy (IMRT) is a powerful, relatively new technology. This therapy can be used to target skull base tumor cells while limiting radiation to important normal tissues such as the eyes, optic nerves, brain, brainstem, adjacent cranial nerves, inner ear, salivary glands, and spinal cord. There are 5 principal advantages of IMRT compared to traditional radiation therapy. These are: (1) decreased chance of harming normal cells; (2) decreased radiation dosage to sensitive surrounding tissue; (3) delivery of higher radiation dosage to cancer cells; (4) precise radiation distribution; and (5) increased chance of destroying tumor cells.

A more traditional radiation therapy is called 3-dimensional conformal radiation therapy (3D CRT) that uses digital diagnostic imaging, a computer workstation and specialized software to conform the radiation beam to the shape of the tumor. IMRT is the latest advancement in 3D CRT technology. IMRT not only uses 3D imaging and treatment delivery, but also allows use of varying intensities of radiation to produce dosage distributions that are more conformal to the tumor volume than those possible with 3D CRT.

In IMRT, small beams, sometimes referred to as beamlets, with varying intensities can be aimed at a tumor from many angles. The intensity of each beamlet can be controlled. The radiation dose can be made to bend around important normal tissues in a way that is impossible with traditional radiation techniques. Special high speed computers, treatment-planning software, multileaf collimators which control the radiation beams, diagnostic imaging, and patient-positioning devices are used to plan individual treatment and control the radiation during therapy (Figures 31 and 32). IMRT uses inverse treatment planning in which the computer workstation and associated software are used during treatment planning to determine the ideal beam arrangement and intensity based on the desired dosage. IMRT can improve the effectiveness of radiation therapy by delivering a larger radiation dose to tumor cells while reducing the dose to surrounding normal cells. The anatomical position of the tumor and surrounding normal tissues must be accurately defined for IMRT to be effective. CT and MRI scans provide the necessary 3D anatomical information which is used within the software platform during the treatment planning.

In contrast to gamma knife radiosurgery, but similar to fractionated stereotactic radiotherapy, a regimen of IMRT is usually given over several weeks. The total dose of radiation and the number of treatments needed depend on the size,
location, and type of tumor, the patient’s general health, and other medical therapy the patient is receiving.

**TomoTherapy**

In the same way that IMRT has improved on 3D techniques to allow more precise treatment to a specific target, TomoTherapy takes it a step further. The TomoTherapy machine (TomoTherapy Inc., Madison, WI), has an appearance similar to a traditional diagnostic CT scanner (Figure 33). However, it is really a CT scanner and a linear accelerator combined. The linear accelerator delivers high energy radiation to treat a target, and the CT scanner is used to ensure that the patient is positioned properly on a daily basis. The CT is not of diagnostic quality, as high energy radiation is used (vs low energy used for diagnostic scans); but the scans are clear enough to detect bony anatomy and most soft tissue anatomy well enough, and small positioning changes can be made (within a few millimeters) to ensure as accurate a treatment as possible.

With IMRT, there are a specific number of stationary beams, usually 7 or 9, which are directed at the target from various angles. With TomoTherapy, however, radiation is delivered in a circular motion around the patient; and, after approximately every 7° of rotation, radiation is delivered to the target.

---

**Figure 29** Gamma knife radiosurgery. An example of what is being described as an “innovative” combined microsurgery and radiosurgery approach to the management of acoustic neuromas. Advocates of this method anecdotally assert that better hearing preservation and facial nerve outcome can be achieved. With this example, essentially a biopsy of the tumor was performed, followed by gamma knife radiosurgery. Ethical and cost-effectiveness issues are raised. **Figure 30** Gamma knife radiosurgery. Poor treatment plan including poor conformation of radiation dose to tumor margin (brightest circle, yellow, represents 13 Gy at the 50% isodose line). Note excessive radiation delivered to brainstem (a portion receives 13 Gy at the 50% isodose line) and inadequate treatment of internal auditory canal portion of tumor (portion outside of the 50% isodose line). (Published with permission, copyright © 2007, P.A. Wackym, M.D.)

**Figure 31** Stereotactic radiotherapy using intensity modulated radiosurgery. The Novalis Shaped Beam Surgery system is shown. This system is described as a high resolution intensity modulated radiotherapy instrument and technique. (Published with permission, copyright © 2007, BrainLAB AG, Munich, Germany.)

**Figure 32** Multileaf collimator. Intensity modulated radiotherapy (IMRT) systems use multileaf collimators that shape the radiation fields that are delivered to the tumor. The Novalis Beam Shaper uses 3 mm fine leaves for high resolution IMRT. (Published with permission, copyright © 2007, BrainLAB AG, Munich, Germany.)

**Figure 33** The TomoTherapy machine has an appearance similar to a traditional diagnostic CT scanner; however, it is really a CT scanner and a linear accelerator combined. The linear accelerator delivers high energy radiation to treat a target, and the CT scanner is used to ensure that the patient is positioned properly on a daily basis. The CT scans are able to detect bony anatomy and most soft tissue anatomy and therefore positioning changes within a few millimeters ensures treatment accuracy. delivered to the patient. Therefore, instead of 7 or 9 beams, this is like having approximately 51 beams encircling a target. The result is a con-formal treatment around a specific target, while sparing normal structures nearby. TomoTherapy is a new technology and has been available only since the mid- to late-1990s; therefore, new applications for its use are still being developed and at this point in time, there are no published studies using TomoTherapy for stereotactic radiotherapy. However, it is estimated that the accuracy of TomoTherapy is approximately within 1 mm, using an aquaplast mask for immobilization of the head (compared to 0.5 mm with the stereotactic head frame used with gamma knife), and there may be a role for treating certain tumors, such as brain metastases, in the future with TomoTherapy, either with fractionated treatment or a single fraction. One dosimetric difference between TomoTherapy and IMRT is that with TomoTherapy, the patient tends to have more low dose radiation to a larger area (since the beams are coming from 360°); while with traditional IMRT, the low dose region is smaller, but the hot spots in and around the target tend to be higher. The clinical implications of having a larger low dose region are not known at this time. Therefore, based on these differences, the radiation oncologist and surgeon may choose 1 technology over the other for certain clinical cases.

**CyberKnife Stereotactic Radiosurgery**

**Overview of Treatment Planning.** The CyberKnife system’s LINAC maneuverability offers the radiosurgery team several treatment options. The treatment planning system is designed to support the radiosurgery team in determining the optimal plan, including beam weight, targeting positions, dose distributions, and other factors for each patient’s treatment. The CyberKnife stereotactic radiosurgery system permits the following planning and delivery options: (1) inverse planning; (2) nonisocentric delivery; and (3) hypofractionation. The system is based on CT scanning. MR images can be fused with the CT to provide optimal information on soft tissue as well as skeletal anatomy. CT angiography can be used when vascular skull base lesions, such as arteriovenous malformations or extensive glomus jugulare tumors are to be treated with this technique.

Additionally, the CyberKnife system provides a range of treatment options, including the ability to use either forward or inverse treatment planning, allowing the radiosurgery team to customize each patient’s treatment plan. With forward treatment planning, the radiation oncologist determines what dose to deliver from a particular targeting position. Subsequently, the planning software calculates the total dose within the lesion for the user. With inverse treatment planning, the radiation oncologist specifies total dose to be delivered to the tumor, and the surgeon and radiation oncologist set boundaries to protect adjacent critical structures. The software determines targeting positions and dose to be delivered from a particular targeting position. While other stereotactic radiosurgery systems offer the inverse planning option, the number of possible plans is somewhat limited by the constraints of the delivery system. The flexibility of the robotic arm supporting the linear accelerator potentially allows the CyberKnife to implement a wider range of treatment plans than other systems. Furthermore, because the system does not require the use of a stereotactic head frame temporarily attached to the patient’s head, it allows scanning, treatment planning, and quality assurance to take place at any time prior to treatment itself.

**Dose Distribution.** The CyberKnife system offers a choice of nonisocentric or an isocentric treatment approach. With other stereotactic radiosurgery systems, a fixed calculated isocenter is used. Isocentric treatment, or multiisocentric treatment, involves filling the lesion with a single or multiple, overlapping spherically shaped dose distributions. Isocentric treatment is effective for spherical lesions. However, with irregularly shaped lesions, isocentric delivery can produce significant dose heterogeneity (Figure 34). Clinically, this is not a significant issue, provided that the treatment plan accounts for the relationship of the maximum dose to the critical structure to be considered. For example, if a gamma knife radiosurgery treatment plan for a vestibular schwannoma uses 12 Gy at the 50% isodose line, the maximal radiation dose at the “hot spot” will 24 Gy. During the treatment planning, assessment of the plan quality would include visualizing where this maximal dose would be located and during this assessment, determination that this maximal dose was adjacent to the facial nerve or brainstem. Similarly, it is important to determine the conformation of the treatment plan to the tumor volume to determine regions which may be undertreated by delivery of inadequate doses, resulting in areas that would allow continued tumor growth.

Nonisocentric treatment plans are also possible with the CyberKnife system. The delivery of these treatment plans is possible because of the robotic arm which, because of the 6 degrees of freedom (discussed below) enables the delivery of radiation to complex treatment volumes. The beams originate from arbitrary points in the workspace and are delivered into the lesion. The result is a nonisocentric concentration of beams within the lesion (Figure 35). Nonisocentric treatment allows nonsymmetrical irradiation.

With the CyberKnife system, the treatment plan can utilize fractionated or hypofractionated approaches. Fractionated treatment is possible because localization of the lesion is achieved using image guidance technology. Dose delivery over 2 to 5 treatment sessions, termed hypofractionation, is another option with the CyberKnife system. Although not directly applicable in managing tumors within the posterior fossa, it has been suggested to be particularly useful in the treatment of large tumors. The argument for fractionation is that lowering the dose for each of a number of treatments, as opposed to a single, larger dose, allows healthy tissue to rejuvenate between treatments. The advantage of fractionated or a single radiation dose remains an active area of investigation and debate. Because of the rigid fixation that occurs with securing the stereotactic headframe in gamma knife radiosurgery, fractionated, or hypofractionated delivery of radiation is not possible. Furthermore, it remains to be determined if equal accuracy can be achieved by these 2 systems or if there is an advantage of fractionation or hypofractionation in the treatment of skull base tumors.

**Localization.** The CyberKnife system’s use of stereotactic principles for tumor localization differs from other stereotactic radiosurgery systems in 1 specific way. It uses an image guidance technology that depends on the skeletal structure of the patient's head (compared to 0.5 mm with the stereotactic head frame used with gamma knife), and these differences have implications for planning and delivery options.

Figure 36 Ceiling-mounted diagnostic-energy X-ray sources emit low-dose X-rays through the patient’s tumor treatment area. A morphous silicon image detectors capture X-ray images from ceiling-mounted diagnostic-energy X-ray sources to produce live radiographs. The operating system (typically located adjacent to the treatment room) correlates patient location detected by image guidance system with reassembled CT scan and directs the robot to adjust position accordingly. The compact linear accelerator mounted on a computer-controlled robotic arm which adjusts position to maintain alignment with the target, compensating for any patient movement and uses X-band technology for mobility. (Published with permission, copyright © 2007, Acuray Incorporated, Sunnyvale, CA.)

the body as a reference frame (Figure 36). In addition, it continually monitors and tracks patient position during treatment. The CyberKnife’s operating system correlates live radiographic images with preparative CT scans to determine patient and tumor position repeatedly over the course of treatment. The imaging information is transferred from the computer’s operating system to the robot so that it may compensate for any changes in patient position by repositioning the LINAC.

Treatment Delivery. The CyberKnife's stereotactic radiosurgery system utilizes a compact 6-MeV linear accelerator, a computer-controlled robotic arm with 6 degrees of freedom, and an image guidance technology that does not depend on a rigid stereotactic frame and thereby enables treatment of extracranial sites. Potential benefits of this approach include: (1) increased access to and coverage of any target volume including the ability to treat lesions in and around the cranium that are unreachable with other systems, for example, in the lower posterior fossa and foramen magnum; (2) enhanced ability to avoid critical structures; (3) capability to treat lesions in the neck and spine; (4) ability to treat lesions throughout the body; (5) delivery of highly conformal dose distributions; (6) option of fractionating treatment; and (7) potential to target multiple tumors at different locations during a single treatment, for example, skull base and neck.

The CyberKnife system's computer-controlled robotic arm has 6 degrees of freedom. The robot can position the LINAC to more than 100 specific locations or nodes. Each node has 12 possible approach angles, translating to over 1,200 possible beam positions. The treatment planning system determines a set sequence of approach angles, beam weights, and dose distributions. The calculated plan can be incrementally improved by the physicist and physicians. The actual delivery follows a step-and-shoot sequence. The patient is placed in a position approximating that of the CT scan. Image detectors acquire radiographs of the tumor region. The image guidance system software then compares the real time radiographs with the CT information to determine location of the tumor. This information is transmitted to the robot to initialize the pointing of the LINAC beam. The robotic arm then moves the LINAC through the sequence of preset nodes surrounding the patient. At each node, the LINAC stops, and a new pair of images are acquired from which the position is reetermined. Corrected position is transmitted to the robot which adapts beam pointing to compensate for any movement. LINAC delivers the preplanned dose of radiation for that position. The entire process is repeated at each node. The total time from imaging to robot compensation is about 7 to 10 seconds. The total treatment time depends on the complexity of the plan and delivery paths, but is comparable to standard LINAC treatments. Each treatment session ranges from 30 to 90 minutes. Physicians may elect to treat with a single dose, a hypofractionated dose typically two to five sessions, or a more traditional fractionated regimen. Outcomes following CyberKnife treatment of vestibular schwannomas are emerging at this time.42

SUMMARY

There is diversity in the techniques and instrumentation used to perform stereotactic radiosurgery and radiotherapy. The field continues to evolve rapidly, and advances are being made in improving accuracy, effective radiation dose, and parameters necessary to maximize patient outcome. Stereotactic radiosurgery and radiotherapy, just as any other treatment modality, have advantages and disadvantages that must be discussed with a patient who has a vestibular schwannoma or other skull base tumor. An informed decision to pursue observation, microsurgery, or stereotactic radiosurgery or radiotherapy, or a combination of these methods must be made, and it remains the responsibility of the surgeon to provide a balanced view as to the relative advantages and disadvantages of each method.

FINANCIAL DISCLOSURE

None of the authors have a financial interest in any of the companies discussed in this chapter.

REFERENCES

The nasal cavity and paranasal sinuses comprise an anatomically complex aggregate of mucosa-lined airspaces within the bones of the face and skull. These airspaces contribute to a variety of functions, including: the warming and humidification of air; olfaction; lightening the skull; giving resonance to the voice; absorbing traumatic forces; and aiding in immune defense. Familiarity with the nuances of sinonasal anatomy is critical to understanding function and to mastering safe surgical technique.

EMBRYOLOGY

Nose

External Aspect of the Nose. The nose develops from the frontonasal process which, along with the maxillary and mandibular processes, is one of the 3 facial outgrowths visible in the fourth fetal week. In the fifth fetal week, ectodermal plaques develop on the lateral aspects of the frontonasal process and become paired nasal placodes, which are early precursors of the nares. By day 34, these convex placodes develop into concave nasal grooves, and the medial and lateral sides of the placodes begin to protrude forward to become medial and lateral nasal processes (Figure 1).

The nasal placodes develop into nasal grooves, eventually become blind-ending nasal pits by the seventh fetal week as the maxillary process grows forward and downward. It is at this time in fetal life that forward growth of both the medial and lateral ridges of the nasal placodes leads to development of the medial and lateral nasal processes, which ultimately contribute to formation of the nares and septum. The ultimate contributions of the facial processes to mature soft tissue and skeletal structures are summarized in Table 1.

Figure 1 The frontonasal, maxillary, and mandibular processes can be appreciated. The nasal placode, which later develops into the nasal pit can be seen within the medial and lateral nasal processes. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

Adapted from reference 1.
The second ethmoturbinal forms the middle turbinate while the third ethmoturbinal forms the superior turbinate. The fourth and fifth ethmoturbinals typically regress, but in some individuals persist and fuse to form the supreme turbinate (Figure 2).

The anatomic correlates of these ethmoturbinals, namely the uncinate process, middle turbinate and superior turbinate, in addition to the ethmoid bulla, have lamellar attachments to the lateral nasal wall that are used as important landmarks during sinus surgery (Table 2). The development of the ethmoturbinals is followed by the development of the paranasal sinuses.

**Paranasal Sinuses**

The frontal, maxillary, and ethmoid sinuses arise from evaginations of the lateral nasal wall, whereas the sphenoid sinus arises from a posterior evagination of the nasal capsule. The sinuses begin to develop in the third fetal month and only 2, the ethmoid and maxillary sinus, are present at birth. The development, vascular supply and innervation of each sinus are summarized in Table 3.

The arteries supplying the sinuses originate from either the internal or external carotid artery, or both. The sensory innervation of the sinuses derives from either the first branch of the trigeminal nerve, the second branch, or both. Where sensory innervation is supplied by V1, the corresponding arterial supply originates from the ophthalmic artery (external carotid), and where innervation is supplied by V2, the arterial supply is derived from the internal maxillary artery (external carotid). The correlation between carotid blood supply and trigeminal nerve supply may relate to the course of fetal stapedial artery, a derivative of the second branchial arch. Its 2 major divisions, the dorsal (supraorbital) and ventral (maxillomandibular), run parallel to V1 and V2, respectively. Before the stapedial artery regresses, the dorsal division anastomoses with the ophthalmic artery and the ventral division anastomoses with the internal maxillary artery, bringing V1 and V2 into proximity with the internal and external carotid blood supplies, respectively.  

**Maxillary Sinuses.** The maxillary sinus begins as an outpouching of the lateral nasal wall at the tenth fetal week. It begins posterior to the descending portion of the first ethmoturbinal (the developing uncinate) and superior to the maxilloturbinal (the developing inferior turbinate). Nasal capsule resorption allows the maxillary sinus to enter into the developing maxillary process. The sinus is present at birth and expands in early childhood with the development of the maxilla and teeth. The floor of the maxillary sinus gradually descends through childhood. Until the age of 9, the floor of the sinus is above that of the nasal cavity. By age 9 the floor is generally at the level of the nasal floor and continues to descend as the maxillary sinus pneumatizes further. Pneumatization often brings the maxillary dentine into close proximity with the maxillary sinus; thus dental disease can cause maxillary sinusitis, and tooth extraction can occasionally result in oral-antral fistulae.

**Ethmoid Sinuses.** The ethmoid sinuses begin as evaginations of the lateral nasal wall at the third month of fetal life. The anterior ethmoid cells begin their development anterior to the second ethmoturbinal, while the posterior ethmoid cells originate posterior to the second ethmoturbinal, thus explaining why the basal lamella of the middle turbinate (second ethmoturbinal) ultimately defines the functional drainage paths of the anterior and posterior ethmoid sinuses. The anterior ethmoid drains through the middle meatus, anterior to the basal lamella of the middle turbinate through the middle meatus, whereas the posterior ethmoid drains through the superior meatus, posterior to the basal lamella. The ethmoid cells are present at birth and pneumatize further between years 0 to 3 and 7 to 12.

**Frontal Sinuses.** An outpouching medial to the most superior aspect of the uncinate process develops during the fourth fetal month. This frontal recess expands and grows cephalad after birth to form the frontal sinus which becomes radiologically apparent at years 7 to 12. The left and right frontal sinuses develop independently, thus accounting for their asymmetry.

**Sphenoid Sinuses.** The sphenoid sinuses are unique in that they do not arise from outpouchings of the lateral nasal wall, but arise from within the nasal capsule of the embryonic nose. They remain undeveloped until age three. By age 7 the pneumatization has typically reached the sella turcica; and, by age 9 to 12, pneumatization is generally complete. The posterior pneumatization can be arrested in certain individuals giving rise to 3 configurations of the sphenoid sinuses: conchal (fetal), presellar (juvenile), and sellar (adult) (Figure 3). The sellar type is the most common, representing 86% of adult sinuses, whereas the presellar (11%) and conchal (3%) variants are less common. A well-pneumatized sphenoid sinus is advantageous for transphenoidal surgical approaches to the sella and clivus, since critical structures such as the sella, optic nerve, and carotid artery are skeletonized and well visualized. Hypopneumatized sphenoid variants require drilling of sphenoid bone to access the skull base and thus make transphenoidal approaches more difficult.

**PHYSIOLOGY AND MICROSCOPIC ANATOMY**

**Air Flow**

The nasal airway serves important physiologic functions, including filtration, humidification, and olfaction; these functions are dependent upon unrestricted airflow through the nasal cavity. Air which passes from the nares to the lungs encounters its greatest resistance at the internal nasal valve. Bounded medially by the anterosuperior aspect of the nasal septum and laterally by the upper lateral cartilage, the triangular internal nasal valve has a cross-sectional area of 20 to 40 mm² on each side. The internal nasal valve is the narrowest part of the upper respiratory tract, and it provides about 50% of the total airway resistance. The velocity of inspired air increases through the small cross-sectional area of the internal nasal valve and creates a Venturi effect (Figure 4). If the structural integrity of the nasal valve is compromised, the soft tissue structures may collapse in these high flow areas due to the Venturi effect, resulting in nasal obstruction.

Nasal resistance is also affected by the nasal cycle. Present in roughly 80% of individuals, the nasal cycle is an autonomic variance of blood flow to the erectile tissue of the nasal airway that results in alternating engorgement of the nasal airway from side to side. The periodicity of the nasal cycle varies from 2 and 1/2 to 4 hours. The nasal cycle may be abolished by exogenous stimuli such as topical oxymetazoline. Postural changes may also affect nasal resistance; when an individual lies on their side, the nasal mucosa on the gravity-dependent side will engorge and cause increased resistance.
superior turbinate; and to a slightly lesser degree the superior aspect of the middle turbinate. These structures define the olfactory cleft. Olfactory physiology is discussed in Chapter 38, “Olfaction and Gustation.”

Microscopic Anatomy

The sinonasal cavities are lined with pseudostratified ciliated columnar epithelium composed of 4 basic cell types: ciliated columnar epithelial cells, nonciliated columnar cells, basal cells, and goblet cells (Figure 5).

Ciliated respiratory epithelial cells are found throughout the respiratory tract except for the nasal vestibule, the posterior oropharyngeal wall, portions of the larynx, and terminal rami of the bronchial tree. The ciliated cells have 50 to 200 cilia per cell, and each cilium has a 9 plus 2 microtubular structure with dynein arms. Experimental data indicate a typical ciliary beat frequency of 700 to 800 times a minute, with mucociliary transport occurring at a rate of 1 cm/minute (although the normal range can vary widely).

Warming and Humidification

As air passes through the nose, it is warmed and humidified. The increase of nasal airway temperature is logarithmic as it passes from anterior to posterior. In typical ambient conditions, air is quickly heated in the anterior segment of the nose and is more slowly heated posteriorly. The total increase in air temperature, as air leaves the nasopharynx, is approximately 8°C. Inspired air is also dramatically humidified by the nose, with an increase in ambient humidity from 40 to 98% between the nasal vestibule and the glottis.7,8

Olfaction

Olfaction is another important physiologic function of the nasal cavity. The olfactory bulb sends filae through the cribiform plate to from the olfactory neuroepithelium. The olfactory neuroepithelium is distributed in 3 major areas: the superior septum; the superior aspect of the superior turbinate; and to a slightly lesser degree the superior aspect of the middle turbinate. These structures define the olfactory cleft. Olfactory physiology is discussed in Chapter 38, “Olfaction and Gustation.”

E = external; I = internal.
Nonciliated cells are characterized by microvilli which cover the apical aspect of the cell and serve to increase surface area. The function of basal cells is unknown, but it is theorized that they may serve as pluripotent stem cells. Goblet cells produce glycoproteins which are responsible for the viscosity and elasticity of mucus and respond to parasympathetic and sympathetic neural inputs. Between 20 and 40 mL of mucus are secreted from the normal nose daily from 160 cm² of nasal mucosa. The cilia beat within the lubricating periciliary layer fluid, termed the sol layer. The outer, more viscous mucus layer, is termed the gel layer. The gel layer provides a confluent lining for the nasal cavity onto which inhaled particles can impact. Eighty percent of particles larger than 12.5 µg are filtered from the air before they reach the pharynx.³

Mucociliary Clearance

The ciliated cells of the respiratory epithelium move mucus through the sinonasal cavity in an organized, directional fashion toward the nasopharynx and pharynx, where the mucus is swallowed or expectorated. Mucociliary clearance serves a hygienic function to clear the nose of particulate debris and potential by-products of infection or inflammation. A pattern of mucus flow can be mapped for each sinus, as seen in the examples of the frontal and maxillary sinus in Figure 6.

Ostio-ameatal Complex. The ostio-ameatal complex represents a common central pathway of mucociliary clearance for the anterior ethmoid, maxillary, and frontal sinuses. The ostio-ameatal complex is not a true anatomic designation, rather a functional area. It encompasses several structures that drain into the middle meatus: the maxillary ostium, ethmoid infundibulum, anterior ethmoid cells, and the frontal recess (Figure 7). Focal inflammation or mass obstruction in the ostio-ameatal unit can disrupt mucociliary flow in multiple sites “upstream,” potentially propagating rhinosinusitis.³

ANATOMY OF THE NASAL CAVITY

Nasal Septum

The mature nasal cavity is divided in the midline by a parting wall, the nasal septum. The nasal septum is derived from both bony and cartilaginous sources. The septum is formed anteriorly by the quadrilateral cartilage and premaxilla; posteriorly by the perpendicular plate of the ethmoid bone and the sphenoidal crest; and inferiorly by the crests of the vomer, maxillary, and palatine bones (Figure 8).
Nasal Mucous Membrane

The epithelial lining of the nasal cavity changes as one moves from anterior to posterior. The skin within the nasal vestibule is a keratinized, squamous cell epithelium containing vibrissae and sebaceous glands. At the leading edge of the inferior turbinate, the epithelium transitions into a cuboidal cell type and then into pseudostratified ciliated columnar respiratory epithelium. At the most posterior aspect of the nasopharynx, the mucosa returns to a nonkeratinized, squamous cell epithelium.

Nasal Innervation

Sensation to the nose is supplied mainly by the ophthalmic and maxillary divisions of cranial nerve V. The ophthalmic division gives rise to the nasociliary nerve, which divides into the anterior and posterior ethmoid and infratrochlear branches. The anterior ethmoid nerve passes over the cribriform plate and enters with the anterior ethmoid artery by way of the anterior ethmoid foramen and then courses through the incisive canal. A lateral branch, the posterior inferior nasal nerve, passes downward and forward to supply the middle and inferior turbinates (Figure 9). The maxillary division of cranial nerve V gives rise to the posterior superior nasal nerves that enter the nose by way of the sphenopalatine foramen and pass over the anterior face of the sphenoid bone to reach the nasal septum as the sphenopalatine nerve and then course through the incisive canal. Upon entering the nose, the sphenopalatine nerve divides into posterior lateral nasal and posterior septal branches. Sensation to the nose is supplied mainly by the ophthalmic and maxillary divisions of cranial nerve V. The ophthalmic division gives rise to the nasociliary nerve, which divides into the anterior and posterior ethmoid and infratrochlear branches. The anterior ethmoid nerve passes over the cribriform plate and enters with the anterior ethmoid artery by way of the anterior ethmoid foramen and then courses through the incisive canal. A lateral branch, the posterior inferior nasal nerve, passes downward and forward to supply the middle and inferior turbinates (Figure 9).

Blood Supply

The blood supply of the nasal cavity is derived primarily from the anterior and posterior ethmoid arteries, (branches of the ophthalmic artery) and the sphenopalatine artery (a terminal branch of the internal maxillary artery). The anterior ethmoid artery crosses the medial rectus and penetrates the lamina papryracea. The artery then courses across the roof of the ethmoid sinus within a thin bony covering, eventually supplying the cribriform plate and anterior part of the septum. This artery, when identified, is the most posterior landmark for a frontal recess dissection (Figure 10). The posterior ethmoid artery emerges from the orbit, approximately 12 mm posterior to the anterior ethmoid artery. It supplies a smaller posterior region, including the olfactory cleft. The internal maxillary artery enters the pterygomaxillary fossa and emerges into the nasal cavity through the sphenopalatine foramen as the sphenopalatine artery. The sphenopalatine foramen is located just lateral to the posterior end of the middle turbinate. Upon entering the nose, the sphenopalatine artery divides into posterior lateral nasal and posterior septal branches.

Venous drainage follows a course parallel to that of the sphenopalatine artery and its branches, draining into the ophthalmic plexus and partly into the cavernous sinus. This valveless venous system predisposes the spread of infection from the nose upward into the cavernous sinus.

There are 2 areas of arterial anastomoses that are often implicated in epistaxis: Kiesselbach plexus, which gives rise to anterior bleeding, and Woodruff plexus, which gives rise to posterior bleeding. Kiesselbach plexus is located over the anterior nasal septum and is formed by anastomoses between the sphenopalatine, greater palatine, superior labial, and anterior ethmoid arteries. Woodruff plexus is located over the
posterior part of the middle turbinate and inferior meatus and is made up of anastomoses between branches of the internal maxillary artery, namely, the posterior nasal, sphenopalatine, and ascending pharyngeal arteries.

**Inferior Turbinate**

The most conspicuous of the lateral nasal wall structures on anterior rhinoscopy is the inferior turbinate. The inferior turbinate is composed of bone covered by mucoperiosteum, soft tissue embodiing a cavernous plexus, and an overlying respiratory mucosa. The inferior turbinate bone articulates with the lacrimal bone anteriorly, and attaches to the medial process of the maxilla and palatine bone laterally. The cavernous plexus can become engorged with blood in response to the nasal cycle or to various environmental triggers.

**Middle Turbinate**

The middle turbinate forms the medial boundary of the middle meatus and serves as an important central landmark in sinus surgery (see Figure 7). The orientation of the middle turbinate runs along 3 different planes in its course from anterior to posterior and can be conceived schematically in thirds. The anterior third of the middle turbinate runs along a sagittal plane. This portion of the middle turbinate is most readily observed on anterior rhinoscopy, and it is attached superiorly to the lateral nasal wall and cribiform plate.

At the middle third, the turbinate reflects from a sagittal to a coronal orientation, forming the basal lamella of the middle turbinate as it traverses to insert on the lateral nasal wall. It is this transverse portion of the middle turbinate that separates the anterior ethmoid cells from the posterior ethmoid cells. Anterior to the basal lamella of the middle turbinate, the cells drain through the middle meatus. Posterior to the basal lamella, the cells drain through the superior meatus.

The posterior third of the turbinate runs in an axial plane with its attachment continuing along the lateral nasal wall. The posterior end of the middle turbinate inserts adjacent to the sphenopalatine foramen and to the emergence of the sphenopalatine artery into the nose.

**Superior Turbinate**

The superior turbinate is the most posterior of the 3 turbinates. It shares a common superior insertion onto the skull base with the middle turbinate and helps define the medial boundary of the posterior ethmoid cells. Medial to the superior turbinate and lateral to the septum is the area of the sphenoethmoidal recess, where the sphenoid ostium can be found.

**Concha Bullosa**

Any of the turbinates may pneumatize to form a concha bullosa, considered a normal variant of nasal anatomy. The middle turbinate is most commonly involved. Bolger has classified the pneumatization depending on whether the pneumatization is high in the lamella, in the bulbous portion, or throughout the whole structure. The presence of a well-pneumatized concha bullosa can predispose to anatomic narrowing of the sinus outflow tracts and lead to sinus obstruction.

**Nasolacrimal Duct (NLD)**

The NLD drains tears from the lacrimal sac into the nasal cavity. It originates in the lacrimal fossa in the inferomedial part of the orbit and runs along the posterior aspect of the maxillary vertical buttress. The duct courses several millimeters anterior to the maxillary sinus ostium, and thus care must be taken to avoid injury to this structure during maxillary antrostomy. The duct empties through Hasner valve, below the bony attachment of the inferior turbinate, into the inferior meatus (Figure 11).

**ANATOMY OF THE PARANASAL SINUSES**

**Maxillary Sinus**

The maxillary sinus has a pyramidal shape defined by 4 major boundaries: the maxillary face anteriorly; the ascending process of the palatine bone medially; the orbital floor superiorly, and the pterygomaxillary space posteriorly. The infraorbital nerve traverses along the roof of the maxillary sinus and exits through the infraorbital foramen roughly 6 to 7 mm below the inferior orbital rim. The nerve can be dehiscent within the maxillary sinus up to 14% of the time (Figure 12).

Behind the posterior wall of the maxillary sinus lies the pterygomaxillary fossa, which contains the internal maxillary artery, sphenopalatine ganglion, the vidian canal, the greater palatine nerve, and the foramen rotundum. The floor of the maxillary sinus is formed by the alveolar process of the maxilla. Roots of the molar teeth may occasionally be dehiscent through the floor of the sinus.

**Maxillary Ostium.** The natural maxillary ostium is the anatomic merging point for mucociliary flow in the maxillary sinus. The maxillary ostium is located at the anteromedial aspect of the sinus near the roof of the sinus. The maxillary ostium drains into the ethmoid infundibulum, lateral to the lower one-third of the uncinate process. The natural ostium is typically elliptical in shape, and rests about 2 mm posterior to the anterior most insertion of the uncinate process (Figure 13). The ostium size averages 2.4 mm in diameter, but can vary widely among individuals.

Two bony dehiscences, or anterior and posterior fontanelles, may exist along the medial wall of the maxillary sinus. These fontanelles are usually covered by mucosa but in some individuals may be patent, thereby forming an “accessory ostium.” Endoscopic examinations of the nasal cavity reveal an accessory opening in the posterior fontanelle of the maxillary sinus in roughly 25% of patients. Because mucociliary clearance moves mucus to the natural ostium and...
not to the accessory ostia, these patent fontanelles are considered nonfunctional ostia and should not be confused for the native natural ostium during maxillary sinus surgery (Figure 14).

Infraorbital Ethmoid (Haller) Cell. Occasionally, an anterior ethmoid cell may pneumatize along the orbital floor inferior and lateral to the ethmoid bulla. When extensively pneumatized, this infraorbital ethmoid cell may narrow the ethmoid infundibulum and predispose patients to maxillary sinus obstruction. This entity was described by Haller in 1765, and the cell was given his name; but it is generally agreed that the term infraorbital ethmoid cell is more descriptive and is preferred.13

Ethmoid Sinus

The ethmoid sinus is composed of multiple individual cells, separated into anterior and posterior compartments by the basal lamella of the middle turbinate. The lateral boundary of the ethmoid is the medial wall (lamina papyracea) of the orbit. The medial boundary is formed by the middle turbinate in the anterior ethmoid and by the superior turbinate in the posterior ethmoid. The posterior border is the face of the sphenoid sinus. Superiorty, the ethmoid roof separates the ethmoid sinus from the intracranial cavity.

Superomedially the ethmoid roof thins considerably in the area of the cribriform plate, through which olfactory fila enter the cranial cavity. Depending on the pneumatization pattern of the ethmoid sinus, additional ethmoid air cells can be found outside the usual confines of the ethmoid labyrinth, extending to the maxillary, frontal, and sphenoid sinuses.

The Ethmoid Lamellae. A series of ethmoid lamellae, with attachments to the lateral nasal wall, develops from the ethmoturbinals and the ethmoid bulla. These 5 lamellae are encountered sequentially during ethmoid sinus surgery and can be important orienting landmarks for the surgeon. Listed from anterior to posterior, the lamellae are summarized in Table 2.

First Lamella: Uncinate Process. The uncinate process is a crescent shaped operculum that overlies the ostium of the maxillary sinus. The uncinate process typically must be removed during endoscopic maxillary antrostomy to reveal the natural ostium of the maxillary sinus. Oriented sagittally, it forms the anterior and medial boundary of the ethmoid infundibulum. Anteriorly, the uncinate process inserts on the ethmoidal

Figure 16 A n endoscopic view of the right nasal cavity shows the nasal septum (NS), middle turbinate (MT), ethmoid bulla (EB), and uncinate process (UP). The hiatus semilunaris can be appreciated as the cleft between the ethmoid bulla and uncinate process.

Figure 17 Endoscopic view of the left middle meatus with instrument placed behind the ethmoid bulla in the retrolubar space.

Figure 18 The 3 Keros subtypes characterize varying depths of the olfactory groove, defined by the length of the lateral lamellae of the cribriform plate. Type I: 1 to 3 mm in length; Type II: 4 to 7 mm; and Type III: greater than 8 mm. (Adapted from reference 7)
The basal lamella of the middle turbinate separates the anterior ethmoid cells from posterior ethmoid cells (see Figure 7). It represents the coronally oriented attachment of the middle turbinate to the lateral nasal wall. The basal lamella of the middle turbinate is traversed during ethmoid sinus surgery to enter the posterior ethmoid cavity.

Fourth Lamella: Basal Lamella of the Superior Turbinate. The superior turbinate defines the medial border of the posterior ethmoid sinus. The posterior ethmoid cells drain into the superior meatus which is the space between the basal lamella of the superior turbinate and the basal lamella of the middle turbinate. The ostium of the sphenoid sinus lies medial to the superior turbinate within the sphenoethmoidal recess.

Fifth Lamella: Basal Lamella of the Supreme Turbinate. The supreme turbinate basal lamella is present in roughly 15% of the population. Due to its rarity, it does not serve as a helpful anatomic landmark during sinus surgery. The ethmoid roof is a critical landmark for surgical dissection. The slope of the ethmoid roof varies and is thicker laterally and thinner medially. The thinnest portion of the ethmoid roof lies at the lateral lamella of the cribriform plate, adjacent to the superior part of the attachment of the middle turbinate. Thus at the lateral lamella of the cribriform plate, there is the portion of the ethmoid roof that is most susceptible to injury during sinus surgery. When the olfactory groove is deep, the lateral lamella of the cribriform plate can be elongated, thus placing a larger area of skull base at risk for surgical injury. The 3 Keros subtypes that distinguish those patients at higher risk for damage to the lateral lamella of the cribriform plate based on the depth of the olfactory groove (Figure 18).

Frontal Sinus

The frontal sinus is formed by an outgrowth of the ethmoid labyrinth that pneumatizes superiorly into the frontal bone. The drainage of this sinus occurs at its inferior and medial extent. The frontal sinus outflow tract begins at the frontal infundibulum, then descends through the frontal ostium to the middle meatus via the frontal recess. The term “nasofrontal duct” should be avoided when referring to the drainage pathway below the frontal sinus.

Figure 19 The variable attachment of the uncinate process can either be to: (A) the lamina papyracea; (B) the middle turbinate; or (C) the ethmoid roof. The first scenario leads to frontal sinus outflow that is medial to the uncinate, the other 2 lead to lateral outflow. (Adapted from reference 5.)

Figure 20 The 4 frontal cell types can be seen in these coronal computed tomography scans. (A) A cell above the agger (1); more than 1 cell above the agger (2). (B) A cell extending from the ethmoid into the frontal sinus (3). (C) A cell completely within the frontal sinus (4). (Adapted from reference 10.)
ostium, as it is not a tubular structure or true duct. It is instead a recess that has a variable shape depending on what cells have pneumatized at its base.\textsuperscript{14} Specifically, the configuration of the recess will change based on the orientation of the uncinate process, ethmoid bulla, agger nasi, frontal cells, and supraorbital ethmoid cells. The boundaries of the frontal recess are the lamina papyracea laterally, the middle turbinate medially, the posterolateral wall of the agger nasi anteriorly, and the ethmoid bulla posteriorly. Suprabullar cells or the suprabullar recess may alternatively define the posterior border of the frontal recess.

**Agger Nasi.** The agger nasi, which means “nasal eminence,” is the portion of the lateral nasal wall located just anterior to the middle turbinate insertion. It is the remnant of the ascending portion of the first ethmoturbinal. The agger nasi is often pneumatized, and the resulting agger nasi cell is considered part of the anterior ethmoid labyrinth. The agger nasi is bordered anteriorly by the frontal process of the maxilla, posterolaterally by the frontal recess, anterolaterally by the nasal bones, inferomedially by the uncinate process of the ethmoid bone, and inferolaterally by the lacrimal bone. The agger nasi forms the anterior border of the frontal recess; when extensively pneumatized, the agger nasi cell can obstruct frontal sinus outflow and can predispose to frontal sinusitis. Dissection of the agger nasi may thus be critical to establishing adequate surgical patency of the frontal sinus.

**Uncinate Process.** The superior most aspect of the uncinate process is an important determinant of frontal sinus outflow. The insertion site of the uncinate process is variable and may fall under one of 3 main patterns: to the lamina papyracea laterally, to the roof of the ethmoid superiorly, or to the middle turbinate medially.\textsuperscript{15} A lateral attachment to the lamina papyracea is the most common arrangement (70%) and results in frontal sinus outflow medial to the uncinate process.\textsuperscript{15} It is instead a recess that has a variable shape depending on what cells have pneumatized at its base.\textsuperscript{16} Specifically, the configuration of the recess varies in thickness, with the anterosuperior wall and roof being the thinnest (<2 mm thick). The sphenoid sinus can pneumatize as far as the sellar, preclival, the sphenoid wings, and the foramen magnum but typically takes the form of the sellar, presellar, and conchal pneumatizations as described earlier (Figure 3). The walls of the sphenoid vary in thickness, with the anterosuperior wall and roof being the thinnest (<2 mm thick). The sphenoid sinus lies adjacent to vital structures such as the internal carotid artery, optic nerve, the Vidian nerve, the cavernous sinus, and foramen rotundum. Many of these structures can be identified as indentations on the roof and walls of the sinus in an extensively pneumatized sphenoid sinus. A small percentage may have dehiscence of bone over such vital structures as the optic nerve (4 to 6%) and carotid arteries (25%).\textsuperscript{21} The ostium of the sphenoid sinus can be found in the sphenoidomental recess, between the posterior part of the septum and the superior turbinate (Figure 21).

**Sphenoid Sinus**

The sphenoid sinus can pneumatize as far as the clivus, the sphenoid wings, and the foramen magnum but typically takes the form of the sellar, pre-sellar, and conchal pneumatizations as described earlier (Figure 3). The walls of the sphenoid vary in thickness, with the anterosuperior wall and roof being the thinnest (<2 mm thick). The sphenoid sinus lies adjacent to vital structures such as the internal carotid artery, optic nerve, the Vidian nerve, the cavernous sinus, and foramen rotundum. Many of these structures can be identified as indentations on the roof and walls of the sinus in an extensively pneumatized sphenoid sinus. A small percentage may have dehiscence of bone over such vital structures as the optic nerve (4 to 6%) and carotid arteries (25%).\textsuperscript{21} The ostium of the sphenoid sinus can be found in the sphenoidomental recess, between the posterior part of the septum and the superior turbinate (Figure 21).

**Sphenoidomental (Onodi) Cell.*** A posterior ethmoid cell that pneumatizes posteriorly into the region of the sphenoid sinus is termed a sphenoidomental, or Onodi, cell. Because sphenoidomental cells are positioned superior to the native sphenoid sinus, the optic nerve and carotid artery may often course through the lateral aspect of the sphenoidomental cell instead of the sphenoid sinus proper (Figure 22). Failure to recognize the presence of a sphenoidomental cell could result in inadvertent damage to the optic nerve or carotid artery. The term sphenoidomental cell is a more descriptive and anatomically accurate term and is preferred to the eponym.\textsuperscript{17}

**REFERENCES**

Olfaction and Gustation
Richard L. Doty, PhD
Alexis H. Jackman, MD

The chemical senses determine the flavor of foods and beverages and provide a sensitive and early means for detecting dangerous environmental situations, including the presence of fire, spoiled food, and leaking natural gas. These senses are important to otorhinolaryngologists as (a) their stewardship falls within the purview of their specialty, (b) some otolaryngologic operative procedures compromise the functioning of these senses, (c) alterations in chemosensory function can be an early sign of a number of other diseases, including Alzheimer's disease and idiopathic Parkinson disease, and (d) losses or distortions of chemosensation are of considerable personal and practical significance to the patient. The latter should not be underestimated and is particularly acute for patients whose lifestyle, livelihood, or immediate safety depend upon smelling and tasting (e.g., cooks, firemen, homemakers, plumbers, professional food and beverage tasters, employees of natural gas works, chemists, and numerous industrial workers).

This chapter provides an overview of the anatomy and physiology of the smell and taste systems, describes basic chemosensory pathology, and discusses means for quantitatively assessing, managing, and treating disorders of these sensory systems.

THE OLFACTORY SYSTEM

Anatomy and Physiology

Olfactory Neuroepithelium. The olfactory neuroepithelium contains the olfactory receptors of cranial nerve I (CN I), as well as free nerve endings from CN V, and lines the cribriform plate and sectors of the superior turbinate, middle turbinate, and septum. Although it reportedly comprises approximately 2 cm² of the upper recesses of each nasal chamber, it is not a homogenous structure, at least in the adult, as metaplastic islands of respiratory-like epithelium accumulate within its borders beginning early in life, presumably as a result of insults from viruses, bacterial agents, and toxins. On the basis of immunohistochemical and anatomical criteria, at least 6 major classes of cells can be identified in this neuroepithelium: bipolar sensory receptor cells, supporting or sustentacular cells, microvillar cells, Bowman gland and duct cells, goblet basal cells, and horizontal basal cells. The approximately 6 million receptor cells are derived embryologically from the olfactory placode and, thus, are of central nervous system (CNS) origin. The cilia of these cells, which extend into the mucus of the nasal lumen, harbor the 7 domain transmembrane olfactory receptors. The axons of these cells ultimately unite into bundles of 50 or so "fila" ensheathed by glial cells that traverse the cribriform plate to form the outermost layer of the olfactory bulb. The sustentacular cells insulate the receptor cells from one another and extend microvilli, rather than cilia, into the mucus. These cells contribute to the mucus of the region and may be involved to some degree in deactivating odorants and xenobiotic agents. The function of the approximately 600,000 microvillar cells located at the epithelial surface is unknown. The Bowman glands are a major source of the mucus in the olfactory region, whereas the gobose and horizontal basal cells are the progenitor cells of the other cell types (Figure 1).

Olfactory Bulb and Olfactory Cortex. The first processing station in the olfactory system, the olfactory bulb, is located directly over the cribriform plate. Its neural components are arranged in 6 concentric layers: the olfactory nerve layer, the glomerular layer, the external plexiform layer, the mitral cell layer, the internal plexiform layer, and the granule cell layer (Figure 2). The receptor cell axons of the olfactory nerve layer enter the glomeruli within the second layer of the bulb, where they synapse with the dendrites of the mitral and tufted cells within the spherical glomeruli. These second-order cells, in turn, send collaterals that synapse within the periglomerular and external plexiform layers, resulting in "reverberating" circuits in which negative and positive feedback occur. Indeed, mitral cells modulate their own output by activating granule cells (which are inhibitory to them). Whereas the olfactory bulbs of younger persons have thousands of glomeruli arranged in single or double layers within the glomerular layer, older persons typically have far fewer numbers of glomeruli, reflecting the decrease in olfactory receptor cell numbers within the neuroepithelium. After the age of 80 years, such structures are nearly absent. Both endogenous and exogenous factors influence olfactory bulb structure, including early malnutrition. The mitral and tufted cell axons project ipsilaterally to the primary olfactory cortex via the olfactory tract without an intervening thalamic synapse. The primary olfactory cortex is comprised of the anterior olfactory nucleus (AON), the piriform cortex, the olfactory tubercle, the entorhinal area, the periamygdaloid cortex, and the corticomedial amygdala. Some projections occur, via the anterior commissure, from pyramidal cells of the AON to contralateral elements of the primary olfactory cortex. A number of projections from primary to secondary (i.e., orbitofrontal) cortex are direct, whereas others relay within the thalamus. Odor memories are stored not only in the hippocampus, but also within the piriform cortex. Interestingly, functional imaging studies have found that odors reliably and significantly activate, in a concentration-dependent manner, posterior lateral areas of the cerebellum,
whereas sniffing alone tends to activate mainly anterior central cerebellar regions. The cerebellar activity may reflect the circuits involved in modulating sniff size relative to the intensity of an odor or other movement-related behaviors.

**Olfactory Transduction.** Humans can detect and discriminate among thousands of airborne odorants. A total of 10 to 15% of the incoming airstream is shunted toward the olfactory cleft during inhalation (Figure 3). Of the odorant molecules within this deflected airstream move from the air to the largely aqueous phase of the olfactory mucus, where they diffuse or are actively transported via "odorant binding proteins" to the olfactory receptors. After activation, the receptor signal is transported via signal transduction pathways and neuronal networks to the brain.

**Receptor Cell Regeneration.** The olfactory epithelium is the primary source of olfactory information to the brain. It is a dynamic tissue that undergoes continuous production of new olfactory receptor cells. The regenerative capacity of the olfactory epithelium is depicted in Figure 4. The process begins with the generation of a pool of progenitor cells located in the basal layer of the olfactory epithelium. These cells can undergo mitosis and give rise to a variety of cell types, including olfactory receptor neurons, supporting cells, and stem cells. The stem cells are responsible for maintaining the population of progenitor cells and for producing new olfactory receptor cells. The newly generated olfactory receptor cells migrate to the apical surface of the olfactory epithelium and differentiate into mature receptor cells.

**Classification of Olfactory Disorders.** Smell dysfunction can be reliably classified as follows: anosmia: inability to detect olfactory sensations; partial anosmia: ability to perceive some, but not all, such sensations; hyposmia: decreased sensitivity to odors; hyperosmia: abnormally acute smell function; dysosmia: distorted or perverted smell perception to odor stimulation (sometimes termed cacosmia or parosmia, depending upon the nature of the perversion); phantosmia: a dysosmic sensation perceived in the absence of an odor stimulus, for example, an olfactory hallucination; and olfactory agnosia: inability to recognize an odor sensation, even though olfactory processing, language, and general intellectual functions are essentially intact, as in some stroke patients. Olfactory dysfunction can be either bilateral (binasal) or unilateral (uninasal), although most commonly such dysfunction is bilateral. Although presbyosmia is sometimes used to describe smell loss due to aging, this term is less specific than those noted above (i.e., it does not distinguish between anosmia and hyposmia) and is laden, by definition, with the notion that it is age per se that is causing the age-related deficit.

**Clinical Evaluation of Olfactory Function.** Three steps are involved in assessing a patient with chemosensory dysfunction: (a) obtaining a detailed clinical history; (b) testing olfactory function quantitatively; and (c) physically examining the head and neck.

**History.** To determine the cause of olfactory loss, it is important to determine antecedent events such as head trauma, upper respiratory tract infections, toxic exposures, or iatrogenic interventions, for example, surgical procedures, although in some patients a determination of the basis of the problem is complicated. It is also valuable to note whether the olfactory loss has been sudden or insidious. Olfactory dysfunction can be either bilateral (binasal) or unilateral (uninasal), although most commonly such dysfunction is bilateral. Although presbyosmia is sometimes used to describe smell loss due to aging, this term is less specific than those noted above (i.e., it does not distinguish between anosmia and hyposmia) and is laden, by definition, with the notion that it is age per se that is causing the age-related deficit.
the olfactory receptor region or degeneration of more central neural structures. Intermittent loss can be indicative of an intranasal inflammatory process.22

Questions regarding sinonasal symptoms such as epistaxis, discharge (clear, purulent or bloody), nasal obstruction, allergies, and somatic symptoms, including headache or irritation, may have localizing value. When a clear-cut cause is not apparent, the clinician must explore a number of potential avenues to ascertain likely causal events or combinations of causal events. It is essential that potential underlying medical conditions known to have chemosensory consequences (eg, renal failure, liver disease, hypothyroidism, diabetes, or dementia) be identified or ruled out. A detailed assessment of the medications being used prior to and during the onset of the dysfunction is important, as many common medications (eg, antihypertensive and antilipid agents, and antibiotics) can produce smell or taste disturbances. Importantly, medication-induced deficits may take some time to appear, so simply because a patient has been taking a drug for some time does not rule out its possible causative involvement. Likewise, some medication-induced alterations may not disappear immediately upon drug cessation.

A review of the patient’s social history, including past and current employment as well as tobacco, alcohol, or recreational drug use, may also provide clues to etiology (eg, chronic alcoholism or Wernicke Korsakoff syndromes). A family history of smell dysfunction may suggest a genetic cause. Delayed puberty in association with anosmia (with or without midline craniofacial abnormalities, deafness, and renal anomalies) suggests the possibility of Kallmann syndrome or some variant thereof. Subtle signs of central tumors, dementia, parkinsonism, and seizure activity (eg, automatisms, occurrence of black-outs, auras, and déjà vu experiences) should be sought in both the history and physical examination.

Quantitative Olfactory Testing. Many patients are inaccurate in describing their chemosensory function; some are unaware of a chemosensory deficit, whereas others overstate the nature of their problem. Hence, the otolaryngologist should employ modern means for quantitatively assessing olfactory function in the office setting. Reliable quantitative testing is needed to (a) verify the validity of the patient’s complaint, (b) characterize the exact nature and degree of the problem, (c) monitor accurately changes in function over time (including those resulting from therapeutic interventions), (d) detect malingering, and (e) obtain an objective basis for determining compensation for disability. In the past, many physicians have tested olfaction by simply asking the patient to identify several crude odorants, such as licorice, coffee grounds, or tobacco, placed under the nose. Unfortunately, such qualitative testing can lead to false positives (eg, patients have difficulty identifying odors without response alternatives), lacks reliability, has no normative reference, and is easily faked by malingers.

During the last quarter century, a number of standardized and practical psychophysical tests have been developed.23 The most widely used test is the 40-item University of Pennsylvania Smell Identification Test or UPSIT (commercially known as the Smell Identification Test; Figure 4).23 This reliable (test–retest r = 0.94) test employs microencapsulated (“scratch and sniff”) odorants and is available in 7 languages. It can be self-administered in 10 to 15 minutes in the waiting room by most patients and scored in less than a minute by nonmedical personnel. In addition to providing a percentile rank of a patient’s performance relative to age- and sex-matched controls, an absolute determination of normosmia, mild microsmia, moderate microsmia, severe microsmia, anosmia, or probable malingering can be made.

In some cases, unilateral testing is warranted, although usually olfactory problems are bilateral. To assess olfaction unilaterally, the naris contralateral to the tested side should be occluded without disturbing the nasal valve region. This can be easily accomplished by sealing the contralateral naris using a piece of Microfoam tape (3M Corporation, Minneapolis, MN) cut to fit the naris borders (Figure 5). The patient is instructed to sniff the stimulus normally and to exhale through the mouth. Such occlusion not only prevents air from entering the olfactory cleft from the contralateral naris (orthonasal stimulation), but also prevents active movement of odor-laden air into the occluded side from the rear of the nasopharynx (retro nasalal stimulation).

The measurement of olfactory event-related potentials (OERPs) is available in only a handful of specialized centers. In essence, synchronized brain electroencephalographic (EEG) activity induced by repeated pulsatile presentations of an odorant is isolated from overall EEG activity. Averaging of responses from repetitive stimulation increases the signal-to-noise ratio. Although OERPs are relatively sensitive and useful in detecting malingering, they presently are unable to localize where in the olfactory pathway an anomaly exists, unlike their visual and auditory counterparts. Unfortunately, OERP testing requires specialized and expensive equipment capable of delivering odorant pulses with rapid rise times (~30 to 40 ms) to the olfactory neuroepithelium within a background of continuously flowing warmed and humidified air without inducing confounding somatosensory sensations.24

The electro-olfactogram (EOG) is another electrophysiological measure of the olfactory system.25 This surface potential, detected via an electrode placed on the surface of the olfactory mucosa, reflects summed generator potentials mainly from olfactory receptor neurons. The recording of the EOG is, from a practical perspective, more difficult than that of the OERP, and far fewer patients are amenable to such recording.

Figure 4 Booklet 1 of the 40-odorant University of Pennsylvania Smell Identification Test (UPSIT; commercially known as the Smell Identification Test). Each page of 4 10-page booklets contains a microencapsulated odorant that is released by means of a pencil tip, and a multiple-choice question as to which of 4 possibilities smells most like the odorant. Forced-choice answers are recorded on columns on the last page of the test. (Photograph courtesy of Sensonics, Inc., Haddon Hts., NJ. Copyright © 2005, Sensonics, Inc.)
The placement of the recording electrode is performed under endoscopic guidance. Since local anesthesia must be avoided, this can be quite unpleasant. Importantly, even after the electrode has been placed correctly placed on mucus membrane containing olfactory neuroepithelium, an electrical potential cannot be readily detected in some patients. This may reflect the topographical distribution of specific olfactory receptors in combination with the relatively few number of odorants used, or the presence of metaplasia of respiratory-like epithelium within the olfactory neuroepithelium.

Physical Examination, Laboratory Tests, and Medical Imaging. Careful otolaryngologic and neurologic assessment is warranted in patients complaining of olfactory dysfunction.20-21 Nasal endoscopy, employing flexible or rigid endoscopes, should be performed, with specific attention being paid to the area of the olfactory cleft. The nasal cavity should be inspected for the presence of pathologic masses, polyps, or muco-sal lesions. In addition, any mucosal adhesions between the turbinates and the septum should be noted, as they may compromise airflow to the olfactory receptor region. The nasal mucosa should be assessed for evidence of inflammation such as the erythema, edema, nodularity, as well as erosion or ulceration. Furthermore, nasal secretions should be carefully examined. Mucopus below the eustachian tube orifice suggests involvement of the osteomeatal complex, whereas mucopus above this orifice suggests posterior ethmoid and/or sphenoid sinus disease. Unusual sparciousness, dryness, and crust ing, as is seen in atrophic rhinitis, suggests atrophy of the lamina propria. A pale mucus membrane can be indicative of allergy, usually resulting from edema within the lamina propria. Industrial or environmental pollutants as well as tobacco smoking can produce metaplasia within the epithelium in addition to swelling, inflammation, exudates, erosion, and ulceration.

Visual field and acuity tests, as well as optic disc examinations, should be performed to determine whether intracranial mass lesions that produce increased intracranial pressure (papilledema) and optic atrophy are present (eg, the Foster Kennedy syndrome, which consists of ipsilateral anosmia, ipsilateral optic atrophy, and contralateral papilledema caused by a meningioma of the ipsilateral optic nerve).

Blood serum or other laboratory tests may help to identify or confirm underlying medical conditions that may relate to the dysfunction, including infection, inflammatory diseases, nutritional deficiencies, for example, B6, B12, allergy, diabetes mellitus, and thyroid, liver, and kidney disease. Although biopsies of the olfactory neuroepithelium can be made, their interpretation is hindered by sampling issues and the fact that metaplasia of respiratory-like epithelium occurs throughout the olfactory neuroepithelia of even persons with normal olfactory function.

Medical imaging can be invaluable in understanding the basis of a number of smell and taste disturbances. Magnetic resonance imaging (MRI) is the method of choice for evaluating soft tissue, for example, olfactory bulbs, tracts, and cortical parenchyma. Computed tomography (CT) is the most useful and cost-effective technique to assess sinonasal tract inflammatory disorders and is superior to MRI in the evaluation of bony structures adjacent to the olfactory pathways, for example, ethmoid and cribiform plate. Coronal CT scans are particularly useful in evaluating paranasal anatomy. Plain radiographs have substantial limitations, and are rarely useful. Positron emission tomography (PET), functional MRI (fMRI), and single-proton emission computed tomography (SPECT) have limited usefulness at the present time.

Detection of Malingering

Traditionally, it has been suggested that malingering can be detected reliably by having a patient inhale a strong CN V stimulant, such as ammonia, and asking whether a smell is perceived. If denial occurs, the assumption is made that malingering is present. Unfortunately, this procedure is unreliable, since usually CN V stimulants produce reflexive coughing, secretion from nasal membranes, or other rejection reactions which the patient obviously cannot deny. Furthermore, CN V thresholds vary considerably, such that some patients experience little reaction to the ammonia and truthfully report perceiving no sensations. Indeed, anosmia is associated with heightened CN V thresholds.20

A preferred method of the detection of malingering is to employ forced-choice psychophysical tests, such as the UPSIT. On such tests, malingering appears as the reporting of fewer incorrect responses than expected on the basis of chance (as would be expected in an anosmic). Since, in the case of the UPSIT, there are 4 response alternatives for each item and the patient must provide an answer even if no smell is perceived, 25% of the items, on average, should be correctly identified by chance alone, that is, 10 out of 40. A sampling distribution exists around this expected probability, and empirical data are available on this point.21 The theoretical probability of a true anosmic having an UPSIT score 5 or less is less than 5 in 100. The theoretical probability of a true anosmic scoring 0 on the UPSIT is lesser than 1 in 100,000.23 In general, if a patient scores within the probable malingering region of UPSIT scores, the UPSIT should be administered again to confirm the apparent avoidance of correct responses. Multiplication of the 2 probabilities is then used to establish the statistical likelihood of malingering. Malingering is also suspected if patient reports smell loss in the presence of a clear DERP, although olfactory agnosia in such cases cannot be ruled out.

It is noteworthy that malingering is sometimes discovered in head injury patients by their scores on forced-choice taste tests, rather than their scores on forced-choice smell tests, since bonafide smell loss is, in fact, present (negating the ability to avoid correct answers on the olfactory element of the examination). Such malingering implies relatively normal taste function, and reflects the patient’s naïve attempt to embellish the “taste loss” which, in fact, results from lack of retronasal stimulation of the olfactory receptors.

Evidence for a general tendency to malingering can also be obtained using neuropsychological tests specifically designed for this purpose, for example, tests sensitive to head trauma patients trying to feign memory disturbances. Among those that are widely used is Rey Memory Test (RMT), also known as the Rey 3 × 5 Test and the Rey 15-Item Memory Test.21 The rationale behind this test is that malingers typically fail at a memory task that all but the most developmentally disabled or severely brain injured persons perform easily.

Causes of Olfactory Dysfunction

Olfactory dysfunction can result from 3 general causes: (a) conductive or transport impairments from nasal passage obstruction (eg, by chronic rhinosinusitis, polyposis, excessive mucus secretion), (b) sensorineural impairment from injury to the olfactory neuroepithelium, for example, by viruses, airborne toxins, and (c) central olfactory neural impairment from injury to CNS structures, for example, tumors, masses impinging on the olfactory tract. These categories, however, are not mutually exclusive. For example, both blockage of airflow to the receptors and damage to the receptors and/or more central elements of the olfactory system can be simultaneously present or occur in stages. Thus, chronic rhinosinusitis can produce damage to the olfactory neuroepithelium in addition to blocking airflow, and altered neuroepithelial function can, over time, lead to degeneration within the olfactory bulb, a central structure.

There are numerous causes of olfactory disturbance (Table 1). Most cases of chronic
Table 1 Reported Agents, Diseases, Drugs, Interventions and Other Etiologic Categories Associated with Olfactory Dysfunction

Air pollutants and industrial dusts
- Acetone
- Acids, eg, sulfuric
- Ashes
- Benzene
- Benzoil
- Butyl acetate
- Cadmium
- Carbon disulfide
- Cement
- Chalk
- Chlorine
- Chromium
- Coke/coal
- Cotton
- Cresol
- Ethyl acetate
- Ethyl and methyl acrylate
- Flour
- Formaldehyde
- Grain
- Hydrazine
- Hydrogen selenide
- Hydrogen sulfide
- Iron carboxyl
- Lead
- Nickel
- Nitrous gases
- Paint solvents
- Paper
- Pepper
- Peppermint oil
- Phosphorus oxychloride
- Potash
- Silicone dioxide
- Spices
- Trichloroethylene

Drugs
- Adrenal corticosteroids (chronic use)
- Amino acids (excess)
- Caffeine
- Histidine
- Analgesics
- Antipyrine
- Anesthetics, local
- Cocaine HCl
- Procaine HCl
- Tetracaine HCl
- Anticancer agents, eg, methotrexate
- Antihistamines, eg, chlorpheniramine maleate
- Antimicrobials
- Griseofulvin
- Lincomycin
- Macrolides
- Neomycin
- Penicillins
- Streptomycin
- Tetacyclines
- Tyrothricin
- Antihyperemics
- Mercury/gold salts
- o-Penicillamine
- Antithyroids
- Methimazole
- Propylthiouracil
- Thiouracil
- Antivirals
- Cardiovascular/antihypertensives
- Gastric medications

Endocrine/metabolic disorders
- Addison disease
- Congenital adrenal hyperplasia
- Cushing syndrome
- Diabetes mellitus
- Froelich syndrome
- Gigantism
- Hypergonadotropic hypogonadism
- Hypothyroidism
- Kallmann syndrome
- Pregnancy
- Panhypopituitarism
- Pseudohypoparathyroidism
- Sjögren syndrome
- Turner syndrome

Infections—viral/bacterial
- Acquired immunodeficiency syndrome (AIDS)
- Acute viral rhinitis
- Bacterial rhinosinusitis
- Bronchiectasis
- Fungal
- Influenza
- Rickettsial
- MCFerlarian

Lesions of the nose/airway blockage
- Adenoid hypertrophy
- Allergic rhinitis
- Perennial
- Seasonal
- Atrophic rhinitis
- Chronic inflammatory rhinitis
- Hypertrophic rhinitis
- Nasal polyposis
- Rhinitis medicamentosa
- Structural abnormality
- Deviated septum
- Weakness of alae nasi
- Vasomotor rhinitis

Medical/surgical interventions
- Adenectomy
- Anesthesia
- Anterior cranioectomy
- Arteriography
- Chemotherapy
- Frontal lobe resection
- Gastrectomy
- Hemodialysis
- Hyphophysectomy
- Infusion vaccination
- Laryngectomy
- Oophorectomy

Neoplasms—intranasal
- Neuro-olfactory tumors
- Esthesioneuroepithelioma
- Esthesioneuroblastoma
- Esthesioneurocytoma
- Esthesioneuroepithelioma
- Other benign or malignant nasal tumors
- A denocarcinoma
- Leukemic infiltration
- Nasopharyngeal tumors with extension
- Neurofibroma
- Nasal tumors with extension
- Schwannoma

Neoplasms—extranasal and extracranial
- Breast
- Gastrointestinal tract
- Laryngeal
- Lung
- Ovary
- Testicular

Neurologic disorders
- Amyotrophic lateral sclerosis
- Alzheimer disease
- Cerebral abscess (esp. frontal or ethmoidal regions)
- Down syndrome
- Familial dysautonomia
- Guam amyotrophic lateral sclerosis/Parkinson disease/dementia
- Head trauma
- Huntington disease
- Hydrocephalus
- Korsakoff psychosis
- Migraine
- Meningitis
- Meningitis
- Meningitis
- Meningitis
- Myasthenia gravis
- Paget disease
- Parkinson disease
- Refsum syndrome
- Restless leg syndrome
- Syphilis
- Syringomyelia
- Temporal lobe epilepsy
- Hamartomas
- Mesial temporal sclerosis
- Sarcoid/pneumonic
- Vasculard injury/anoxia
- Small multiple cerebrovascular accidents
- Subclavian steal syndrome
- Transient ischemic attacks
- Nutritional/metabolic disorders
- A beta lipoproteinemia

Paranasal sinus exenteration
- Radiation therapy
- Rhinoplasty
- Temporal lobe resection
- Thyroidectomy

Note that categories are not mutually exclusive.

Viral Upper Respiratory Infections. Upper respiratory system viruses, for example, influenza and colds, are the most common cause of permanent smell loss in adulthood. Factors that predispose individuals to viral-induced smell dysfunction or the mechanisms underlying it remain unclear although direct insult to an already compromised neuroepithelium is most likely. In rare cases, central structures may also become involved. If neural damage is present, topical or systemic corticosteroid treatment is ineffective. Reduced numbers of olfactory receptor cells and other epithelial abnormalities are commonly found in biopsies taken from the olfactory neuroepithelia of patients with postviral anosmia or hyposmia.

Head Trauma. Smell loss or distortion occurs in approximately 15% of patients with significant head trauma but can be present even in mild cases where rapid acceleration/deceleration of the brain has occurred (coup contrecoup injury). In general, the severity of trauma is roughly correlated with the degree of loss. Occipital blows tend to produce more frequent and more severe olfactory deficits than frontal blows. The physiological mechanisms involved include shearing of the olfactory fila and contusions of the olfactory bulb and frontal and temporal poles. Although the cribiform plate may become fractured in some cases, such fractures are not a prerequisite for smell loss. In a study of 268 patients evaluated at the University of Pennsylvania Smell and Taste Center who had experienced head trauma, 66.8% had anosmia and 20.5% hyposmia. Of 66 patients retested 1 month to 13 years later, only three, none of whom initially had anosmia, regained normal olfactory function. Dysosmia prevalence decreased from 41.1 to 15.4% over posttrauma periods averaging several years.

Even though the loss of smell following head trauma is usually immediate, this is not always the case, and it may take the patient a while to recognize the presence of the loss. In some cases delayed loss reflects delayed receptor cell death. Rodent research shows that intracranial hemorrhage and ischemia can lead to degeneration of the olfactory neuroepithelium without transection of the olfactory nerves.

Paranasal Sinus Disease. It is now apparent that the olfactory loss associated with nasal or sinus disease is not due solely to decreased conduction of airflow to the olfactory receptors. Although medical, for example, administration of topical or systemic steroids, or surgical, for example, excision of polyps, treatment can improve olfactory function in some cases, return to normal levels is not the norm. In the case of rhinosinusitis, for example, factors other than, or in addition to, nasal airflow blockage are responsible for the loss. Chronic inflammation is likely toxic to olfactory neurons. Hence, many cases of rhinosinusitis have a significant sensorineural component. The severity of histopathology within the olfactory neuroepithelium of chronic rhinosinusitis patients is correlated with the degree of smell loss, as measured by the UPSIT. Olfactory biopsies from patients with nasal disease are less likely to yield olfactory neuroepithelial tissue than biopsies from controls. The same is true for anosmic versus nonanosmic rhinosinusitis patients.

Systemic Diseases. Olfactory disturbances may be due to pathologic manifestations of systemic disease. Ciliary dysfunction syndromes, such as Kartagener syndrome and immotile cilia syndrome, are accompanied by chronic rhinosinusitis and often associated with olfactory loss. Granulomatous diseases causing nasal lesions include both infections, such as leprosy and tuberculosis,
and connective tissue disorders, such as Wegener granulomatosis and lupus erythematosus. Olfactory loss in these diseases may be due to direct damage to the olfactory neuroepithelium, obstruction of the nasal airway secondary to nasal secretions, or obstruction of airflow to the olfactory cleft resulting from the collapse of the cartilaginous and bony framework. Wegener granulomatosis is a systemic disease characterized by necrotizing vasculitis affecting small arteries of the respiratory tract and kidney. In the upper airway, nasal ulcerations are frequently observed. In addition to mucosal damage, septal perforation and collapse can contribute to olfactory loss by altering nasal airflow. Nasal sarcoidosis, a non-caseating granulomatous disease associated with olfactory loss, typically presents with small yellowish excrescences of the septal mucous membrane, atrophy of submucosal glands, and abundant crusting.

CNS Neoplasms. Olfactory disturbances can arise from tumors impinging on the olfactory bulbs or tracts, such as frontal lobe gliomas, olfactory groove meningiomas, and suprasellar ridge meningiomas arising from the dura mater of the cribiform plate. Other tumors located on the floor of the third ventricle, pituitary tumors extending above the sella turcica, and tumors in the temporal lobe or uncinate convolution of the cribriform plate foramina by ossification is common in skulls of older persons.46 Other age-related factors, such as the development of pathology related to Alzheimer disease (see below), may also contribute to the age-related losses in smell function.47

Neurodegenerative and Other Neuropathological Diseases. An exciting chapter in the study of olfaction has been the discovery that a number of neurological disorders are commonly accompanied by olfactory deficits, including Alzheimer disease, idiopathic Parkinson disease, Huntington disease, alcoholic Korsakoff syndrome, Pick disease, the Parkinsonism dementia complex of Guam, amyotrophic lateral sclerosis, schizophrenia, and multiple sclerosis.48–51 Indeed, olfactory dysfunction appears to be the first clinical sign of Alzheimer disease and idiopathic Parkinson disease.52–53 Although usually considered a neurodevelopmental disorder, smell loss is present in patients with schizophrenia and appears to be correlated with disease duration, suggesting a possible degenerative component in olfaction-related pathways.54 Interestingly, patients with schizophrenia have much smaller olfactory bulbs and tracts than those of matched controls.54

Several studies provide data suggesting that smell testing is useful in identifying persons at risk for later significant cognitive decline and Alzheimer disease. Graves and colleagues administered a 12-item abbreviated version of the UPSIT (termed the Brief-Smell Identification Test or B-SIT) and several cognitive tests to 1,985 Japanese–American people around the age of 60, and then retested these people 2 years later.55 Sixty-nine percent of the follow-up participants were genotyped for apolipoprotein E (apoE). Low B-SIT scores in the presence of one or more APOE-e4 alleles were associated with a very high risk of subsequent cognitive decline. The B-SIT identified persons who came to exhibit later cognitive decline better than did a global cognitive test. More recently, the UPSIT was administered by Devanand and colleagues to 90 outpatients with mild cognitive impairment and to matched healthy controls at 6-month intervals over a 5-year period.56 Patients with mild cognitive impairment had lower UPSIT scores than did controls. Most importantly, patients with low UPSIT scores (<34) were more likely to develop Alzheimer disease than the other patients. Low UPSIT scores, combined with lack of awareness of olfactory deficits on the part of the patients, predicted the time to development of Alzheimer disease. UPSIT scores from 30 to 35 showed moderate to strong sensitivity and specificity for diagnosis of Alzheimer disease at follow-up.

The underlying cause for the olfactory deficit of Alzheimer disease is not yet clear, even though Alzheimer disease is associated with loss of neurons in the AON, olfactory bulb, and layer II of the entorhinal cortex.49 Disproportionate numbers of neuritic plaques and neurofibrillary tangles are found within limbic brain regions which receive olfactory bulb projections. Several lines of evidence suggest that neurofibrillary tangles, rather than neuritic plaques, are most closely associated with the smell loss.57 Central cholinergic deficits may also be involved, since (a) individuals with no history of cognitive loss that are in the early histopathologic stages of Alzheimer disease exhibit a cholinergic deficit within the inferior temporal lobe and (b) drugs that alter cholinergic function alter the ability to smell. For example, the cholinesterase inhibitor physostigmine improves odor discrimination performance, at least in rats,58 whereas scopolamine, a muscarinic cholinergic antagonist, reportedly decreases olfactory sensitivity in humans.59

In idiopathic Parkinson disease, bilateral olfactory deficits are present early on in the disease, perhaps even during the preclinical period and occur at a higher frequency than some cardinal signs of this disorder, for example, tremor.53 The olfactory impairment is unrelated to use of anti-parkinson medications, duration of illness, and severity of the symptoms, such as tremor, rigidity, bradykinesia, or gait disturbance.60 Since smell loss is absent or infrequent in a number of other neurological disorders that exhibit similar motoric signs, smell testing can aid in differential diagnosis in some cases.60 For example, patients with essential tremor, progressive supranuclear palsy, multiple system atrophy and parkinsonism induced by the prion toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) exhibit little or no olfactory dysfunction.61 It is of interest that familial Parkinson disease is also associated with olfactory impairment that occurs independently of the Parkinsonian phenotype.62

It has been generally assumed that olfactory function in multiple sclerosis is normal, since
the axons of the primary olfactory receptors are unmylinated. However, myelin is present in other segments of the olfactory pathway, and at any one time, about a third of multiple sclerosis patients exhibit some degree of smell loss.63 Furthermore, the degree of olfactory loss is directly related to the number of MRI-determined plaques in central brain regions associated with olfactory processing, for example, inferior middle temporal lobe and periorbital frontal cortex (Figure 8).50,63 Indeed, a seemingly 1:1 longitudinal association is present between UPSIT scores and changes in plaque load over time (Figure 9),64 implying that olfactory function waxes and wanes as the plaque numbers increase and decrease. In effect, knowledge of a patient’s UPSIT score accurately predicts the plaque load in the olfaction-related regions, and vice versa.

**Exposure to Neurotoxic Agents.** A number of environmental and industrial chemicals have been linked to olfactory dysfunction, including acrylates, benzene, cadmium, cigarette smoke, formaldehyde, manganese, solvents, and nickel dust, among others, although few well-controlled studies exist in this area and most reports are largely anecdotal.65 The best documented cases are those related to exposure to aerosolized heavy and transitional metals, such as present in welding fumes.50 In many cases, the decrements are specific to the exposed compounds and reflect long-term adaptation rather than damage to the olfactory receptors, being reversed after the worker is away from the workplace for a relatively short period of time. In the case of cigarette smoking, olfactory ability decreases as a function of cumulative smoking dose. Long-term cessation of smoking leads to a gradual improvement of olfactory function that is inversely related to the cumulative smoking dose. Long-term cessation rather than damage to the olfactory bulbs or tracts, can, in some cases, be addressed surgically. However, inflammatory causes of sinonasal disease are more likely to be treated medically or in combination with surgery. Quantitative olfactory testing is advised before and after treatment to ensure an accurate assessment of the intervention and to assess long-term outcomes. Examples of treatments that have restored olfactory function in some patients include allergic management, topical and systemic corticosteroids, antibiotics, and functional endoscopic sinus surgery. A brief course of systemic corticosteroid therapy can be useful in distinguishing between conductive and sensorineural olfactory loss as patients with the former will often respond positively to the treatment. Longer-term systemic corticosteroid therapy, however, is not advised. Topical nasal corticosteroids may be ineffective in altering smell dysfunction because the corticosteroid fails to penetrate the higher recesses of the nose. A binhaling nasal drops or sprays in the head-down Moffett position can sometimes increase efficacy.

**Other Causes.** As noted earlier in this chapter, medications commonly affect smell function and should be considered early in an evaluation, especially in the context of a new drug therapy (see Table 1). Olfactory hallucinations occur in mesial temporal lobe seizures and migraine, as well as in some other central brain lesion disorders. In epilepsy, the hallucinations are usually unpleasant and are rarely isolated events.33 Recent work suggests that olfaction is compromised in the morbidly obese, although the basis for this dysfunction is unclear.68

**Prognosis and Treatment of Olfactory Disorders.**

Prognosis is better for patients when smell loss is less severe, that is, for patients with UPSIT scores >25. This likely reflects, in cases having sensorineural damage, less extensive necrosis within the basal cell layer of the neuroepithelium and possibly less fibrosis around the foramina of the cribiform plate that can prevent regeneration or appropriate migration of receptor axons to the bulb. It is important for many patients to know the true degree of olfactory loss, given that prognosis relates to the magnitude of the loss. Quantitative testing places the patient’s problem into perspective; it can be therapeutic for an older person to learn that, while his or her smell function is not what it used to be, it still falls above average for his or her peer group.

Mechanical obstruction secondary to distorted intranasal architecture or intranasal tumors can often be addressed surgically. However, inflammatory causes of sinonasal disease are more likely to be treated medically or in combination with surgery. Quantitative olfactory testing is advised before and after treatment to ensure an accurate assessment of the intervention and to assess long-term outcomes. Examples of treatments that have restored olfactory function in some patients include allergic management, topical and systemic corticosteroids, antibiotics, and functional endoscopic sinus surgery. A brief course of systemic corticosteroid therapy can be useful in distinguishing between conductive and sensorineural olfactory loss as patients with the former will often respond positively to the treatment. Longer-term systemic corticosteroid therapy, however, is not advised. Topical nasal corticosteroids may be ineffective in altering smell dysfunction because the corticosteroid fails to penetrate the higher recesses of the nose. A binhaling nasal drops or sprays in the head-down Moffett position can sometimes increase efficacy.

Sensorineural causes of olfactory dysfunction are more difficult to manage. When spontaneous recovery occurs in head trauma patients whose loss reflects damage to the olfactory receptor cell axons, it typically occurs within 3 or 4 months of the injury. Patients who quit smoking tobacco typically have dose-related improvement in olfactory function and flavor sensation over time,69 although tobacco smoking by itself rarely causes complete loss of the sense of smell. Some central olfactory neural impairments, for example, tumors within the medial temporal lobe or tumors that impinge upon the olfactory bulbs or tracts, can, in some cases, be resected in a manner that allows for at least some restoration of olfactory function.

Some patients with extremely debilitating chronic dysosmia (usually of a number of years duration and often unilateral), in whom weight loss is marked or daily functioning is greatly impaired, are benefited by surgical intervention, for example, ablation of regions of the olfactory neuroepithelium or olfactory bulb removal. Of the surgical approaches, intranasal ablation or...
stripping of tissue from the olfactory neuroepithelium on the affected side is more conservative and less invasive than removal of the olfactory bulb and/or tract via a craniotomy. Should the dysosmia appear after intranasal intervention, additional or repeat ablations can be performed. In the majority of individuals, demonstrable smell loss does not accompany the dysosmic condition. In general, at least some degree of olfactory system function is required for the dysosmia to occur.

When olfactory disturbances are attributed to a particular medication, discontinuance, dose changes, or substitution of other modes of therapy can be effective, although rapid reversal of the problem rarely occurs. Even though there are advocates for zinc and vitamin therapies, there is no compelling evidence that these therapies work except in rare cases where frank zinc or vitamin deficiencies are present.

**THE GUSTATORY SYSTEM**

**Anatomy and Physiology**

Such sensations as sweet, sour, bitter, and salty, as well as possibly “metallic” (iron salts), “umami” (monosodium glutamate, disodium guanylate, and disodium inosinate), and “chalky” (calcium salts), are mediated via the taste buds of the gustatory system. Unlike olfaction, taste sensations are carried by several cranial nerves, i.e., CNs VII, IX, and X), as discussed below. Because of this fact, complete loss of taste function is rare from peripheral insults or trauma (since all nerves would have to be involved) and is more likely due to systemic or central causes. Intratraheal CN V free nerve endings are also stimulated by some foods and beverages, for example, carbonated or spicy foods, contributing to the overall gestalt of flavor. Hence, a piece of milk chocolate in the mouth is not only sweet but has texture and temperature. The sensation of “chocolate,” however, is dependent upon retronasal stimulation of the olfactory receptors. Unfortunately, many patients and their physicians fail to distinguish between “taste” sensations mediated by the taste buds from CN I-mediated “taste” sensations, for example, strawberry, chocolate, meat sauce.

**Taste Buds.** The goblet-shaped taste buds are distributed over the dorsal surface of the tongue, the margin of the tongue, the base of the tongue, the soft palate, pharynx, larynx, epiglottis, uvula, and the first third of the esophagus. The majority of taste buds are found on the lingual surface within the protruding papillae. Of the four types of papillae—fungiform, foliate, circumvallate, and filiform—only the first three harbor taste buds. Taste buds are continually bathed in secretions from the salivary glands and nearby lingual glands. von Ebner glands discharge into the troughs surrounding the circumvallate papillae, and lingual glands empty into the long fissures between the folds of the elongated foliate papillae on the posterior aspect of the margin of the tongue. The saliva contains not only such proteins as amylase (which initiates starch breakdown of foodstuffs), but also growth factors important for wound healing and the maintenance of taste buds. Indeed, removal of the submandibular and sublingual salivary glands leads to taste bud loss that can be prevented by supplying epidermal growth factor in the drinking water.

The human tongue contains, on average, around 4,600 taste buds. Each taste bud comprises 50 to 150 thin epithelial cells arranged much like the segments of an orange or grapefruit (Figure 10). The opening to the taste bud is termed the taste pore, and the excavation below the pore is termed the taste pit. Several types of cells are found within the taste bud, including cells that project microvilli into the taste pit and basal cells from which other cell types arise. On the basis of the density of their apical regions, light cells, dark cells, and intermediate cells can be identified within each bud. Like the cells of the olfactory neuroepithelium, taste bud cells have the propensity to replace themselves periodically, with the time course for at least some of this “turnover” apparently being between 2 and 3 weeks.

**Gustatory Neural Transduction.** A tastant must be in solution to enter the taste pore. Hence placing sugar or salt crystals on a dry lingual surface does not immediately lead to sweet or salty sensations, a common mistake made by some practitioners in attempting to assess taste function. After entering the taste pore, the tastant initiates the transduction process via 1 of 2 mechanisms: (a) activating receptors coupled to G-proteins that, in turn, activate second messenger systems (a process that occurs with sweet and bitter tasting stimuli); and (b) directly gating apical ion channels on the microvilli within the taste bud pit (a process that occurs with sour and salty tasting stimuli). Gustducin, a G-protein for taste reception, has been identified in taste receptor cells of fungiform, foliate, and circumvallate papillae.

Taste threshold sensitivity is directly related to the number of taste papillae and hence taste buds that are actively stimulated. Furthermore, taste thresholds are inversely correlated with stimulus duration. Interestingly, there are agents, when swished in the mouth, that selectively alter the quality of taste sensations. For example, miraculin, a glycoprotein from the berry of the African shrub Syncapsanum dilitcium, temporarily changes most sour-like sensations to sweet sensations. Gymnemic acid, an extract from the leaves of the Indian plant Gymnema sylvestre, can mitigate the perception of sweet sensation (and the corresponding electrophysiologic activity) without significantly changing the perception of the other taste qualities.

**Taste Afferent Nerves.** Different taste buds are innervated by different cranial nerves, depending upon the region of the oral cavity in which they are located. Unlike CN I, such nerves are mixed motor and sensory nerves that transmit multiple forms of information. An understanding of this fact can be important when clinical syndromes that involve taste dysfunction are considered. The nerve fibers from each of the taste nerves enter the brainstem and synapse within the nucleus of the tractus solitarius (NTS), which extends from the rostreralateral medullary cauda along the central border of the vestibular nuclei (Figure 11).

Taste sensations from (a) the taste buds of the fungiform papillae on the anterior two-thirds of the tongue (and the corresponding electrophysiologic activity) without significantly changing the perception of the other taste qualities.

**Figure 10** Schematic of tongue showing the three major types of taste bud-containing papillae (B) and their general lingual location (A). Structure of taste bud is shown in C. Although rough distribution of the trigeminal (CN V) and glossopharyngeal (CN IX) cranial nerves is shown in A, CN IX likely projects more anteriorly than depicted. Not depicted is the chorda tympani branch of the facial nerve (CN VII) that innervates taste buds on the anterior tongue (see Figure 11). In C, 1 and 2 are supporting cells, which secrete materials into the lumen of the taste bud. 3 is a sensory receptor cell, whereas 4 is a basal cell from which the other types of cells arise. (Modified from reference 72 with permission. Copyright © 1983, Oxford University Press.)
branch of the glossopharyngeal nerve (CN IX). The taste buds in the region of the nasopharynx are supplied by the pharyngeal branch of this nerve. The nerve cell bodies of these gustatory afferent fibers are found within the petrosal ganglion immediately outside the jugular foramen, where the fibers eventually pass to enter the cranium. CN IX also innervates the stylopharyngeal muscle, the parotid gland, the baroreceptors of the carotid sinus, and the pharyngeal mucus membrane.

The taste buds on the epiglottis, aryepiglottal folds, and esophagus are innervated by the vagus nerve (CN X) via the internal portion of its superior laryngeal branch. Nontaste sensory functions are mediated by this nerve in such areas as the external ear, external auditory canal, external surface of the tympanic membrane, and the vocal cords. CN X also mediates afferents to the TTN, fibers project to the primary taste cortex deep in the parietal operculum and adjacent perisylvian regions, including the frontal operculum, superior temporal gyrus (opercular part), and inferior sectors of the pre- and postcentral gyrus. A second-ary cortical taste region is present within the caudomedial/caudolateral orbitofrontal cortex, several millimeters anterior to the primary taste cortex.

Central Gustatory Regions: Functional Anatomy. The first central relay station of the gustatory system is the NTS in the medulla. The afferents from CN VII, IX, and X synapse within the NTS in descending (and overlapping) order. Cells from the NTS also make reflexive connections, via the reticular formation, with cranial motor nuclei that control such taste-related behaviors as chewing, licking, salivation, swallowing, and preabsorptive insulin release, as well as the muscles of facial expression. The major gustatory projections from the NTS, however, are the tertiary ones that ultimately lead to activation of cortical gustatory structures. These occur via the thalamic taste nucleus (TTN) in primates, that is, the parvicellular division of the ventroposteromedial thalamic nucleus. From the TTN, fibers project to the primary taste cortex deep in the parietal operculum and adjacent parainsular cortex. PET and fMRI studies have found taste stimulus-induced activation largely within the insula and perisylvian regions, including the frontal operculum, superior temporal gyrus (opercular part), and inferior sectors of the pre- and postcentral gyrus. A secondary cortical taste region is present within the caudomedial/caudolateral orbitofrontal cortex, several millimeters anterior to the primary taste cortex.

The specific role of the gustatory cortical regions in the processing of taste information is not clear. These regions contain multimodal neurons responsive to touch and temperature as well as taste. Some structures within the right hemisphere may play a more important role in taste perception than their left hemisphere counterparts. For example, citric acid presented to the whole mouth increases regional cerebral blood flow (rCBF) more in the right than in the left anteromedial temporal lobe and more in the right than in the left caudomedial orbitofrontal cortex although bilateral activation is observed in the caudolateral orbitofrontal cortex. Also, patients who have had right anterior temporal lobe resection for intractable seizure activity have higher citric acid recognition thresholds than both controls and left anterior temporal lobe resection patients. There is some evidence, however, that handedness may need to be controlled in such studies. Thus, whereas fMRI data suggest that the superior part of the insula is activated by tastants similarly in left- and right-handed subjects, this is not the case for the inferior insulae, where the left is relatively more activated in right-handed subjects, and the right is relatively more activated in left-handed subjects.

Classification of Gustatory Disorders

Gustatory disorders can be classified in a manner similar to olfactory disorders: ageusia: inability to detect qualitative gustatory sensations from all (total ageusia) or some (partial ageusia) tastants; hypogeusia: decreased sensitivity to tastants; dysgeusia: distortion in the perception of a normal taste, for example, an unpleasant taste induced by a stimulus that is normally associated with pleasant sensations or the presence of a taste in the absence of a stimulus (sometimes termed phantogeusia); gustatory agnosia: inability to recognize a taste sensation, even though gustatory processing, language, and general intellectual functions are essentially intact. Some patients complain of oral sensations of burning or numbness which may or may not have their genesis in gustatory afferents, for example, burning mouth syndrome (BMS) in which the sensation of “burning” occurs within the mouth without obvious physical cause.

Total ageusia is rare and, when present, is usually produced by central, for example, ischemic or medication, events since regeneration of taste buds can occur and peripheral damage would have to involve multiple pathways to induce taste loss. Thus, while 433 of 585 patients (74%) studied at the University of Pennsylvania Smell and Taste Center who exhibited olfactory loss complained of both smell and taste disturbance, fewer than 4% had verifiable whole-mouth gustatory dysfunction, and even that was limited. Regional deficits are much more common. For example, in one study, sensitivity to 3 concentrations of NaCl was measured on the tongue tip and 3 cm posterior to the tongue tip in 12 young (20 to 29 years of age) and 12 elderly (70 to 79 years of age) subjects. On average, the young...
subjects were more sensitive to NaCl on the tongue tip than on the more posterior stimulation site and exhibited, at both tongue loci, in increase in detection performance as the stimulus concentration increased. The elderly subjects, who would be expected to exhibit, at worse, moderate deficits on whole-mouth testing, performed at chance levels.88

The majority of patients are unaware of regional taste deficits. In fact, most patients can sustain loss of taste sensation on half of the anterior part of the tongue following unilateral sectioning of the chorda tympani in middle ear surgery without noticing the problem. Such lack of awareness stems, in part, from the redundancy of the multiple taste nerves, as well as compensatory mechanisms.

Clinical Evaluation of Gustatory Function

History. A history similar to that described earlier for patients complaining of olfactory disturbance should be obtained from patients complaining of gustatory disturbance. Specific consideration as to the type of stimuli that can or cannot be detected by the patient is essential to distinguish between retronasal CN I flavor loss and true taste-bud mediated gustatory loss. One should specifically inquire whether the patient can detect the saltiness of potato chips, pretzels, or salted nuts, the sourness of vinegar, pickles or lemons, the sweetness of sugar, soda, cookies or ice cream, and the bitterness of coffee, beer, or tonic water. If the patient indicates that there is a problem in such detection, the possibility of a true taste bud-mediated dysfunction exists.

Previous or current problems with salivation, chewing, swallowing, oral pain or burning, dryness of the mouth, periodontal disease, speech articulation, bruxism, or foul breath odor should be ascertained. Inquiry as to diet, oral habits, smoking problems, and possible problems with acid reflux is relevant, given that acid reflux into the oral cavity can irritate or damage taste buds. Recent dental work or exposure to radiation should be noted. Documentation of hearing or balance problems should be made; since past or current ear infections or surgery can result in altered chorda tympani function and produce taste loss or distortions. A careful assessment of medication usage is critical. As described in detail later in this chapter, many drugs, including lipid-reducing agents, antibiotics, and antihypertensives, can produce significant distortions or other alterations in taste function.

Physical Examination. A thorough head and neck examination is essential for ascertaining the potential cause of a gustatory disorder.21 Nongustatory deficits in CN VII, IX, and X can shed light on whether gustatory dysfunction may be present. For example, abnormal facial muscle function, swallowing, salivation, gag reflex, or voice production. Changes in epithelial color, or visual signs of scarring, inflammation, or atrophy of lingual papillae should be noted. Neoplastic lesions in the tongue’s musculature should be ruled out by palpation. Specific attention to the condition of the teeth and gums is important since exudates produced by gingivitis may produce or contribute to dysgeusic symptoms. An inspection of the nature and integrity of the fillings, bridges and other dental work should also be made, for example, disimilar metals can induce small electrical currents that, in turn, produce abnormal oral sensations. In individuals in whom an explanation of the taste problem is not clear, neuroimaging to rule out CNS tumors or lesions should be performed.

In some instances, it may be useful to evaluate biopsies of circumvallate or fungiform papillae to determine the presence of pathology. The tongue can also be stained with a dark food dye and photographed under high illumination and low power magnification to allow for counting or better visualizing selected classes of papillae. In general, there is a high correlation between the number of fungiform papillae and the number of taste buds.21

Quantitative Gustatory Testing. Quantitative taste testing is rarely performed in the clinic, largely because of issues of practicality, for example, time and expense of preparing and presenting limited shelf-life taste stimuli. While a number of whole-mouth taste tests have been described in the literature,90 regional taste testing is needed to establish the function of each of the nerves innervating different taste bud fields. As noted above, whole-mouth tests are insensitive to even complete dysfunction of one or several of the nerves that innervate the tongue.

Regional taste testing can be made using either chemical or electrical stimuli. The former requires applying known concentrations of liquid stimuli (eg, sucrose, citric acid, caffeine, and sodium chloride as prototypical representatives of sweet, sour, bitter, and salty taste qualities) to the tongue or oral cavity (in some cases in comparison with blank trials), rinsing the stimuli off between trials, and expectorating after each presentation. Such testing can be quite time consuming. For example, if responsiveness to each of the 4 basic taste qualities is to be made on left and right anterior (CN VII) and posterior (CN IX) tongue regions, 16 trials (4 tastants x 4 tongue regions) would be needed to present a single stimulus for each quality. Since multiple stimuli are required to produce reliable responses, the number of trials increases considerably.

In the regional chemical test employed at our centre, a single suprathreshold concentration of each of 4 stimuli (sucrose, citric acid, sodium chloride, and caffeine) is used. The stimuli are equated for perceived intensity (using a magnitude matching procedure) and are presented at the same volume (15 μL from an Eppendorff pipette; Brinkman Instruments, Westbury, NY) and kinematic viscosity (1.53 mm²/s using tasteless cellulose gum). Equating viscosity eliminates context effects and tactile cues and increases control of solution spread when placed on the tongue in microliter quantities. The stimuli are presented 6 times to each tongue region, resulting in a test consisting of 96 stimulus trials and 96 rinses. Testing time is between 1 and 1½ hours. The task of the subject is to report the presence of a sweet, sour, bitter, or salty sensation using a forced-choice procedure with these 4 alternatives available and to rate the perceived intensity of the stimulus on a standardized rating scale with logarithmic visual properties.

A more practical approach to taste testing is to employ an electrogustometer, a device that presents brief μA currents to small regions of the tongue for known durations (Figure 12).90 No stimulus preparation or rinsing is required. Electrogustometric thresholds can be obtained easily, although their relationship to chemical thresholds is still not clear and extreme care must be taken to apply the stimulator to the exact same region of the tongue on each trial, as considerable regional variation in sensitivity is present. At low current ranges electrogustometry has been demonstrated to activate only taste afferents, not trigeminal (CN V) afferents. In general, electrical thresholds are correlated with the number of taste papillae and buds in the regions evaluated.90 Unfortunately, sound normative data based upon forced-choice testing paradigms are still generally lacking for such devices.

Imaging Studies. Imaging studies of the gustatory pathways can be useful in explaining the gustatory symptoms of some patients. In addition to detecting large central lesions and tumors, modern MRI techniques can detect discrete lesions, for example, infarcts, within brain structures that correlate both with patient complaints and with the results of sensory testing. As noted in detail in the next section, MRI-determined infarcts in the pons have been repeatedly associated with ageusia and dysgeusia.91,92

Causes of Gustatory Dysfunction

Although central or systemic factors are the most likely causes of ageusia, local factors can significantly alter taste perception. Proximal mechanisms include: (a) the release of foul-tasting materials from oral medical conditions,
for example, gingivitis, sialadenitis, (b) problems in movement of tastants to the taste buds, for example, damage to taste pores from a burn, (c) damage to the taste buds proper, as from caustic or allergic reactions to toxins or oral products, (d) damage to taste nerves, for example, Bell palsy, dental or surgical procedures, and (e) CNS damage, for example, from tumors, epilepsy, or infarcts. One cause of dysgeusia can be the use of different metals in the mouth that set up subtle electrical currents within the oral cavity. The more common causes of taste disorders are discussed below.

**Aging.** Although whole-mouth taste acuity declines with age, the perceptual decrease is not as marked as that seen for olfaction. Compared to younger persons, the elderly tend to perceive tastes as being less intense. In conjunction with the loss seen with the sense of smell, decrements in taste function can be harmful to some of the elderly, leading to anorexia, weight loss, malnutrition, impaired immunity, and worsening of a medical illness. Whole-mouth testing reveals moderate degrees of age-related taste loss, whereas regional taste testing reveals marked age-related decrements.

**Viral Infection.** Bell palsy is the most frequent cause of facial nerve damage. Usually of viral origin, for example, Herpes simplex, this disease affects both sexes of all ages. This disorder typically begins with pain in or behind the ipsilateral ear, followed by symptoms of unilateral facial weakness over the course of a few days. Hyperacusis occurs in many cases, due to a weakening of the stapedius muscle. Aft commonly accompanied by ipsilateral taste loss over the anterior two-thirds of the tongue, patients are often unaware of the taste problem without formal testing. It has been suggested that return of taste function by 2 weeks after onset is a positive prognostic indicator for complete and relatively rapid recovery from facial paresis, whereas longer lasting taste impairment is associated with poor prognosis. The taste-salivary reflex arc, which extends from the taste nerves via the NTS to the parasympathetic fibers innervating the salivary glands, can also be compromised in this disorder.

Ramsey Hunt syndrome results from a recrudescence of latent Herpes zoster virus within the geniculate ganglion and results in pain and vesicles in the external auditory canal or soft palate. Bartoshuk and Miller described a patient with the Ramsey Hunt syndrome that involved both CN V and CN IX on the left side. Intensity ratings were obtained for each of the 4 taste qualities at regular intervals across a nearly 600-day period for the front, back, and palate regions. About 3 months after the Herpes zoster oticus attack, the entire left side of the patient was devoid of taste function. After 400 days, all taste qualities were perceived on the left back and palate regions, but only sweetness could be perceived on the left front. Full taste recovery of the anterior part of the tongue was not present even by the end of the nearly 600-day-long testing period.

**Burning Mouth Syndrome.** In some cases, BMS, also termed glossodynia or glossalgia, is associated with salty or bitter dysgeusias. This poorly understood syndrome is characterized by idioopathic intense “burning” pain within the mouth without obvious physical cause. To what extent this disorder is mediated via gustatory or CN V afferents is not known. BMS typically begins by late morning and is continues throughout the day. Suggested causes include: (a) diabetes mellitus (possibly predisposing to oral candidiasis), (b) nutritional and hormonal deficiencies, for example, iron, folic acid, B vitamins, zinc, and estrogen, (c) denture allergy (including reactions to amalgam fillings), (d) mechanical irritation from dentures or oral devices, (e) parafunctional habits of the mouth, for example, tongue thrusting, teeth grinding, or jaw clenching, (f) tongue ischemia as a result of temporal arteritis, (g) oral candidiasis, (h) periodontal disease, (i) reflux esophagitis, and (j) geographic tongue. Anxiety and depression are common in the BMS population.

**Central Lesions and Tumors.** Taste dysfunction has been attributed to a variety of tumors and lesions, including vestibular schwannomas, tumors of the hypophysis with marked extracranial growth, facial nerve schwannomas extending into the middle cranial fossa, and cerebellopontine angle lesions. Contralateral dysgeusia has been observed in patients with lateralized infarcts of the thalamus and in patients with infarcts in the corona radiata (reflecting the crossed taste pathways at this level of the nervous system). Unilateral lesions above the brainstem do not usually cause complete loss of function because of the multiple areas involved in processing taste information.

Gustatory problems can arise from damage to the brainstem structures related to taste, often in conjunction with impairment of other cranial nerves or long tracts. Regions susceptible to damage include the NTS and the pontine tegmentum, which involves both gustatory lem-nisci. Hemageusia from an ipsilateral multiple sclerosis plaque at the midpontine tegmentum has been reported. Similarly, ageusia to all taste qualities on the right side of the tongue was noted in a patient who had a small hemorrhage in the right tegmentum of the middle pons. Three cases of ipsilateral hemageusia due to focal ischemic lesions in the brainstem have been described.

A common cause of unilateral hypogeusia resulting from a brainstem infarct is shown in Figure 13. In this case, ischemic activity is evident in a region of the upper medulla near the right NTS. Note that, in this image, the patient’s right side is on the left side of the picture. This individual complained of dysgeusia on the right side of the tongue and, upon testing had a decrement in the ability to discern sweet, sour, bitter, and salty sensations that was greater on the right than on the left. Both CN VII and CN IX seemed to be involved.

**Head and Neck Trauma.** Trauma-related taste loss is much less common than trauma-related smell loss, with fewer than 1% of persons with major head injury exhibiting ageusia to sweet, sour, salty, or bitter taste qualities. Nonetheless, taste loss as well as dysgeusia can occur in some types of head trauma. For example, basilar temporal bone fractures and other injuries that impinge upon the middle ear have the potential for impairing chorda tympani nerve-mediated taste function unilaterally, as well as for altering salivary secretion. Injury to the lingual nerve in and around the mouth and tongue can also occur in some traumas. This nerve, a branch of the mandibular division of CN V, is the most proximal pathway to the tongue for general somatic sensation (touch) and special visceral sensation of taste (owning to concurrent facial nerve fibers).

**Iatrogenic Injury.** Numerous surgical interventions can induce taste dysfunction. The glossopharyngeal nerve is susceptible to damage during tonsillectomy, bronchoscopy, or laryngoscopy, reflecting the close proximity of the lingual branch of this nerve to the muscle layer of the palatine tonsillar bed. Surgical treatment for snoring, for example, uvulopalatoplasty, as well as such surgery-related procedures as endotracheal intubation, and the employment of a laryngeal mask, have all been associated with taste loss or alteration.

The chorda tympani nerve is at particular risk from surgical procedures that involve the middle ear, given its course between the malleus and the incus. The nerve is often stretched or sectioned during tympanoplasty, mastoidectomy, and stapledectomy, in some cases producing long-lasting symptoms. Bull, for example, found that 78% of patients with bilateral section and 32% of patients with unilateral section of the chorda tympani had persistent adverse gustatory symptoms.

Shafer and colleagues evaluated gustatory function in 17 patients before third molar extraction and at 1 and 7 months thereafter. On average, an approximately 15% reduction of perceived intensity was observed 1 month after extraction for NaCl, citric acid, and quinine hydrochloride. The taste quality of NaCl was identified correctly less often after than before third molar extraction. Citric acid intensity perception had not recovered by 6 months after the surgery. These data suggest that not only do gustatory deficits commonly occur after third molar extraction, but they can persist for at least 6 months after surgery. Furthermore, they seem to be associated with the depth of impaction.

Frey syndrome, a well-described complication of parotidectomy, also referred to as gustatory stimulated facial sweating, results from a misdirected growth of regenerating parasympathetic nerve fibers. Instead of innervating the parotid gland, regenerated nerve fibers innervate sweat glands in the overlying skin. Although usually provoked by taste stimuli, there is suggestion that such responses can come, in some cases, from the smell of food or even emotional excitement. Damage to the auriculotemporal nerve can produce a rare clinical syndrome of postrumatic
gustatory neuralgia, defined as a paroxysmal, lancinating facial pain in the cutaneous distribution of the auriculotemporal nerve following gustatory stimulation.\textsuperscript{102,112} This condition can result from iatrogenic injury, for example, parotid gland surgery, temporomandibular joint surgery, carotid endarterectomy, orthognathic surgery, and oncologic surgery, as well as by viral induced damage and is characterized by episodic, transient, electric shock-like pain in the preauricular region.\textsuperscript{102}

Medications. Medications produce taste disturbances more frequently than olfactory disturbances. Such side effects can be very debilitating and, in rare instances, have contributed to extreme weight loss and even suicide. Among offending agents are antiproliferative drugs, lipid-reducing drugs, antihypertensive drugs, diuretics, antifungal agents, antihypertensive drugs, antibiotics, and drugs with sulfahydryl groups, such as penicillamine and Captopril.\textsuperscript{28} For example, 0.6 to 2.8\% of patients taking the antifungal agent terbinafine (Lamisil) report taste loss. The loss is more generalized across tongue regions for sucrose, citric acid, and quinine than for sodium chloride, which approximately one-fourth of all cardiac medications (including antiplatelet agents, adrenergic blockers, angiotensin-converting enzyme inhibitors, angiotensin II antagonists, calcium channel blockers, vasodilators, antiagglutinants, antirrhymics, and various diuretics) employed in the United States are listed in the Physicians’ Desk Reference as having potential side effects of either “altered taste,” “bad taste,” “bitter taste,” or “metallic taste.”

Radiation Therapy. Radiotherapy for head and neck cancer can induce taste loss and dysgeusia, salivary dysfunction, and conditioned taste aversions. Such problems can alter quality of life and, on occasion, appetite to the degree that nutrition is compromised. Symptoms usually begin early in the course of treatment and posttreatment recovery can take months and, in rare instances, years.\textsuperscript{115} The cause of such disturbances can be quite varied, including direct radiation-induced damage to taste cells and buds, salivary glands, and taste nerve fibers (which normally provide trophic factors that maintain the integrity of the taste bud). The xerostomia secondary to salivary gland damage can influence food transport, protection from bacterial invasion, and salivary proteins potentially involved in taste transduction\textsuperscript{116} and can aid in the promotion of opportunistic oral infections, for example, oral candidiasis.\textsuperscript{117} Although typically idiosyncratic and transient, some taste aversions can be long lasting and can produce generalized anorexia and cachexia. A means for mitigating such aversions is to have the patient consume a novel food immediately before the first course of chemotherapy or radiotherapy. This simple maneuver somehow focuses the aversion primarily on the novel food and interferes with the formation of conditioned aversions to preferred dietary items.\textsuperscript{118}

Other Causes. Among other reported causes of taste dysfunction are hypothyroidism, renal disease, liver disease, myasthenia gravis, Guillain–Barre syndrome, numerous neoplasms, and familial dysautonomia (a genetic disorder with lack of taste buds and papillae). Idiopathic dysgeusia has been associated with blood transfusion.\textsuperscript{119} Complaints of taste loss or distortion are reported in many carcinomas and mass lesions. For instance, while squamous cell carcinoma of the mucous membranes of the upper aerodigestive tract can interfere with taste by direct destruction of receptors, mass lesions along the course of CN VII, IX, and X may cause impairment through neural compression. Carcinoma-related malnutrition may also lead to ageusia.

A persistent and unpleasant sweet dysgeusia has been described in 3 patients with small cell carcinoma of the lung.\textsuperscript{120} The dysgeusia was the presenting symptom in all 3 individuals, and hyponatremia secondary to the syndrome of inappropriate secretion of antidiuretic hormone was present in each case. Resolution of the dysgeusia paralleled an increase in serum sodium concentration after water restriction alone. The close association between the dysgeusia and the low serum sodium concentration suggests that hyponatremia was the causative factor, rather than the carcinoma, antidiuretic factor, medications, or chemotheraphy.

Gustatory symptoms have been reported in association with epileptic seizures. Examples of taste sensations that have been reported in such cases include “peculiar,” “rotten,” “sweet,” “like a cigarette,” “like rotten apples,” and “like vomitus.”\textsuperscript{3} Some of these “tastes,” however, likely represent smell sensations that are mis categorized as tastes by both the patients and their physicians.

Selective taste nerve damage or alterations may produce some forms of hypergeusia and dysgeusia. For example, anesthetizing 1 chorda tympani nerve reportedly increases the perceived intensity of bitter substances, such as quinine, and can aid in the promotion of opportunistic oral infections, for example, oral candidiasis.\textsuperscript{117}

Although typically idiosyncratic and transient, some taste aversions can be long lasting and can produce generalized anorexia and cachexia. A means for mitigating such aversions is to...
the central projection areas of the different taste nerves.

**Treatment of Taste Dysfunction**

As in the case with other sensory systems, prognosis in cases of taste dysfunction is likely inversely related to the degree of neural or structural damage, although clinically such damage can rarely be assessed. Fortunately, the taste nerves and buds appear to be relatively resilient, as many cases of taste loss or distortion spontaneously resolve over time.¹² In some dysgeusia cases, antifungal and antibiotic treatments have been reported to be useful, although double blind studies of the efficacy of such treatments are lacking, and some of these agents themselves can produce taste disturbance. Chlorhexidine employed in a mouth wash has been suggested as having possible efficacy for some salty or bitter dysgeusias, possibly as a result of its strong positive charge.¹² In the case of neural damage from viruses or other agents, presumably the damaged taste afferents regenerate. Thyroid replacement therapy reportedly brings back taste sensitivity to normal levels in cases of taste loss secondary to hypothyroidism.¹² Taste disorders caused by medications can, in some instances, be reversed by discontinuing the offending drug, by employing alternative medications, or by changing drug dosage. It should be kept in mind, however, that a number of pharmacologic agents appear to induce long-term alterations in taste that may take months to disappear after drug discontinuation.

Since most BMS patients are postmenopausal, dysgeusias associated with this disorder may, in some cases, respond to estrogen replacement therapy. Topical capsaicin may also be helpful in some cases. Given that BMS is often associated with anxiety and depression, tricyclic antidepressants, for example, amitriptyline, desipramine, nortriptyline, and benzodiazepines appear, in selected instances, to have some therapeutic efficacy.¹²⁴

**CONCLUSIONS**

Disorders of the chemical senses of taste and smell are relatively common, particularly in the elderly, and can result from a broad array of causes. Such causes range from simple irritation of the receptive elements to serious neurological disorders, including Alzheimer disease and idiopathic Parkinson disease. In this chapter, a succinct overview of the anatomy and physiology of the chemical senses, as well as of the primary causes of chemosensory dysfunction, has been provided. Approaches to therapy have been discussed, with an emphasis on the need for quantitative evaluation of patients before initiating surgical or medical interventions. Clearly, a number of disorders of the chemical senses can be approached with optimism, so long as the physician establishes the exact nature of the problem and is aware of the available avenues of treatment and objective assessments of efficacy.

Cellular Biology of the Immune System

Bradley F. Marple, MD
Raghu S. Athré, MD

The questions of how man acquires and fends off disease have plagued humanity since the beginning of time. The ancients saw disease as a manifestation of god’s will and performed sacrifices to prevent angering the gods and becoming ill. In 1796, Edward Jenner showed that smallpox could be prevented by inoculation of cowpox, a less virulent virus. He initially made the observation that women who milked cows were somehow immune to smallpox after they contracted cowpox, which was similar to smallpox, but never fatal. To further the knowledge base of the immune system and its workings, Louis Pasteur presented his landmark paper on germ theory in 1879 to the French Academy of Sciences. He is credited with linking disease with microorganisms and thereby set the stage for all future research in the field of immunology.

THE HUMAN IMMUNE SYSTEM

The human immune system is a remarkable collection of many different cell types that work in synchronized orchestration to protect the host against a seemingly infinite number of possible environmental pathogens, while still not actively against itself. Any entity capable of eliciting an immunologic response is termed an antigen.

The human immune system can distinguish between very similar antigens, even antigens that may differ by a single amino acid. This characteristic is termed specificity. Immune system responses are highly specific and are tailored to an individual antigen. For example, exposure to varicella may afford the host lifelong immunity to varicella, but not to paramyxovirus.

The immune system deals with many invading microorganisms by releasing cytotoxic chemicals that are deadly to the invading microorganism and to cells infected by the invading microorganism. Therefore, it is imperative that such responses are targeted only to foreign microorganisms and infected cells and not to normal host cells. The immune system has an intrinsic property in recognizing self from nonself; and, when this regulation pathway is disturbed, autoimmunity results. Autoimmunity is when the immune system starts attacking normal cells. An example of such a disease condition is myasthenia gravis. In myasthenia gravis, the immune system produces an immune response against the acetylcholine receptor in the neuromuscular junction producing progressive muscular weakness with repetitive muscular contraction.

The immune system can be broken down into 2 large divisions: the innate immune system and the acquired immune system. Innate immunity is a nonspecific, genetically derived system that is present in each individual at birth. Examples of tissues and substances involved in the innate immune system include the skin, mucous membranes, saliva, tears, perspiration, and gastric acid. Each one of these acts to retard the growth of pathogenic microorganisms and inhibit their infective capability. Acquired immunity is specific and adaptive in that it reacts with antigens to produce a specific immune response to that particular antigen. Furthermore, the acquired immune system learns which antigen it has been exposed to so that future exposure to the same antigen produces responses that are faster and more robust. This type of immunity will be discussed in this chapter.

Acquired immune responses can be divided into 2 subgroups: antibody-mediated and cell-mediated responses. Antibodies, also known as immunoglobulins (Igs), are proteins that circulate in the blood and are produced by specialized cells named B cells. Antibodies bind to antigen in a specific manner and can initiate several types of responses such as binding to and killing bacterial cells or binding and inactivating a bacterial toxin. On the other hand, cell-mediated responses involve the production of specialized cells that react with antigens on the surface of cells. An example of this is a viral-infected cell presenting foreign viral antigens on its surface. The cell-mediated immune response would bind the foreign antigen and initiate a sequence of events that would result in the death of the infected cell before the virus could replicate.

What Are Lymphocytes?

Immune system cells are also known as white blood cells. The category of white blood cells includes such cell types as macrophages and lymphocytes. Lymphocytes are the specialized cells that react in a specific manner to antigens and elicit and propagate immune responses. Lymphocytes can be further characterized as either B cells or T cells. B cells are responsible for antibody-mediated immune response, and T cells are responsible for cell-mediated immune responses. There exist 2 types of T cells: helper T cells and cytotoxic T cells. Cytotoxic T cells kill infected cells that exhibit foreign antigens, whereas helper T cells modulate and enhance the immune response to antigens.

Lymphocytes represent 1 of the most numerous cell types in the body. The combined total mass of all lymphocytes is equivalent to the mass of the brain! Lymphocytes develop from pluripotent stem cells that give rise to all blood cells including lymphocytes, red blood cells, and platelets. This maturation from pluripotent stem cells occurs in the bone marrow in adults and in the liver in fetuses. Also, T cells are "sensitized" in the thymus gland. Since the adult bone marrow, fetal liver, and thymus gland are involved in the production of lymphocytes, they are referred to as the primary lymphoid organs.

All leukocytes are derived from a common progenitor cell. The first division in the schema of differentiation is between the myeloid cell line and the lymphoid cell line. The myeloid cell line gives rise to monocytes, neutrophils, eosinophils, basophils, erythrocytes, and platelets. On the other hand, the lymphoid cell line gives rise to T cells, B cells, and natural killer (NK) or large granular lymphocytes. Cells. Differentiation of a pluripotent stem cell into either the myeloid line or the lymphoid line is mediated through receptors on the stem cell surface and interaction with various soluble chemicals (cytokines) and through stem cell surface receptors. Presence of different cytokines and expression of different cell surface receptors guide the pluripotent cell down either the myeloid or lymphoid cell pathway. Stromal support cells in the bone marrow also control cell proliferation and maintenance via the release of cytokines such as interleukin-4 (IL-4), IL-6, IL-7, IL-11, and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Figure 1).

Other than B cells and T cells, NK cells are the last major subtype of lymphoid line. NK cells are also called large granular lymphocytes. NK cells are larger than B and T cells and do not have antibody or T cell receptors on their surface. The role of NK cells is to kill virally infected cells and tumor cells. NK cells do this in a nonspecific manner. Furthermore, activation of NK cells can cause secretion on interferon-gamma (IFN-γ), which subsequently causes proliferation of other cell types. T cells that have been activated can
A complex immune response occurs. B cells and other hematopoietic cells migrate to the thymus gland, where the rest of their maturation occurs.10 B cells and other hematopoietic cells mature in the bone marrow. T cell precursor cells leave the bone marrow and mature in the thymus gland. Mature lymphocytes then enter the circulation and are exposed to potential antigens in the secondary lymphoid organs.

Precursor T cells leave the marrow and travel to the thymus gland, where the rest of their maturation occurs.10 B cells and other hematopoietic cells mature in the marrow itself.11 Once the B cells and T cells have matured, they are released into the blood, where they travel to the secondary lymphoid organs. Secondary lymphoid organs include the lymph nodes, tonsils, adenoid, spleen, and epithelial-associated lymph tissue in the skin, gastrointestinal tract, and respiratory tract (Figure 2). In the secondary lymphoid organs, mature lymphocytes are exposed to antigens. The blood is essentially filtered, and some of the lymphocytes become activated as they are exposed to their specific antigen. Activated lymphocytes secrete IL-2, which can cause proliferation of NK cells.8,9 These mechanisms work in concert to amplify the immune response to foreign antigens.

Activating T cells leave the marrow and travel to the thoracic duct, which empties into the subclavian vein. Thus, the entire fluid system collects into various ducts and finally empties into the lymph fluid system. The lymph fluid system percolates through the lymph node and initiates downstream immune responses. The other lymphocytes percolate through the lymph node and end up in the lymph fluid system. The lymph fluid system collects into various ducts and finally empties into the thoracic duct, which in turn empties into the subclavian vein. Thus, the entire system recirculates.

Differentiating between B cells and T cells is difficult. Prior to activation, both types of cells appear morphologically the same. Following activation, B cells secrete antibodies, and therefore develop extensive networks of rough endoplasmic reticulum in the cytosol. This way, B cells and T cells can be differentiated since T cells do not have a significant amount of rough endoplasmic reticulum. However, B cells and T cells can also be differentiated because of their cell markers. Different cells have different proteins on their cell surface. For example, T cells have either the CD4 or CD8 protein on their cell surface. By using antibodies to these proteins, the cells can be sorted in the laboratory.

Pluripotent stem cells differentiate into 2 main classes, the myeloid line and the lymphoid line. The myeloid line subdivides into 5 categories of precursor cells: CFU-GM, BFU-Eo, BFU-BM, BFU-MEG, and BFU-E.10 CFU-GM cells give rise to monocytes, macrophages, and neutrophils. Monocytes mature in the bone marrow and are released into the circulation. In the circulation, they travel to various tissues, penetrate the tissue and become tissue macrophages. Examples of tissue macrophages include Kupffer cells and microglial cells. Cytokines such as stem cell factor (SCF), IL-3, IL-6, IL-11, and GM-CSF stimulate the proliferation of the myeloid line of stem cells.14 Further differentiation is guided by other cytokines such as macrophage colony stimulating factor (MCSF) to induce end-line differentiation into monocytes and macrophages. The other postmyeloid differentiated ones give rise to the following cells: CFU-Eo → eosinophils, CFU-BM → basophils, BFU-MEG → platelets, and BFU-E → erythrocytes. Similar to the example given above with monocytes and macrophages, other interleukins and cytokines govern the differentiation of precursor cells to the aforementioned cell types.14

Figure 2 Diagram of secondary lymphoid organs.

SPECIFICITY, CLONAL SELECTION, AND HOMING

As alluded to earlier, binding of an antigen to its receptor is a specific event. This gave rise to the lock and key hypothesis. Each receptor on a T cell or B cell can be viewed as a lock, and their corresponding antigen as the key. Activation of a T cell or B cell requires binding its specific antigen to its receptor. The exact 3-dimensional portion of an antigen molecule that reacts with a receptor is called the epitope. A particular antigen may have multiple epitopes, though 1 of those epitopes may induce a more robust immune response. That epitope is deemed to be the immunodominant epitope. Any 1 antigen may activate multiple lymphocytes. However, even activation of multiple lymphocytes will only represent a small portion of the overall lymphocyte pool.

The lock and key hypothesis presented above logically leads us to the next question: How does the body respond to the seemingly infinite number of antigens if each antigen requires a separate receptor? The method by which the immune system produces such a diversity of receptors is by a process called clonal selection.15 This theory states that each host randomly generates a set of lymphocytes with specific receptors to antigens that have never been encountered by the host organism. The immune system is composed of numerous families of ancestral lymphocytes. Each ancestral lymphocyte is predetermined to produce a lymphocyte with a particular antigenic specificity. These lymphocytes are produced despite the fact that the host has not been exposed.
to that specific antigen. Each mature lymphocyte that is derived from 1 particular ancestral lymphocyte is a clone with the exact same receptor configuration. Once the host organism is exposed to an antigen, those lymphocytes with receptors for that particular antigen are chosen to multiply and mature.

Thus far, it has been established that lymphocytes start off in the primary lymphoid organs, circulate through the body to the secondary lymphoid organs, and return back to the circulatory system. Lymphocytes have certain homing receptors on their surface that guide them toward secondary lymphoid organs. Secondary lymphoid organs such as lymph nodes have special venules leading to the lymph node called high endothelial venules. These high endothelial venules have specialized mucin-like glycoproteins that are expressed solely on the surface of high endothelial venules. This specialized glycoprotein binds to an E-selectin molecule that is expressed on the surface of most lymphocytes. As the lymphocyte nears the lymph node, interactions between the E-selectin molecule on the surface of the lymphocyte and the specialized glycoprotein on the surface of the high endothelial venule cause the lymphocyte to slow down and start rolling along the surface of the high endothelial venule. Subsequently, a different molecule on the surface of the lymphocyte belonging to the integrin family of proteins binds to a counter-molecule on the surface of the high endothelial venule causing adhesion of the lymphocyte and extravasation of the lymphocyte into the lymph node (Figure 3). Similar types of homing cell surface receptors and counter-molecules guide individual lymphocytes to their respective locations within a lymph node. For example, T cells and B cells are segregated into different locations within a lymph node. In various disease states, the numbers of homing receptors may be upregulated. An example of this occurs in nasal polyposis. In patients with nasal polyposis, there is an upregulation of cell surface integrin, very late activation antigen 4 (VLA-4), on eosinophils and vascular cell adhesion molecule 1 (VCAM-1) on the blood vessels of nasal polyps. VLA-4 and VCAM-1 are a receptor/counter-receptor pair that allows homing of eosinophils to nasal polyps. Such homing mechanisms are important in recruiting specific types of leukocytes to areas of inflammation or areas where immune responses are needed.

**PRIMARY AND SECONDARY IMMUNE RESPONSES**

One of the characteristics of the immune system is memory. This characteristic is the reason we retain lifelong immunity to common viral pathogens encountered as children, and the reason why vaccinations work. The primary immune response is the resultant response when the immune system is exposed to an antigen for the first time. Once the immune system is triggered with antigen, antibody, and cell-mediated responses lag for several days, rise exponentially, and then taper off slowly. The secondary immune response results if the immune system is challenged with antigen following several weeks, months, or even years. The secondary immune response differs from the primary response in that the initial lag period is essentially nonexistent and the height of the response is more robust than in the primary response. Therefore, the immune system has essentially remembered its exposure to the initial antigen and responded to the invading antigen (Figure 4).

The theory of clonal selection presented above allows us to explain conceptually immune memory. T cells and B cells in the secondary lymphoid organs can be characterized into 3 stages of maturation: virgin cells, activated cells, and memory cells. Virgin cells are those lymphocytes that have never been exposed to antigen. As virgin cells are exposed to antigen, some become activated cells and others become memory cells. Activated cells carry out immune responses; activated B cells secrete antibodies, and activated T cells carry out cell-mediated responses. Memory cells are not actively involved in carrying out immune responses. Rather, they multiply and await a repeat exposure to the same antigen. If the immune system encounters the same antigen again, the memory cells are triggered. Memory cells bind antigen more tightly than virgin cells, have higher affinity receptors, adhere more strongly to other cells, and transduce intracellular messages more effectively. When memory cells are triggered, some memory cells become activated cells, and others are induced to become more memory cells for subsequent exposures to the same antigen (Figure 5).

**ANTIBODIES**

Antibodies are Igs synthesized exclusively by B cells. Antibodies are 1 of the most abundant protein components in the blood. All antibody molecules synthesized by an individual B cell are identical. Virgin B cells do not secrete antibodies. They synthesize antibodies and insert them onto their cell surface. These antibody molecules on the surface of the B cell serve as receptors for antigens. When the specific antigen for a particular antibody is encountered and binds an antibody receptor on the surface of a virgin B cell, the B cell is either activated or becomes a memory B cell.
If the B cell is activated, it becomes a plasma cell and secretes soluble, rather than membrane-bound, antibody with the same antigen specificity as the original virgin B-cell antibody receptor. Activated B cells that secrete antibodies are termed plasma cells. Plasma cells have dedicated a great proportion of their intracellular machinery to the production and secretion of antibodies. Hence, the lifespan of plasma cells is relatively short.22

Antibodies are Y-shaped molecules. The 2 arms of the “Y” each have an antigen-binding site (Fab) and are linked to a common “tail” (Fc) region via a flexible hinge region (Figure 6). Both antigen-binding sites on a particular antibody molecule are identical and are specific for 1 particular antigen. Because of the fact that each antibody molecule can bind 2 epitopes, they are said to be bivalent. Antigens with 3 or more epitopes can cross-link and form large lattice structures. The hinge region described earlier contributes to the efficiency of antigen binding and lattice formation by affording flexibility in the distance between the 2 antigen-binding sites within the antibody molecule.

The role of antibodies in the schema of the immune system is not solely to bind antigen and form lattice networks. The Fc region of the antibody molecule can confer additional functional properties to the antibody molecule. To understand this concept, a more in depth understanding of antibody structure and types of antibodies is necessary.

Antibody Classes

There are 5 main classes of antibodies: IgA, IgE, IgG, IgD, and IgM. Each class has a distinctive type of heavy chain. The 5 types of heavy chains are α, ε, γ, δ, and μ. Antibodies composed of α heavy chains fall within the IgA class of antibodies, antibodies with ε heavy chains form IgE, and so on.23

IgM, composed of μ heavy chains, is the first class of antibody produced. IgM is produced by B cells as a membrane-bound receptor composed of 2 light chains and 2 μ heavy chains. These nonactivated cells are called virgin B cells. Some virgin B cells also have IgD receptors composed of δ heavy chains. The IgM and the IgD receptors on any 1 individual virgin B cell have the same antigen specificity.9

IgM is also the first antibody produced in the primary immune response. Once a virgin B cell binds antigen in its Fc region, it either becomes activated or becomes a memory B cell. If the B cell becomes activated, it starts to secrete IgM molecules with the same receptor specificity as the original membrane-bound IgM receptor. IgM is secreted as a pentamer of 5 four-chain units to form a macromolecule capable of binding 10 total epitopes (Figure 7). Each individual IgM molecule in the pentamer is linked to its adjacent partner via a special protein chain called a J chain (joining chain). The J chain binds 2 adjacent Fc regions. The binding of antigen by pentameric, secreted IgM causes the Fc region to bind and activate complement proteins, which in turn can unleash a cytotoxic biochemical attack on the surface of an invading microorganism. IgD is present within the body only in small amounts. The exact role of IgD other than serving as a membrane-bound receptor is unknown.9

The second major class of antibodies is the IgG family composed of γ heavy chains. The IgG family is subdivided into 4 subclasses: IgG1, IgG2, IgG3, and IgG4. IgG antibodies are important in the secondary immune response and the primary antibodies produced during the secondary or memory immune response. In addition to binding and activating complement proteins, the Fc portion of an IgG molecule can activate a variety of immune responses to remove antigens or infected cells, such as chemotaxis, opsonization, phagocytosis, and cell-mediated cytotoxicity.23

Figure 7 Schematic of an IgM molecule. IgM exists as a pentamer.

Figure 5 Pictorial representation of clonal selection theory.

Figure 6 Schematic of an antibody molecule.
of antigen bound IgG molecules can activate and trigger macrophages and other phagocytic cells (Figure 8). Subsequently, the phagocytic cells engulf and destroy the invading microorganism. IgG antibodies are the only class of antibody that can traverse the placenta; also, IgG molecules are secreted in breast milk and subsequently taken up by the neonatal gut.23

IgA is the principal class of antibodies present in secretions such as tears, saliva, and mucus. IgA molecules exist in a dimeric state with a J chain joining the 2 individual Fc regions (Figure 9). This macromolecule binds to a specific receptor complex on the basal surface of epithelial cells. The entire IgA macromolecule/receptor complex is engulfed into a vesicle and transported across the breadth of the cell. The vesicle subsequently fuses with the luminal membrane to release the IgA dimeric macromolecule into the lumen of the secretory duct (Figure 10).

IgE is the final class of antibodies.23 The Fc portion of the IgE molecule binds to a Fc receptor on the surface of mast cells and basophils with an extremely high affinity. The binding of antigen to this complex triggers the basophil or mast cell to release a variety of preformed, biologically active amines. The most important of these amines is histamine, which causes vasodilation, increase vascular permeability, and bronchoconstriction.4,24 This forms the basis of allergic reactions, such as hay fever, allergic rhinitis, and food allergies. Mast cells can also activate a specialized type of white blood cell called eosinophils. Eosinophils are important in immunity against parasites and can kill various types of parasites if they are coated with IgE or IgA antibodies.

### Antibodies and Complement

The complement system is a family of approximately 20 soluble proteins that are mostly synthesized by the liver. The complement system complements the antibody response and protects the body against bacterial infections. Individuals with deficiencies in the production of complement proteins have increased susceptibility to bacterial infections, as do individuals with antibody deficiencies. Complement proteins are produced in the inactive form and are triggered by antigens on the surface of invading bacterial organisms by immune mediators secreted during an immune response or by antibodies bound to the cell surface of an invading microorganism. Once complement proteins are activated, they in turn activate downstream proteins, which in turn work in concert to kill the invading bacterium.25,26

The early components of the complement cascade belong to 2 pathways: the classical pathway and the alternate pathway (Figure 11). The classical pathway is activated by IgG or IgM antibodies bound to the surface of invading bacteria. The alternate pathway is directly activated by polysaccharides on the surface of invading bacteria. Therefore, the alternate pathway represents 1 of the initial lines of defense against invading bacteria before the entire immune system has responded.

The early complement proteins are proenzymes. Once the first enzyme in the series is activated, it generates a serine protease that cleaves and activates the next component in the pathway. The cascade also amplifies the response such that activation of a few early complement proteins triggers a large response. Furthermore, cleavage of the complement proenzyme reveals an active enzyme and a small membrane binding site. This causes the activated complement proteins to
adhere to the membrane of the invading bacterium, rather than diffusing into the bloodstream.

The classical and alternative pathways both merge at the cleavage of C3 into C3a and C3b. C3b acts as a protease bound to the bacterial membrane to cleave and activate the remainder of the late-stage complement proteins. The end result of activation of these complement proteins is that a macromolecule composed of these activated complement proteins is formed. This macromolecule acts as a transmembrane channel and perforates the bacterial cell wall causing bacterial death (Figure 12).

C3a acts as a diffusible signal that promotes inflammation and recruits white blood cells. The destructive properties of complement proteins make it essential that their activity is regulated and localized to prevent destruction of normal tissues. We have already discussed two methods in the regulation of complement proteins. First, complement proteins are secreted in an inactive form and have to be activated by antigen. Second, cleavage of inactive complement proteins not only activates the complement protein, but also creates a membrane binding site that holds the activated complement protein to a localized portion of the bacterial cell membrane. This, specific inhibitor proteins exist in the blood to rapidly deactivate complement proteins to prevent widespread destruction of normal tissue. Finally, activated complement proteins are inherently unstable. They rapidly deactivate if the next protein in the cascade is not in the immediate vicinity. These methods act in concert to control the potency and action of the complement system.

**Antibody Diversity**

A discussion regarding antibody structure and types of antibodies has been presented thus far. The body can generate a seemingly limitless number of different antibodies. Scrutiny of amino acid sequences of different antibodies has led to the discovery that antibody diversity is achieved via hypervariable regions within each chain. Antibodies are composed of 2 light chains and 2 heavy chains. Each light chain (κ or λ) is composed of 1 constant region (C\(_K\)) and 1 hypervariable region (V\(_K\)). Similarly, heavy chains are also composed of hypervariable (V\(_H\)) and constant regions (C\(_H\)) (Figure 13). Heavy chains \(\alpha\), \(\delta\), and \(\gamma\) are composed of 1 variable and 3 constant domains; whereas, \(\mu\) and \(\epsilon\) heavy chains are composed of 1 variable and 4 constant domains. The variable segment of the light chain and the variable segment of the heavy chain together form the antigen-binding site or Fab segment of the antibody molecule. The constant regions of the heavy chain (C\(_H\)) combine to form the Fc region of the antibody molecule, which confers the biologic properties of the antibody molecule.

The human body makes approximately \(10^{15}\) different antibody molecules without previous immune stimulation. Just as other proteins, antibodies are encoded by genes, which are transcribed and translated. The human genome contains less than \(10^9\) genes, yet produces more than \(10^{15}\) antibodies. This paradox lends itself to the question: “How can the body make more antibodies than it has genes?” The human body has a unique, compact method of dealing with this problem.

Antibodies are composed of heavy and light chains. Each chain is composed of (V) variable segments, (C) constant segments, and (J) joining segments. There exists a set of genes that codes for each 1 of these segments. Therefore, a set of genes exists that encodes light chain variable segments, light chain constant segments, and light chain joining segments. Similarly, a set of genes exists that encodes each of the above segments for heavy chains. Prior to transcription, a gene from the variable light chain set, a gene from the constant light chain set, and a gene from the joining light chain are brought together. For example, if there exist \(10^4\) different variable light chain genes, \(10^2\) different constant light chain genes, and \(10^2\) different joining segment genes, there exist \(10^6\) different light chains that can be produced. A similar algorithm can be performed for heavy chains, giving \(10^{15}\) different heavy chains. If any light chain can combine with any heavy chain, \(10^{23}\) different antibody combinations can be produced. The numbers presented above are given for illustration purposes only. An additional factor that aids in antibody diversity is the high frequency of somatic mutations that occurs at the site of gene segment joining. In sum, it is easy to see how a virtually endless number of antibodies can be produced from a relatively small number of gene segments.

**T-Lymphocytes**

Thus far, we have focused our discussion on B cells. T cells form the other major class of lymphocytes. T cell responses fall into the category of cell-mediated responses. Similar to B-cell responses, T-cell responses share the characteristic of specificity. T cell responses, however, act only in short range and interact with other cells. In contrast, B cells secrete antibodies that act at great distances away from the original B cell. T cells interact with other cells in 1 of 2 fashions. They can either kill the interacting cell or use the interacting cell in a signaling cascade to recruit other cells and enhance the immune response. In either case, the cell that the T cell interacts with is called the target cell.

T cells recognize antigen in different fashion from B cells. B cells recognize specific epitopes on an intact antigen molecule. In contrast, T cells recognize small portions of foreign peptide sequences. Furthermore, these peptide sequences must be presented to the T cell on special molecules on the surface of the target cell. The T-cell receptor recognizes the peptide sequence bound to the special molecule combination and subsequently initiates downstream responses. These mechanisms allow T cells to respond effectively against microorganisms that proliferate within cells, such as viruses, and against cells that have ingested foreign extracellular peptides.

There are 2 types of T cells, cytotoxic T cells and helper T cells. Cytotoxic T cells respond to kill cells that present foreign antigen on their surface. Many virus infections and intracellular bacteria can proliferate within a cell, where they are safe from antibody attack. Cytotoxic T cells provide immunity against this type of pathogen by killing the host cell before the pathogen can proliferate and infect other cells. Helper T cells respond to specialized cells that pick up foreign peptides and present them on their surface. Helper T cells subsequently act to enhance the immune response, stimulate proliferation of other T cells, and activate other lymphocytes such as B cells. Two types of helper T cells exist, T\(_\text{H}1\) and T\(_\text{H}2\) cells.

**T-Cell Receptors**

T-cell receptors are heterodimers similar to antibody molecules. Unlike antibody molecules,
T-cell receptors only exist in the membrane-bound form. T-cell receptors are composed of an α chain and a β chain dimer. The 2 chains are held together with disulfide bridges (Figure 14). Each chain has a variable segment and a constant segment. The variable segment extends into the extracellular space, while the constant segment inserts into the cell membrane. The constant segment allows transduction of signals upon binding and activation of the receptor to the intracellular space. A small minority of T cells have receptors composed of γδ dimers. These cells are primarily found in epithelial tissue, such as skin and gut, and in nasal mucosa.6

Diversity in T-cell receptors is created in the same fashion as diversity in B-cell antibodies. Each chain, α or β, is composed of a variable (V) and a constant (C) segment. Numerous genes encode for each of these segments. These genes are joined before transcription in a random manner to give an almost limitless diversity of T-cell receptors.28

Figure 13 Diagram of the constant and hypervariable domains in the light and heavy chains of an antibody molecule.

MAJOR HISTOCOMPATIBILITY COMPLEX PROTEINS

As mentioned above, T-cell receptors can only bind antigen bound to a presenting molecule on the surface of a cell. This specialized presenting molecule is part of the major histocompatibility complex (MHC). MHC proteins were discovered far before their role was identified. It was first noted that MHC proteins serve as the target protein for attack in graft versus host reactions among transplant recipients. The immune system of the transplant recipient attacks the transplanted tissue, which it sees as “foreign.” From such observations, it has been shown the MHC proteins, or their analog, are expressed on the cell surface of all higher vertebrates.

The loci coding for the MHC molecule are present in humans on chromosome 6, one of the most polymorphic areas in the human genome. This means that there exist a large number of different alleles in the population coding for different MHC proteins. Therefore, it is unlikely that any 2 individuals except identical twins will have the exact same MHC protein. It is therefore difficult to match transplant donors and appropriate recipients to minimize the recipient immune reaction against the transplanted organ. The main role of the MHC system is to target T cells to cells expressing foreign antigens. T cells respond to cells expressing foreign MHC proteins in the same fashion as they do to native cells expressing foreign antigens. Therefore, the MHC system serves to determine self from nonself in the immune system.

Two categories of MHC proteins exist in every individual; MHC class 1 (MHC1) and MHC class 2 (MHC2). MHC1 proteins present antigen to cytotoxic T cells, and MHC2 proteins present antigen to helper T cells (Figure 15).29 These 2 classes of MHC proteins are functionally and structurally different. However, they both have a peptide-binding groove that holds small peptide segments of degraded foreign proteins. They present this degraded protein segment to their respective T cell, MHC1 to cytotoxic T cells and MHC2 to helper T cells. T cell receptor can only bind its respective target peptide segment if it is bound to an MHC complex protein. The interaction of the T-cell receptor and the foreign peptide/MHC complex activates the T cell and triggers downstream responses.30

MHC1 and MHC2 proteins differ in their structure. MHC1 proteins consist of 1 long α chain with 3 domains (α1, α2, and α3). The α1 and α2 domains are furthest from the cell membrane and contain the variable amino acid sequences that bind the degraded peptide fragment. The α3 chain is close to the cell membrane. The MHC1 protein is associated with another protein, β2, microglobulin. This protein is a small, extracellular protein that sits adjacent to the α3 subunit. It is not encoded by the MHC locus and is not polymorphic. MHC2 proteins are heterodimers composed of an α chain and a β chain. The α chain is composed of an α1 and an α2 subunit, whereas the β chain is composed of a β1 and a β2 subunit. The α1 and β1 subunits are furthest from the cell membrane and represent the portion of the MHC2 protein that binds the degraded protein fragment for presentation to helper T cells (Figure 16).

MHC1 proteins are expressed on all somatic cells. All cells have the possibility of being infected and being destroyed. MHC2 proteins are only expressed on specialized antigen presenting cells (APC). Examples of APCs include B cells, macrophages, and dendritic cells. These cells take...
up antigen from the extracellular environment and present degraded portions of the antigen on MHC2 proteins to TH cells. Examples of antigens that APCs can take up include botulinus toxin and tetanus toxin. Once taken up and presented to TH cells, TH cells stimulate B cells to produce antibodies against such toxins and stimulate macrophages to destroy ingested pathogens.31

**Helper T Cells**

TH cells form the other major category of T cells. TH cells do not directly kill infected cells like TC cells. Also, TH cells do not respond to MHC1 proteins. In these ways, TH cells differ from TC cells. TH cells activate macrophages to become more effective at engulfing and destroying infected cells and activate other cells to respond to antigen and initiate an immune response.

TC cells are activated by cells bearing foreign antigen being presented on MHC1 proteins. TH cells respond to antigens bound to MHC2 proteins. A schema of how this happens is presented below. An APC takes up foreign antigen from the extracellular space by endocytosis. The antigen is stored within the cell in an endosome. MHC2 proteins are manufactured in the rough endoplasmic reticulum (RER). Inside the RER, these proteins bind to MHC1 proteins that are present inside the RER. The protein/MHC1 complex is then transported to the cell surface.

When a TC cell with a receptor specific for the presented protein binds to the protein/MHC1 complex, the TC cell gets activated. In response to activation, the TC cell secretes IFN-γ. IFN-γ is a signaling molecule that triggers upregulation of translation of MHC1 and MHC2 proteins, enhanced antiviral responses by the immune system, upregulation of manufacture of peptide pumps in the RER, and upregulation of specialized proteasome units. In sum, activation upregulates all of the machinery needed to present foreign antigen on the surface of the infected cell. TC cells act by killing the infected target cell by utilizing 2 mechanisms. The first mechanism utilizes a perforin. A perforin is a pore-forming protein that is secreted by the T cell. This protein punches a hole in the infected cell and causes cell death. In the second mechanism, the TC cell activates a receptor on the infected target cell that causes the infected cell to undergo programmed cell death, apoptosis.32

**Cytotoxic T Cells**

As mentioned above, TC cells bind with MHC1 proteins, and TC cells primarily react to cells that have been infected with intracellular viruses or bacteria. Pathogens that reside within a cell are resistant to attack by antibodies. Such cells have small portions of foreign peptides exhibited on their cell surface, which targets them for attack by TC cells.10

Intracellular pathogens take over the host cellular machinery and produce peptides and proteins. These proteins are manufactured in the rough endoplasmic reticulum (RER). Inside the RER, these proteins bind to MHC1 proteins that are present inside the RER. The protein/MHC1 complex is then transported to the cell surface.

The TC cell receptor specific for the foreign antigen bound to the protein/MHC1 complex, the TC cell gets activated. In response to activation, the TC cell secretes IFN-γ. IFN-γ is a signaling molecule that triggers upregulation of translation of MHC1 and MHC2 proteins, enhanced antiviral responses by the immune system, upregulation of manufacture of peptide pumps in the RER, and upregulation of specialized proteasome units. In sum, activation upregulates all of the machinery needed to present foreign antigen on the surface of the infected cell. TC cells act by killing the infected target cell by utilizing 2 mechanisms. The first mechanism utilizes a perforin. A perforin is a pore-forming protein that is secreted by the T cell. This protein punches a hole in the infected cell and causes cell death. In the second mechanism, the TC cell activates a receptor on the infected target cell that causes the infected cell to undergo programmed cell death, apoptosis.32
TC cells also have IL-2 receptors and can become TH cells. Furthermore, IL-2 only allows proliferation is triggered by antigen-based activation of a MHC2/peptide complex. TH cells need 2 signals more complicated than solely binding to an TH receptor to the peptide/MHC2 complex. The first signal is the binding of the TH receptor to the peptide/MHC2 complex. The second signal is derived from chemical mediators. APC not only have MHC2 proteins on their surface, but also have a specialized signaling molecule termed B7 on their surface. This B7 molecule binds to a countermolecule, CD28, on the surface of the helper T cell. This mechanism can serve as the second signal for activation (Figure 18). Another option exists. In some cases, T \( \_H \) cells are activated by the combination of binding the MHC2/peptide complex and receiving a secreted signal such as IL-1.34

Once a T \( \_H \) cell is activated, the cell secretes IL-2 as well as increases production of surface IL-2 receptors. IL-2 causes the cell to proliferate and increase the immune response (Figure 19). This activation and secretion of IL-2 can continue after the T \( \_H \) cell has left the surface of the APC. T \( \_C \) cells also have IL-2 receptors and can become activated by T \( \_H \) cell secretion of IL-2. IL-2 secretion is triggered by antigen-based activation of a T \( \_H \) cell. Furthermore, IL-2 only allows proliferation of a population of T cells that have encountered the same antigen that triggered initially toward the cellular membrane and fuses with the cell membrane. This effectively places the MHC2 protein/foreign antigenic peptide complex on the cell surface. A T \( \_H \) cell with the appropriate receptor can bind to this complex and become activated.33

Few cells in the body express MHC2 proteins on their surface. Examples of cells that express MHC2 proteins include B cells, macrophages, Langerhans cells in skin, thymic epithelial cells, and interdigitating dendritic cells in lymphoid organs. These cells have MHC2 proteins on their surface and are capable of activating T \( \_H \) cells.28

The process of activating a T \( \_H \) cell is slightly more complicated than solely binding to an MHC2/peptide complex. T \( \_H \) cells need 2 signals to be activated. The first signal is the binding of the T \( \_H \) receptor to the peptide/MHC2 complex. The second signal is derived from chemical mediators. APC not only have MHC2 proteins on their surface, but also have a specialized signaling molecule termed B7 on their surface. This B7 molecule binds to a countermolecule, CD28, on the surface of the helper T cell. This mechanism can serve as the second signal for activation (Figure 18). Another option exists. In some cases, T \( \_H \) cells are activated by the combination of binding the MHC2/peptide complex and receiving a secreted signal such as IL-1.34

Once a T \( \_H \) cell is activated, the cell secretes IL-2 as well as increases production of surface IL-2 receptors. IL-2 causes the cell to proliferate and increase the immune response (Figure 19). This activation and secretion of IL-2 can continue after the T \( \_H \) cell has left the surface of the APC. T \( \_C \) cells also have IL-2 receptors and can become activated by T \( \_H \) cell secretion of IL-2. IL-2 secretion is triggered by antigen-based activation of a T \( \_H \) cell. Furthermore, IL-2 only allows proliferation of a population of T cells that have encountered the same antigen that triggered initially toward the cellular membrane and fuses with the cell membrane. This effectively places the MHC2 protein/foreign antigenic peptide complex on the cell surface. A T \( \_H \) cell with the appropriate receptor can bind to this complex and become activated.33

If a T \( \_H \) cell becomes activated, it can activate B cells with the same antigen specificity. T \( \_H \) cells recognize peptide fragments bound to MHC2 proteins. If a B cell has degraded some of its surface antibody receptors and presents them on an MHC2 protein, a T \( \_H \) cell can recognize those proteins from degraded antibody receptors. Therefore, an activated T cell can bind to B cells that present peptide fragments complexed with MHC2 proteins if the peptide fragment corresponds to a degraded antibody with the same antigen specificity as the T \( \_H \) cell. In other words, if an antigen activates a T \( \_H \) cell, the T \( \_H \) cell subsequently activates B cells that hold the same antigen specificity to mount a more robust immune attack against that 1 specific antigen. B cells also can act as APCs and can activate T \( \_H \) cells. Interactions between T \( \_H \) cells and B cells are not limited to the MHC2 protein complex. B cells have a protein on their surface called CD40. Likewise, activated T \( \_H \) cells have a counterprotein called CD 40 ligand.36,37 The interaction between these 2 proteins acts as a second signal to stimulate B cells to mature, proliferate, and be able to switch the class of antibodies they produce.38

Interrelationships between B and T cells allow the immune system to work in concert and mount a robust response that is highly specific and controlled. Without such safeguards, the immune system could wreak havoc in the body and mount responses against normal tissue as well. Another example of such an interrelationship is the secretion of IL-4 by T \( \_H \) cells. IL-4 causes B cells to mature and promotes the switching of antibody production from IgM to IgE and IgG1. Genetic mutations in the CD40 ligand protein or in the ability to produce IL-4 result in individuals exhibiting severe immune deficiency with susceptibility to many opportunistic infections.

**Figure 18** Comparison of the signals required for activating a helper T cell versus a B cell.

**Figure 19** Once a T \( \_H \) is activated, it can secrete IL2 that further amplifies the immune response.

**INTERRELATIONSHIPS BETWEEN B CELLS AND HELPER T CELLS**

In an earlier section, the activation process for B cells was explained. B cells can also be activated by helper T cells. A recurring pattern that has been shown in this chapter is that each cell type cannot function in isolation from others. Rather, the entire system is intertwined with each cell type being able to be activated in multiple interrelated fashions. It has been explained that B cells contain membrane-bound antibodies, which act as receptors, on their surface. These receptors are in continuous flux. Some of these antibody receptors will be recycled, removed from the cell surface, and ingested. The peptide fragments that result from proteolytic degradation of these receptors bind to MHC2 proteins, and are presented on the surface of the B cell as a peptide/MHC2 complex.22,35

**Figure 19** Once a T \( \_H \) is activated, it can secrete IL2 that further amplifies the immune response.

institutes a policy of positive selection and negative selection.\textsuperscript{10}

T cells are exposed to MHC proteins with a variety of peptides, foreign and self, bound to the peptide-binding groove of the MHC protein. T cells that bind to MHC proteins are allowed to survive, and the rest are destroyed. This selects for the T cells that bind to MHC proteins. T cells that do not bind MHC proteins are destroyed. In the second process of negative selection, T cells that bind to MHC proteins exhibiting self-antigen are destroyed. This eliminates cells that would possibly initiate an autoimmune attack. These mechanisms allow the maturation of only those T cells that can recognize self from nonself and can initiate an immune attack against foreign antigens.

**CYTOKINES**

A comprehensive description of the ever-expanding universe of inflammatory mediators and cytokines would be immense. Cytokines are signaling molecules that have effect over short distances. Cytokines are released by cells and stimulate or inhibit other cells. Two examples of cytokines are TNF\(\alpha\) and IL-1\(\beta\).\textsuperscript{24,39} Both of these chemicals are proinflammatory mediators. They are released by various cells in the immune system, and they act to upregulate the immune response. Their effect can be far reaching and include bone resorption by triggering osteoclasts, enhancement of B-cell proliferation, increased blood flow by triggering endothelial cells, and upregulation of cell adhesion molecules on the surface of endothelial lined vessels that attract other inflammatory cells such as eosinophils. Cytokines influence proliferation and differentiation of leukocytes, immunoglobulin class switching, inflammation induction, immune response modulation, lymphocyte chemotaxis, and lymphocyte adhesion molecule upregulation to mention a few examples (Table 1).

**IMMUNE RESPONSES**

Cell-mediated and humoral responses represent the 2 major categories of immune responses. Cell-mediated responses include T\(\text{H}\) responses, T\(\text{c}\) responses, and NK cell responses. T\(\text{H}\) cells only recognize antigen bound to an MHC2 protein complex. After recognizing the antigen/MHC2 complex and becoming activated, the T\(\text{H}\) secretes IL-2. IL-2 causes proliferation of sensitized T cells, B cells, and NK cells by acting as a positive feedback loop. The end result is that multiple types of cells, all with the same antigen specificity, are triggered and stimulated to create a lethal augmented, yet specific, attack on the offending antigen. T\(\text{H}\) cells primarily secrete IFN-\(\gamma\) and IL-2, both of which induce inflammation.\textsuperscript{27} A subset of T\(\text{H}\) cells secretes IL-4 and IL-13 which act as modulators of B-cell antibody responses.\textsuperscript{40}

T\(\text{H}\) cells orchestrate the acquired immune response. The characteristic inflammation caused by T\(\text{H}\) responses is delayed type hypersensitivity (DTH) response. An example of a DTH response is the tuberculin skin test. In gross clinical appearance, DTH is manifested by local erythema, edema, induration, and warmth at approximately 24 to 48 hours after antigen challenge. On a microscopic level, examination of blood vessels in the area shows accumulation of lymphocytes in the peri-vascular area and fibrin deposition. Long-standing DTH responses produce granulomas characterized by accumulations of macrophages and lymphocytes with extensive fibrosis. Interleukins secreted by the macrophages induce fibroblast proliferation with deposition of fibrin, resulting in fibrosis.

* CTL: cytotoxic T lymphocytes; DC: dendritic cells; GM-CSF: Granulocyte-Monocyte Colony Stimulating Factor; IL: Interleukin; IFN: Interferon; TGF: Tumor Growth Factor; TNF: Tumor Necrosis Factor. ** Italicized activities are inhibited.
The steps of the DTH response are as follows. An antigen challenge is given to a previously sensitized individual. Memory T<sub>H</sub> cells are activated by portions of the antigen that are presented on APCs. As a result, proinflammatory cytokines are secreted that result in upregulation of cellular adhesion molecules (intercellular adhesion molecule-1 [ICAM-1] and Vascular cell adhesion molecule-1 [VCAM-1]) on the endothelium of blood vessels in the local area. More memory T<sub>H</sub> cells are recruited to the area since these cells have ligands for the cell adhesion molecules presented on the surface of the endothelium. These cells become activated as they are presented with degraded portions of antigen complexed with MHC2 proteins on the surface of APCs. Activated T cells secrete IL-2, IFN-γ, and TNF. These cytokines cause the proliferation of T cells, increased expression of cellular adhesion molecules on the endothelium, and recruitment of other cells such as neutrophils and macrophages. The recruited cells all act to phagocytose antigen and secrete various antimicrobial chemicals, which add to the tissue injury. The result is an enhanced immune attack against a specific antigen.

In stark contrast to T<sub>H</sub> cells that orchestrate the immune attack, T<sub>c</sub> cells act as cytotoxic effector cells. Once the T<sub>c</sub> cell recognizes its specific antigen complexed to an MHC1 protein, transmembrane signaling is initiated. The transmembrane signaling occurs via lymphocyte-function-activated antigen-1 (LFA-1) on the T<sub>c</sub> cell with ICAM-1 on the target cell or CD2 on the T<sub>c</sub> cell with LFA-3 on the target cell. Following the intercellular signaling phase, the T<sub>c</sub> cell releases cytotoxic granules into the space between the 2 cells. In the cytotoxic granules is a protein called perforin. This protein perforates the cell membrane of the target cell and causes death of the cell. A second method of killing affected cells is via the Fas system. Binding of the Fas molecule on the surface of the target cell with the Fas ligand on the surface of the T<sub>c</sub> cell causes apoptosis of the target cell. The Fas method appears to be important in elimination of T cells during differentiation and tolerance.

NK cells also contribute to cell-mediated responses. Unlike T cells that are MHC restricted, NK cells do not need to have antigen presented to them only via MHC proteins. NK cells are a discrete entity separate from T cells and B cells and can secrete cytokines independently. They have certain receptors on their cell surface that are unique to NK cells such as CD16, which is a receptor for the Fc portion of immunoglobulins. NK cells also have some receptors common to other lymphocytes such as CD2. NK cells are present in the peripheral circulation, in the liver and in the spleen; their cytokine mechanisms are similar to those of T<sub>c</sub> cells with perforin-mediated and cell induced apoptosis mechanisms. NK cells can lyse tumor cells and play an important defense mechanism against proliferation of tumor and virally infected cells.

The other major category of immune responses is humoral responses. Humoral responses involve B cells and can be subdivided into T cell dependent responses, T-cell independent responses and antibody dependent cellular cytotoxicity. B-cell responses that are T-cell independent involve B-cell responses to large carbohydrate-based antigens such as bacterial cell wall antigens. These large antigens can bridge several antibodies receptor molecules on a B-cell surface and activate the B cell. Subsequently, The B cell secretes antibodies in response to activation that can opsonize or coat the antigen.

T-cell dependent responses are initiated by B cells that bind antigen on cell surface antibody molecules. This receptor/antigen complex is endocytosed, and protein fragments are created. These protein fragments are presented on surface MHC2 proteins, which subsequently bind T<sub>H</sub> cells and activate them. Stabilization of the complex between the T<sub>H</sub> and the B cell is mediated by the coreceptor interaction between CD4 on the surface of the T<sub>H</sub> cell and MHC2 on the surface of the B cell. A tivation of the T<sub>H</sub> cell subsequently induces the expression of a molecule on the surface of the T cell that binds CD40 on the surface of the B cell and induces B-cell proliferation, activation, and secretion of antibodies. Multiple cytokines produced by the interaction of T<sub>H</sub> cells and B cells such as IL-1, IL-2, IL-10, TGF-β, etc are important in regulation of immunoglobulin class switching and immunoglobulin production.

**HYPERSENSITIVITY REACTIONS**

The cell-mediated and the humoral pathways of immune responses have been described above. The result of these pathways is an immune response that is specific, yet efficient, killing foreign antigens as well as native cells that are infected. These same mechanisms can cause injury to normal tissue as well. When these mechanisms cause such injury, it is termed hypersensitivity responses.

These hypersensitivity reactions are characterized into 4 main categories. These categories were originally described by Gell and Coombs in 1963. Although the categorization into 4 categories and the presumed pathophysiology of each subtype are an oversimplification, it does allow the establishment of a basic scheme in which to understand hypersensitivity reactions. Hypersensitivity reactions rarely consist of 1 type only and involve all components of the immune system.

Type 1 hypersensitivity reactions are usually mast cell-mediated reactions that usually manifest within minutes to hours after antigen challenge. These reactions can be IgE dependent or IgE independent. The offending antigen essentially triggers the release of vasoactive and bronchoactive mediators from mast cells and basophils. An IgE-dependent response involves the binding of IgE antibodies to the offending antigen. The IgE antibodies then bind to receptors on mast cells and basophils, which causes these cells to release preformed vasoactive and bronchoactive mediators. Some antigens such as contrast media can cause activation of mast cells in an IgE independent fashion. The end result can cause bronchospasm and hypotension in anaphylactoid reaction.

Type 2 hypersensitivity reactions involve IgG and IgM antibodies that bind to antigens on erythrocytes, platelets, epithelial cells on mucosal surfaces, and antigens on basement membranes. The triggering antigen can be self-antigens, modified self-antigens, or antigenic haptons complexed with self-antigens. When IgG or IgM molecules interface with these antigens, the result is destruction of the target cell causing tissue damage. The target cell can be opsonized, lysed, or killed by antibody-dependent, cell-mediated cytotoxicity.

Examples of this type of reaction are seen in penicillin-induced hemolytic anemia and in quinine-induced autoimmune thrombocytopenia. In each of these examples, the drug in question coats normal cells. The complex of normal cell antigens complexed with the drug is recognized as a foreign antigen and induces an IgG/IgM attack. The attack kills the cell causing the anemia or the thrombocytopenia.

Type 3 hypersensitivity reactions involve complexes of IgG or IgM bound to antigen. These immune complexes are deposited in basement membranes and other normal tissues due to their reduced solubility and initiate an immune attack. This type of reaction was widespread in the early part of the twentieth century when equine sera to treat bacterial infections were used. Antibodies from horses would be injected into the patient in an attempt to cure an infection. The antibody and antigen would form insoluble complexes that deposited in the basement membrane of high flow blood vessels. The immune complex deposits initiated a vigorous complement cascade attack, which resulted in a vasculitis and tissue injury. This condition became known as serum sickness.

Type 4 hypersensitivity or DTH reactions are described above. An example of a DTH response is the tuberculin skin test. DTH reactions result when antigen is administered to a previously sensitized patient with memory T cells. Memory T<sub>H</sub> cells are activated by portions of the antigen that are presented on APCs. As a result, proinflammatory cytokines are secreted that cause upregulation of cellular adhesion molecules on the endothelium of blood vessels in the local area recruiting more memory T<sub>H</sub> cells to the area. These cells become activated as they are presented with degraded portions of antigen complexed with MHC2 proteins on the surface of APCs. Activated T cells secrete IL-2, IFN-γ, and TNF. These cytokines cause the proliferation of T cells, increased expression of cellular adhesion molecules on the endothelium, and recruitment of other cells such as neutrophils and macrophages. The recruited cells all act to phagocytose antigen and secrete various antimicrobial chemicals, which add to the tissue injury.

**CONCLUSIONS**

The immune system is an elegant yet lethal system that specifically can recognize and react to a
seemingly limitless number of foreign antigens. Small genetic alterations in receptors or in the structure of interleukins can wreak havoc on the host by predisposing the patient to numerous opportunistic infections. At the same time, the immune system recognizes self from nonself. Alteration in this fine balance can also lead to a host of disorders such as systemic lupus erythematosus and Wegener granulomatosis to name 2 examples.

Assessment of Nasal Function

Jacquelynne P. Corey, MD
Asli Sahin-Yilmaz, MD

The nasal cavity consists of a rigid framework that includes the bony lateral walls, the cartilaginous septum, and bony portions of the turbinates. There is also a highly vascular mucosal component which is the first contact area between the air and the respiratory tract. The functions of the nasal mucosa, besides being the air passage, include warming and humidifying the inspired air, cleaning and filtering the inspired air, sensing odors in the environment, and contributing to the resonance of speech. A person’s well-being and quality of life are also affected by his or her ability to breathe through the nose.

Alterations in the functions of the nose can be induced by environmental changes in temperature, humidity, and posture, as well as by many pathologic conditions, including structural abnormalities, hyperreactivity of the mucosa, polyps or neoplasms, endocrine or metabolic diseases, drug-induced reactions, and systemic inflammatory or granulomatous conditions. Traditionally, the clinician relies mostly on the history and physical examination to make a diagnosis. However, various subjective or objective tests have been developed that aid the physician. These tests can provide documentation in a standardized fashion, allowing intrapatient, interpatient, and interinstitutional comparisons. They may help decide the type of medical or surgical therapy, as well as monitor the effectiveness of therapy. They may also be helpful in medicolegal cases, especially concerning cosmetic septorhinoplasty.

This chapter gives brief information about the functions of the nose and outlines the methods available for evaluating these functions.

THE NOSE AS THE AIR PASSAGE TO THE LOWER RESPIRATORY TRACT

The nasal airway plays an important role in the normal homeostasis of the body. During normal breathing through the nose, approximately half of the resistance of the airways is located in the nasal airway. Therefore, even small changes in nasal resistance affect the total airway resistance and influence the total respiratory function.

The nose is lined by a highly vascular mucosa containing arterioles, arteriovenous anastomoses, and venous sinusoids. Given a normal anatomy of the septum, nasal congestion is caused by swelling of the venous sinusoids, referred to as venous erectile tissue. Venous erectile tissue is most dense in the inferior and middle turbinates. The capacitance of these vessels is under the control of the autonomic nervous system. It may also be influenced by humoral factors, allowing for direct action on the vasculature, or indirectly by sensory-neural stimulation.

Nasal Cycle

The nasal cycle has been recognized as a physiologic phenomenon that may cause a periodic change in the patency of the nasal airway associated with congestion and decongestion of the nasal venous sinuses. There is no agreement on a definition as to which changes in nasal airflow constitute a nasal cycle. In the ideal cycle, the left and right sides of the nose have identical periods, are 180° out of phase, and have similar airflow, resistance, amplitude, and volume changes. However, wide variations may occur in nasal air volume, with some subjects exhibiting spontaneous and reciprocal changes in unilateral airflow and others exhibiting irregular changes in airflow. These changes range from 21 to 80%. There is an increased amplitude of nasal patency fluctuation in subjects with allergic rhinitis; nasal patency fluctuates spontaneously in both healthy subjects and those with allergic rhinitis at intervals as short as 10 minutes. Commonly, however, the nasal cycle lasts about 4 to 6 hours.

Causes of Nasal Obstruction

Nasal obstruction may be due to irreversible (structural) causes or reversible (mucosal) congestion. Structural causes include bony/cartilaginous deformities of the nasal septum or the nasal valves and chronic (bony) turbinate hypertrophy. Common conditions that cause mucosal (generally reversible) congestion include allergies, infection, nonallergic rhinitis, rhinitis medicamentosa, hormones, and drugs.

Subjective Measurement of Nasal Congestion

Nasal congestion is a subjective complaint of discomfort. The patient's perception of congestion can be influenced by factors such as temperature, posture, emotions, or congestion in other parts of the cavity that the physician is unlikely to detect by an anterior examination of the nose with a speculum.

Subjective scoring of nasal obstruction can be performed by use of ordinal 10-point or a 100 mm visual analog scale (VAS) or a four-step symptom severity score. Seventy-seven percent of patients who have cold symptoms are able to discriminate between high flow and low flow nasal passages by using a 100 mm VAS. However, if the differences in unilateral flow are smaller than 100 cm/s, the percentage of correct responses declines to 50%.

The physician’s assessment of nasal obstruction following anterior rhinoscopy is another subjective method of evaluating the nasal airway. Different scales for the physician’s estimate of the severity of nasal airflow limitation have been used by different investigators. A three-point scale of severity of nasal deviation (Boyce/Eccles three-point scale), employing the otorhinolaryngologist’s assessment of nasal obstruction, correlates with objective measurement by rhinoprimetry (r = .87). The specificity of detecting nasal obstruction with this method is low; it cannot detect “zig-zag” obstructions or the location of the obstruction.

Objective Measurement of Nasal Obstruction

Testing for nasal airflow should be convenient, reliable, and repeatable to aid in treatment planning. A test for nasal blockage should be able to document the location of the blockage as well as the effect of interventions, such as surgery on nasal airflow, volume, and physiology.

Since the late nineteenth century, researchers have tried to develop an accurate method for measuring nasal resistance and nasal patency. Initially, a simple mirror was placed under the nares for detecting nasal airflow. In time, rhinomanometric techniques evolved that measured pressure and flow simultaneously. More recently, we have seen the development of acoustic rhinometry. Other techniques used for objective measurement of the nasal airflow include nasal inspiratory peak flow (NIPF), rhinostereometry, radiographic techniques, and videoendoscopic documentation.

Acoustic Rhinometry

Acoustic rhinometry was first described by Hilberg and colleagues in 1989. This technique uses reflected sound waves for measurement of nasal volume and the cross-sectional areas of the...
nose. It provides a topographic map of the nasal airway by converting the reflected sound wave to an area–distance graph (Figure 1).

The validity of acoustic rhinometry has been proved by comparison of measures obtained by this technique with those obtained by nasal endoscopy, or by imaging methods such as computerized tomography (CT) and magnetic resonance imaging (MRI).

**Principles.** Acoustic rhinometry is based on the principle of analyzing changes in the reflected wave when an incident sound wave passes into the nasal cavity. Variations in the size and contour of the nasal airway cause distortions in the reflected sound wave. The time at which these reflected changes occur gives an estimate of the distance in the nasal cavity to the entity that causes the distortions, and the magnitude of the distortions is a measure of the change in the cross-sectional area.

**Equipment.** A trigger module generates an acoustic pulse that is conducted to the nasal cavity by means of a hollow plastic tube. The nasal end of this tube is fitted with a nosepiece that is placed against the anterior nares. The nosepiece is contoured and is available in different sizes. The sound wave passes through this tube and enters the nasal cavity. An analog-to-digital converter converts these waves into digital impulses that are fed into a computer. The computer uses these data to generate an area–distance graph by using mathematical algorithms. These graphs can be read on screen or printed, providing a topographic map of the nasal passage.

**Technique.** A major advantage of acoustic rhinometry over other methods is that it is very simple to perform and requires minimal patient cooperation. The test is done in a quiet room. The patient is seated comfortably and is allowed to relax for a few minutes before testing. The tester stands in front of the patient or sits to the side. The patient is steadied by fixing of gaze and the tester stands in front of the patient or sits to the side. The tester aligns the nasal tube in the same axis as the nose (Figure 2A and B). The nosepiece is held against the nares on the side to be tested first. A repeated acoustic pulse click is generated for 10 seconds and stopped as soon as a satisfactory curve is displayed on the computer screen. The nosepiece should be held against the nares in such a way as to ensure a seal without causing distortion of the anatomy. This seal can be facilitated by use of a jelly on the outer edge of the nosepiece. The procedure is repeated on the other side. Next, a nasal decongestant is applied, with two sprays of 50 μg each, in each nostril. The test is repeated after 10 minutes. By decongesting the nasal mucosa with a topical spray, the clinician eliminates or minimizes the reversible component. When the test is repeated, it gives a measure of the structural, or irreversible, causes of nasal obstruction. The amount of mucosal decongestion also gives an estimate of whether the mucosa is normal or diseased.

The computer generates a curve that shows the distance in centimeters on the x-axis and the cross-sectional area in square centimeters on the y-axis (Figure 1). The position of the anterior nares is at 0 cm. Only the first 6 cm is used for interpretation because the test loses accuracy in the posterior areas of the nasal cavity. An anterior obstruction at the nasal valve region may cause a distortion of the posterior portion of the curve.

The graph shows three “valleys” or “notches.” These correspond to the nasal valve, the anterior head of the inferior and/or middle turbinate, and the middle of the middle turbinate, respectively.

In 2005, the European Rhinologic Society formed a committee that issued a consensus report on acoustic rhinometry (and rhinomanometry). This comprehensive document provides recommended standards for objective assessment of the nasal airway. In the American terminology, the waves produced by acoustic rhinometry are labeled “valleys” which encompass the three that are commonly seen. These are labeled minimal CSA, mCSA 1, 2, and 3. In the European terminology, the wave patterns are referred to as a “rising W” and the first notch is labeled the “I-notch” for the isthmus.

**Interpretation.** Acoustic rhinometry allows an objective nasal assessment of whether an obstruction is structural, mucosal, or mixed with an objective grading of the disease according to standardized normal values. For grading of mucosal congestion, baseline mCSA 1, 2, and 3 values and total volume before and after the use of a nasal decongestant are noted. The congestion factor (CF) is calculated as follows:

\[
\text{CF} = \left[ \frac{\text{CSA2 (decongested value) - CSA2 (baseline value)}}{\text{CSA2 (baseline value)}} \right]
\]

The CSA2 value for the side that shows the largest difference in the decongested state is used. The CF is then categorized as normal, mild, moderate, severe, or marked. This scale uses normative values obtained from previously published data. The severity of blockage can be calculated by comparison. A difference of greater than two standard deviations from nasal values of CSA2 in the baseline and the decongested state is considered to indicate an abnormality.
Limitations. There may be small variations in measurements performed by different operators, or by the same operator in different sessions. External noise, changes in environmental temperature and humidity, changes in the position of the sound tube, sound leaks around the nares, and pressure changes due to swallowing and breathing are the main factors that influence the reproducibility and accuracy of acoustic rhinometry.21 These variations are generally lesser than 10% and can be minimized by allowing the subject to acclimatize to room temperature (normally for 10 minutes), visually matching up the new with the previous, correct waveform, and performing the testing in a quiet room.

The body surface of an individual may influence the minimal cross-sectional area of the nose. Sex, height, weight, and race may influence the cross-sectional area, but only to a small extent.22,23 Standardization of acoustic rhinometry is currently available for both sexes and all races and ages. Although height and weight may influence the readings, they do not do so in a consistent fashion. Therefore, most standardized reading scales omit this information. A consistent fashion. Therefore, most standardization of acoustic rhinometry is currently available for both sexes and all races and ages. Although height and weight may influence the readings, they do not do so in a consistent fashion. Therefore, most standardized reading scales omit this information.

Clinical Applications. The last decade has seen the clinical uses of acoustic rhinometry expand; clinically relevant studies are now available for normal and diseased nasal passages. A acoustic rhinometry provides a topographic map that can be used for characterizing and localizing the deviations of the nasal septum. It can also identify the relative locations of valve stenosis and turbinat hypertrophy. A acoustic rhinometry is an effective method for comparing preoperative and postoperative values for patients undergoing operations such as septoplasty, turbinate reduction, facial cosmetic procedures (nasal valve reduction, rhinoplasty, osteotomies), cleft lip, palate repairs, and nose surgery, antrochoanal atresia and maxillofacial expansion procedures) and tonsillectomy for pediatric obstructive sleep apnea.24,25 A acoustic rhinometry after sinus surgery with large antrostomies and ethmoid cavities or with a septal perforation will have different patterns or waves that should be carefully monitored with endoscopic anatomy.

A nother use for acoustic rhinometry has been as an aid for the diagnosis and treatment of sleep apnea. A acoustic rhinometry can predict the tolerance of nasal continuous positive airway pressure (CPAP) in patients with sleep apnea.26,32 Subjects whose cross-sectional area is less than 0.6 cm² at the head of the inferior turbinate are not able to tolerate nasal CPAP.32

Rhinomanometry
Rhinomanometry is the measurement of nasal airflow and nasal pressure required to achieve that flow. Rhinomanometry provides an objective, sensitive, and functional measure of nasal patency.

Objective measurements of nasal resistance with rhinomanometry do not correlate well with subjective measurements.33,34 The nasal valve region is the primary determinant of nasal resistance, but the sensation of nasal obstruction may be related to congestion in other parts of the airway or perhaps to other factors such as somatization.3,34

Principles. For a better understanding of the principles of rhinomanometry, it is useful to have some basic knowledge of the ventilation mechanisms of the nose. Fluid-dynamic experiments performed on anatomically exact models of the human nose showed that the flow in the nose can be laminar or turbulent.33 Laminar flow is the simplest type of airflow, in which there is no mixing within the air stream. Pure laminar flow occurs in very low velocity. As the velocity of the airflow increases, turbulent flow is observed. Turbulent flow is characterized by mixing within the air stream, which is a precondition for an exchange between the flowing air and the mucosa.21 Turbulent air corresponds to an airflow of 250 to 500 cm²/s in the nose. Decongestants give rise to increased turbulent airflow.

Nasal resistance is defined as the relationship between transnasal pressure and nasal airflow. During laminar flow, nasal resistance is constant and the relationship between pressure and airflow is linear. However, turbulent airflow, a nonlinear relationship is observed. Rhinomanometry measures the transnasal pressure and airflow, and it provides a nasal resistance value and a graph of the relationship between pressure and airflow.

Equipment. There are various techniques of measuring nasal airflow and pressure. These techniques may be combined in any manner to yield a value for resistance.

Airflow is measured by means of a pneumotachometer and a pressure transducer. The pneumotachometer is a resistor which induces laminar flow across it so that the pressure drop across it varies linearly with the flow. The pressure transducer converts the pressure differential to an electrical equivalent of flow that is measured by electronic means.36

The pneumotachometer may be attached to a nozzle which is inserted into the nasal vestibule. This has the disadvantage of deforming the compliant portion of the nasal valve. The pneumotachometer may also be attached to a face mask. However, this technique has the disadvantage of displacing the facial tissues.

The pneumotachometer may be connected to a head out displacement-type body plethysmograph. This leaves the face unrestricted for manipulation during the procedure. The disadvantage is that this apparatus is bulky and that considerable patient cooperation is required.

Transnasal pressure can be measured by three different techniques.

The anterior method of measurement places a tube at the nasal vestibule of one side, which is occluded while the patient breathes through the other nasal cavity. The posterior method of measurement involves placement of the tube in the oropharynx, passed through closed lips between the tongue and the palate. In this method, the measurement result can differ to a great extent because the measured pressure difference may easily be affected by the position of the soft palate.21 In the postnasal method of pressure measurement, a pediatric feeding tube is lubricated and passed along the floor of the wider nasal cavity to the nasopharynx.

The pressure and flow signals are transferred to a computer, and the data can be analyzed, displayed, saved, and printed.

Technique. In active rhinomanometry, the patient actively breathes through one nasal cavity while the narinochoanal (naris to choana) pressure difference is assessed in the contralateral nasal cavity. This is the most commonly used method of rhinomanometry.21 In passive rhinomanometry, the pressure is measured for each nasal cavity separately at an airflow of 250 cm²/s. This method is rapid but less accurate than the active technique.

New equipment has to be calibrated by the manufacturer, and also by the operator before measurements are taken on a given day. A standard preformed resistor should be used by the operator before and after studies. Rhinomanometric measurements are obtained with the patient in a sitting position after an adaptation period of 20 minutes. During measurement, the patient breathes spontaneously at rest. The mask that is used should not leak and should not result in deformation of the nose. The nasal connections of the pressure tube should not influence the shape of the nasal entrance and should not limit its mobility during testing (Figure 3). As the measurements are taken, the data points for each breath that are displayed on the monitor screen form a sigmoid pressure-flow curve in real time. When a series of breaths display regular repetition of the curve, data acquisition is activated to sample two consecutive breaths. If there is
Interpretation. Nasal congestion can be quantified in terms of total or unilateral nasal airway resistance. Resistance can be reported at a designated flow or a designated pressure. According to international standards, resistance should be given at a fixed pressure of 150 Pa, or according to Boms’ model, at radius 2. In pathologic conditions, if, for whatever reason, a pressure level of 150 Pa cannot be reached, lower nasal pressures of 75 or 100 Pa can be used, but should be taken into account in the interpretation of results. For four-phase rhinomanometry, resistance is determined for phase 1 (ascending inhibitory phase) and phase 4 (descending expiratory phase) by use of the highest possible flow at a pressure of 150 Pa.

In subjects free from signs of nasal disease, the mean total resistance has been reported to be around 0.23 Pa/cm³/s, ranging between 0.15 and 0.39 Pa/cm³/s. A total nasal airway resistance of 0.3 Pa/cm³/s is generally accepted as the upper limit of normal. The range of unilateral nasal airway resistance in healthy volunteers, when recorded over 6 to 8 hours, has been shown to have a fourfold fluctuation over time due to nasal cycling. Therefore, it is not informative to quote a normal value for unilateral nasal airway resistance.

Limitations. Factors that affect nasal resistance include postural changes, exercise, and temperature of the air. There is also the possibility of an air leak around the face mask. The presence of mucus inside the nasal cavity may increase the nasal resistance, therefore, it is suggested that subjects blow their nose gently before a resistance measurement.

Rhinomanometry may take at least 20 to 30 minutes. Anterior rhinomanometry is easy to perform. However, it measures one side of the nose at a time, and it cannot be used if a septal perforation exists. Posterior rhinomanometry overcomes this problem. However, it has the disadvantages that it requires training of the operator, and the possibility of variation in results due to movement of the soft palate and due to bulky equipment. Postnasal measurements also require a trained operator. In addition, manipulation of the nasal mucosa with a catheter may be a confounding factor.

Clinical Applications. The clinical use of rhinomanometry has been limited, but it is an excellent tool for research. It is relatively easy to do the measurements, and if anterior active rhinomanometry is performed, it does not take a long time.

Rhinomanometry can be used for measuring the change in resistance before and after the use of a decongestant in disease states such as allergic or nonallergic rhinitis. If the decongestant causes less than a 35% decrease in resistance, a structural cause may be considered as the reason for nasal blockage.

Rhinomanometry is commonly used in nasal challenge studies. Evidence suggests that rhinomanometry is able to demonstrate the efficacy of treatment with medications such as intranasal corticosteroids or antihistamines. Rhinomanometry may be used for detecting correlations between nasal resistance and sleep apnea, the effect of nose dilators on nasal resistance,
and the efficacy of surgery on the nasal valve or for septal deviation.45

Nasal Peak Flowmetry

Just as expiratory peak flow has been used as a measure of disease control in asthma, investigators have used nasal peak flow to assess upper airway function. The nasal peak flow rate provides a simple, cost-effective, reliable, and objective measure of airflow obstruction.

Several studies have evaluated the validity of this method in assessing nasal function. This test has high sensitivity and a variable correlation with patient symptoms and other objective measures of nasal blockage.46-50 Nasal peak inspiratory flow appears to correlate better than does expiratory peak flow.

Equipment and Technique. Nasal peak flow may be measured as either inspiratory or expiratory. Nasal peak expiratory flow (NPEF) can be measured by use of a mini-Wright peak flowmeter, which is equipped with an air-tight face mask instead of a mouthpiece. The equipment is portable and useful for repeated examinations. During the procedure, the patient is told to hold the device horizontally and to ensure that the face mask forms an air-tight seal around the nose. The patient is instructed to inspire to maximal capacity while keeping the lips closed and to expire with maximal effort through the nose. The maximal flow rate is read from a scale in liters per minute. At least three readings should be obtained, and the highest should be recorded.

NPIF can be measured by use of Y oulten peak nasal inspiratory flow meter attached to a face mask. During the procedure, the device is reset by returning the red cursor to its start position, and the patient is asked to exhale fully. The device is held horizontally. The face mask should form an air-tight seal around the nose (Figure 6). Different masks are available in a variety of sizes to suit different facial shapes. The patient is instructed to close the mouth and inhale forcefully through his/her nose (sniff). This maneuver should be a short inspiratory action of about 1-second duration. The nasal inspiratory flow is recorded from the position of the red cursor on the scale.

Nasal peak inspiratory peak flow meter. This is a noninvasive, inexpensive method of measuring nasal patency. The device is held horizontally, and the mask should form an air-tight seal around the nose. The patient is instructed to close the mouth and inhale forcefully through the nose. This maneuver should be a short inspiratory action of about 1-second duration. The nasal inspiratory flow is recorded from the position of the red cursor on the scale.

Figure 6 Nasal peak inspiratory peak flow meter. This is a noninvasive, inexpensive method of measuring nasal patency. The device is held horizontally, and the mask should form an air-tight seal around the nose. The patient is instructed to close the mouth and inhale forcefully through the nose. This maneuver should be a short inspiratory action of about 1-second duration. The nasal inspiratory flow is recorded from the position of the red cursor on the scale.

Interpretation. No standard limits have been defined for airflow measured by NPIF or NPEF. In a study of healthy subjects, participants who had no nasal symptoms had peak inspiratory nasal flows greater than 2.5 L/s.51 NPIF and NPEF can be used as relative measurement in the same individual over time.58

Limitations. The major disadvantage of NPIF occurs when alar collapse is observed on forced inspiration. The disadvantage of NPEF is the possible expulsion of secretions in the mask on expiration. The limitation of both methods is that they are effort-dependent and assume normal function of the lower airways.52 It has also been shown that, during NPIF testing in patients with partially blocked noses, the eustachian tube can be opened during maximal expiratory, which results in discomfort and a decrease in expiratory effort.53

Furthermore, with NPIF, no information is obtained regarding the structure of the nose or the location of a nasal obstruction, as is the case with acoustic rhinometry. NPIF is not as sensitive as other objective methods of assessing nasal function. Small changes in airway resistance with low dose histamine challenge can be detected with rhinomanometry but not with NPIF.50 At very low flow rates (<30 L/min), NPIF may not be possible, and an assessment should be made by means of other objective testing methods. Also, multiple repetitions of the testing procedure may cause a change in the blood content of nasal erectile tissue and result in changes in airway resistance over time.5

Clinical Applications. NPIF has better reproducibility than does NPEF, and it is the best-validated and best-studied peak flowmetry method. NPIF can be used in children, assuming adequate cooperation. A linear increase in NPIF occurs with age, height, and weight.34

There is a good correlation between NPIF and rhinomanometry when nasal patency is altered with allergen or histamine nasal challenge in the laboratory.55,56 NPIF has been used in the evaluation of medical therapy for seasonal allergic rhinitis,57,58 assessment of occupationally induced rhinitis,59 evaluation of objective measures of septal or alar surgery,60,61 or as an outcome measure in nasal challenge testing.62

Rhinostereometry

Rhinostereometry is a noninvasive method of evaluation of the changes in the thickness of the nasal mucosa of the inferior turbinate. The method is relatively new and has been used in only a few centers.

Rhinostereometry has been used for correlating the subjective sensation of nasal stuffiness with measurements during histamine challenge in healthy subjects. The method has a high correlation with subjective symptom scores during a challenge,63 but there is no significant correlation between acoustic rhinometry and rhinostereometry results during nasal cycling,64 or in subjects who have vasomotor rhinitis.65

Equipment and Technique. The equipment consists of a surgical microscope placed on a micrometer table. The patient is seated and fixed to the measuring apparatus by a plastic tooth splint. The microscope has a small depth of focus, so that changes in the position of the mucosal surface on the medial side of the inferior turbinate are registered along a millimeter scale. Changes of 0.18 mm can be detected.

Limitations. Because it takes some time to focus the subject exactly to the measuring apparatus, rhinostereometry is a time-consuming method. Another limitation of the technique is that it is based on visual assessment by the investigator.

Applications. Rhinostereometry findings have been used as an outcome measure in studies evaluating the effect of nasal decongestants,66 intranasal corticosteroids,67 and nasal hyperreactivity.68 This technique remains principally an experimental tool.52

Videoendoscopic Documentation

Videoendoscopic photodocumentation equipment is widely available in the practice of otolaryngology. A rigid or flexible endoscope is connected to a color camera (analog or digital). The operator passes the telescope, and a recording or print is made of the area of interest. This can be analyzed at a later date. The color and view may vary from visit to visit due to lighting, positioning, and the camera used.

The results compare favorably with other objective methods for nasal patency.69 Digital image analysis of videendoscopic images can be used in patients before and after nasal valve surgery.70

THE NOSE AS A FILTER

The pseudostratified columnar respiratory epithelium of the nasal mucosa is constantly exposed to pathogens and toxins. Mucociliary clearance is a crucial part of the defense against these agents and relies on the characteristics and dynamics of the cilia. These include the number of cells; the frequency, effectiveness, and coordination of ciliary beating the periciliary fluid layer and mucus.71

The nasal mucus blanket has two layers. The outer layer (gel phase) is relatively viscous and moves over the surface of the cilia, which are surrounded by a serous periciliary fluid layer (sol phase). The cilia beat in a coordinated fashion, but their beat frequency varies with physiologic and experimental conditions. In man, the frequency is normally about 15 to 20 Hz, which is equivalent to about 1,000 strokes per minute.72
The coordinated strokes of the cilia result in forward movement of the mucus layer at an average flow rate of 5 mm/min (with a range of 0.5 to 23.6 mm/min).73

**Measurement of Mucociliary Clearance**

The determination of nasal mucociliary clearance (NMCC) provides an integrated measure of ciliary function. The NMCC can be measured by use of traceable particles that may be soluble, such as saccharine, or insoluble, such as charcoal, or by use of radioisotopes.

**Technique.** The saccharine test is the most widely used method for in vivo assessment of NMCC. Before the beginning of the test, the patient is asked to blow the nose to remove excess secretions. A saccharine particle is placed on the medial surface of the inferior turbinate, at least 7 mm behind the anterior end to avoid the area of the mucosa where the cilia beat in an anterior direction.74 The time from particle placement until the subject reports the first sensation of a sweet taste is measured and expressed as a clearance time. The same method can be utilized with substances like charcoal powder, which can be visualized in the nasopharynx and recorded with videendoscopic photo documentation, if needed.

Another method for testing NMCC is by use of a radioisotope method. An insoluble radioisotope such as Tc99 is placed in the anterior part of the inferior turbinate and is followed and recorded with a gamma camera during its course to the nasopharynx. This method can provide an exact mucociliary transport rate in millimeters per minute. The NMCC in healthy adults is about 13 minutes (±3 minutes) for charcoal powder and 17 minutes (±5 minutes) for saccharine.75 In healthy children, the times are 11 minutes (±3 minutes) for saccharine and 5 minutes (±6 minutes) for charcoal.

**Limitations.** Studies on ciliary function in vitro have shown that the performance of cilia can be affected by factors, such as humidity, temperature, and pH. However, the confounding effect of these factors in vivo is unlikely to be very significant.38

Factors in vivo is unlikely to be very significant.38 and pH. However, the confounding effect of these factors, such as humidity, temperature, and pH. However, the confounding effect of these factors in vivo is unlikely to be very significant.38

**Clinical Applications.** Studies on NMCC began in the 1880s. The radioisotope technique was described in 1964. Subsequently, several studies have been performed on the relationship of NMCC with physiologic and pathologic conditions of the nasal mucosa.

The effect of environmental pollutants on NMCC was also studied. A valuable data revealed no effect of ozone on NMCC,77 but other pollutants such as cigarette smoke and sulfur oxides were found to impair NMCC.78 The NMCC changes in the presence of allergic rhinitis and rhinosinusitis39 and after application of intranasal topical corticosteroids.80,81

**The Nose as a Contributor to Subjective Well-Being**

Rhinitis has detrimental effects on the physiologic, physical, and social aspects of patients’ lives and can decrease the quality of life.82 For obtaining a complete measure of the health status of patients with rhinitis, health-related disease-specific quality of life assessments should be made in addition to clinical measurements.

Health-related quality of life (HRQOL) is defined as the functional effect of a disease and its management upon a patient, as perceived by the patient.83 Health-related quality of life can be measured directly by use of generic or disease-specific instruments. To be useful, HRQOL instruments should have good psychometric performance characteristics.83 These performance characteristics include validity, reliability, and responsiveness to change.

**Generic questionnaires** are designed to measure the burden of illness experienced by patients and can be used for comparison of the functional impairments caused by different health states. For example, quality of life in patients with allergic rhinitis can be compared to that of patients with asthma or other diseases. The disadvantage of generic questionnaires is that they lack sufficient depth to capture small but important changes that may occur in a particular disease either spontaneously or as the result of an intervention.84 The most commonly used generic questionnaire for allergic rhinitis is the Medical Outcomes Survey Short Form-36 (SF-36).85 This questionnaire includes a multiitem scale which assesses nine health concepts that can be combined into two primary functions, mental and physical. SF-36 is used extensively in a wide range of medical conditions including allergic rhinitis, acute rhinosinusitis, and nasal polyposis.86-88

**Disease-specific questionnaires** have developed because of the lack of depth of focus of the generic instruments.82 They measure the extent of subjective disturbance of the particular disease symptoms and their emotional and practical effects.82 Although several measures of HRQOL have been developed specifically for rhinitis and sinusitis, few have undergone psychometric testing. Psychometrically validated questionnaires include: the Rhinitis Quality of Life Questionnaire (RQLQ), the Sino-Nasal Outcome Test (SNOT-20), and the RhinoSinusitis Disability Index (RSDI). The RQLQ and SNOT-20 are the most commonly cited.

The RQLQ, developed by Juniper and Guyatt,84 is one of the most frequently used disease-specific questionnaires validated to measure HRQOL. It has been shown to have strong measurement properties and has been translated into 28 languages and is used extensively throughout the world in clinical studies and clinical practice. It has 28 items in seven domains (activity limitations, sleep impairment, non-nasal/eye symptoms, practical problems, nasal symptoms, eye symptoms, and emotional problems). The evaluation ranges from 0 (not troubled) to 6 (extremely troubled), and the overall quality of life is calculated from the mean values for the 28 items. Several versions of the RQLQ have been developed in an effort to increase its efficiency. These include, but are not limited to, an RQLO with standardized activities, mini-RQLQ, RQLO for children and adolescents, and RQLO for nocturnal allergic rhinoconjunctivitis symptoms.89

The SNOT-20, developed by Piccirillo and colleagues,90 is a valid outcome measure for patients with rhinosinusitis. It is a modification of the 31-item Rhinosinusitis Outcome Measure, and it contains 20 nose, sinus, and general items. To complete the questionnaire, patients indicate how much they are affected in each area in a five-point scale, and they identify the five most important items.

The RSDI, another measure of HRQOL, has been used both for patients with allergic disease and those with chronic nasal obstruction. The questionnaire has 30 items comprising three domains: physical, functional, and emotional. Each item is rated on a five-point Likert scale ranging from 0 (never) to 4 (always).91

All of these HRQOL questionnaires have limitations and are still being improved. Future developments will focus on shorter questionnaires and introduction of specific scales for specific purposes.85,92

**The Nose as Source of Resonance for the Voice**

Resonance is the quality of voice that results from vibrations in the pharynx, oral cavity, and nasal cavity. The balance of sound vibration in these cavities determines whether the quality of speech and voice is perceived as normal or as abnormal. Speech resonance can be affected by several conditions related to the nose. Hypernasality is the presence of excessive nasal resonance during production of oral sounds and is due to velopharyngeal insufficiency. Hyponasality is the minimization or elimination of the nasal feature during production of nasal sounds due to obstruction in the nasal cavity or nasopharynx.

Nasometry is a method used for the clinical diagnosis of resonance disorders. It is available for use in a variety of languages. Nasometry uses a headset device worn by the patient which separates the oral and nasal cavities with a baffle plate. A acoustic energy during speech is collected by two microphones, one on the top and one on the bottom of the plate. The signal from each of the microphones is filtered and digitized by custom electronic modules. The instrument computes a ratio of the acoustic data acquired by the microphones.93 This ratio is termed “nasalance” (the acoustic correlate of perceived nasality) and is
THE NOSE AS AIR CONDITIONER

Nasal inspiration is of significant importance for maintaining the internal milieu of the lungs. The air-conditioning capacity of the nose protects the lower airways from ambient conditions that can range in temperature from −42°C to 48°C and from 0% to 100% relative humidity.89 A healthy person may consume up to 350 kcal of heat and 400 mL of water per day to condition the inspired air under moderate environmental conditions.100 In vivo measurements of nasally inspired air showed that most heating and humidification is accomplished in the space between the nasal valve and the middle turbinate.101 Evaluation of the conditioning capacity of the nose has been only investigational. A common performed technique for such evaluation is to insert a probe in the nasopharynx which is equipped with temperature and humidity sensors that continuously sample the airflow. The nasal air-conditioning capacity is calculated from measurements of the air stream temperature and of its relative humidity as it enters the nose and exits into the nasopharynx.102 The conditioning capacity has been investigated in healthy noses as well as in those affected with inflammation and in patients undergoing surgical interventions. Natural and induced allergic challenges have been shown to increase the ability of the nose to condition inspired air.103 Septal surgery improves nasal air-conditioning capacity is calculated from the middle turbinate.101

The sense of smell is important for safety functions such as early detection of smoke, gas leaks, and numerous toxic agents as well as hedonic functions such as eating foods and beverages and detecting of fragrances or aromas. Patients reporting olfactory impairment indicate that they have a high level of disability and have been found to have low quality-of-life measures.107 Accurate assessment of olfactory dysfunction is of vital importance for management of this disability. Information on olfactory dysfunction and its assessment is available in Chapter 38, "Olfaction and Gustation."

CONCLUSIONS

Objective evaluation of nasal function can aid evidence-based medical treatment and research on disorders of the nasal airway. All of the tools for upper-airway evaluation, including objective airway measurement and validated patient questionnaires, have unique strengths and weaknesses that allow each technique to make a distinct contribution to the evaluation and ultimate treatment of patients with upper-airway diseases.

NASAL CAVITY, PARANASAL SINUSES, AND ANTERIOR SKULL BASE

Plain radiographs for the evaluation of the paranasal sinuses are infrequently used in modern practices largely due to the lack of detail they afford and the vast availability of computerized tomography (CT). CT, due to its exquisite ability to display and differentiate hypertrophic mucosa, bone, and air, is the current imaging standard for the evaluation of rhinosinusitis. CT data also serve to guide surgical navigation and planning.

For the neoplastic diseases of the nasal cavity and paranasal sinuses, enhanced magnetic resonance imaging (MRI) is the preferred modality since it better resolves tumor from inflammatory changes and normal anatomic structures, although both CT and MRI are often required to determine the resectability of a particular tumor.

Multidetector (multislice) CT scanners are readily available in many imaging centers and provide a quick and comprehensive evaluation of the head and neck anatomy with thin slices that can be used to reconstruct images in any desired plane in two- and three-dimensional formats (Figure 1). CT uses ionizing radiation, which is a significant concern for the young and for patients who require repeated examinations. Various dose lowering strategies are employed by different manufacturers and radiologists, though the referring physicians should also bear responsibility since elimination of unnecessary CT examinations will have the greatest impact on radiation dose received by the patient. Iodinated contrast material administration is not necessary for rhinosinusitis and is reserved to assess neoplastic diseases and complications of acute sinusitis.

High quality MRI examinations performed at 1.5 tesla and higher magnets are generally needed to demonstrate the intricate anatomy of the sinuses and skull base. In most cases gadolinium-based contrast material is required. T1 and T2 refer to nuclear magnetic resonance tissue relaxation times. Fat saturated postcontrast T1 weighted (T1W) images are of utmost importance in the evaluation of skull base and paranasal sinuses. Even T2 weighted (T2W) scans benefit from the application of fat suppression technique, because otherwise inflammation (bright) and fat (bright) on fast spin echo T2 weighted images (T2WI) may be difficult to differentiate, particularly at the skull base or in the setting of abundant marrow fat, for example, petrous apex.

Rhinosinusitis

Rhinosinusitis refers to a continuum of inflammatory changes in the sinuses and nose regardless of etiology. Using a set of clinical criteria based on the type and duration of symptoms, five forms of rhinosinusitis are described: acute, subacute, chronic, recurrent acute, and acute exacerbation of chronic rhinosinusitis (CRS). There is a large overlap of the imaging findings of these clinical entities, though certain findings such as air-fluid levels and osteitis are quite characteristic for acute and (CRS), respectively (Figure 2).

Air-fluid levels are easily recognized on CT and their specificity in the appropriate clinical setting (absent recent instrumentation or irrigation) is 100% for acute inflammation of the sinus mucosa, though, the sensitivity of this finding is not known. In general, acute sinusitis is a clinical diagnosis, and imaging is not required unless there is a suspicion of a complication of acute sinusitis, which targets the orbit and/or the brain.

Through the natural dehiscences of the bony orbit and/or venous drainage, infection can gain access from the paranasal sinuses to the orbit; subperiosteal phlegmon and abscess may occur when the infection is limited by the periorbita which is a stout layer of connective tissue that lines the entire orbit and also contributes to the periorbita (Figure 3). Orbital cellulitis is a more advanced form of orbital infection and implies that the process has breached the periorbita. Orbital cellulitis can lead to permanent loss of vision due to increased intraorbital pressure and/or vascular thrombosis. Since the cavernous sinus receives venous drainage from the orbit, life-threatening complications, cavernous sinus thrombophlebitis and carotid artery vasculitis, may develop (Figure 4).

Extension of infection to the intracranial compartment is the most feared complication of acute sinusitis and can present in the form of meningitis, epidural abscess, subdural empyema, sinus thrombosis, and brain abscess (Figure 5). Although contrast enhanced CT is appropriate for the evaluation of these complications, MRI is superior to CT, particularly for the intracranial extension of infection. Diffusion weighted imaging, a sequence well known for the ability to detect acute arterial or venous infarctions, is also relatively specific to infected collections and abscesses because of the limited water diffusivity within such lesions.

Pott puffy tumor consists of a subperiosteal abscess and osteomyelitis of the frontal bone secondary to direct spread of infection from the...
In the era of effective antibiotics these complications are quite uncommon and typically affect young children and immunocompromised individuals.

Surveillance CT scans are often obtained in patients before bone marrow transplantation due to risk of aggressive transformation as they receive immunosuppressive medications. Surveillance scans are also performed in patients who are immune compromised in the setting of unexplained fevers. Careful evaluation of the orbits and soft tissues about the paranasal sinuses using both bone and soft tissue windows is crucial in these patients as mild soft tissue induration may be the only sign of early aggressive infection.

**Chronic Rhinosinusitis.** Mucosal thickening is the most common imaging finding of CRS, followed closely by mucus retention cysts. Polyp formation or polypoid mucosal thickening is found in approximately half of the patients with CRS and may indicate a different underlying pathological mechanism. Osteitis, presenting as thickening and/or sclerosis of the sinus walls on CT examinations, is indistinguishable from chronic osteomyelitis in histopathological examination but no microorganism has been demonstrated in humans in association with this condition. CT is an excellent modality to show the presence and extent of these changes in the mucosa and bone. Evaluation of the sinus drainage pathways and the ostiomeatal complex is crucial and best accomplished on either directly scanned or reconstructed (from axial) coronal CT images.

Although the majority of patients with CRS will present with a distribution of mucosal thickening that does not follow a blueprint, certain patterns can be delineated in CT examinations of some of the patients with CRS: (1) opacification of the ostiomeatal complex is commonly associated with ipsilateral maxillary, frontal, and anterior ethmoid disease (Figure 7), (2) opacification of the sphenoethmoid recess predicts ipsilateral sphenoid and posterior ethmoid sinus disease, (3) infundibular opacification is associated with ipsilateral maxillary sinus disease, (4) obliteration of the frontal recess leads to anterior ethmoid and frontal backfill sinusitis, and (5) sinonasal polyposis can be separated both clinically and radiographically from the ordinary mucosal thickening due to its mass effect and erosiveness and is associated with asthma, aspirin sensitivity, and eosinophilia.

The role of anatomic variations of the sinonasal cavity such as nasal septum deviation, concha bullosa, paradoxical middle turbinate, and Haller cells in the pathogenesis of CRS is debatable, but it is important to note these variations on imaging studies because of their potential implications on surgical management (Figure 8). The asymmetry of the ethmoid roof (fovea ethmoidalis), dehiscence of the lamina papryacea, Onodi cells, and position and integrity of the optic and carotid
canals are particularly important since they are implicated in surgical complications.

Sinonasal secretions are relatively hypodense (10 to 25 Hounsfie ld unit [HU]) when they are acute and become hyperdense (30 to 60 HU) in the chronic stage due to increased protein content of the concentrated and desiccated secretions. At times the density may simulate that of acute blood. The varying protein content of sinus secretions in different stages of disease can be identified in CT based on density although this is rarely helpful from a diagnostic standpoint. Most secretions on MRI show low signal on T1 weighted image (T1WI) and high signal on T2WI similar to cerebrospinal fluid (CSF). However, the T1 signal increases and T2 signal decreases with increasing protein content of secretions up to 30% which can create confusing appearances mimicking soft tissue masses (Figure 9). Sinus secretions with a protein concentration above 30% will show very dark signal on both T1WIs and T2WIs that resemble a normally pneumatized sinus.

M ucoceles are epithelium-lined mucus filled cavities arising from the paranasal sinuses that typically cause significant expansion of the sinus with thinning of the sinus walls. Obstruction of sinus drainage is responsible for mucocele formation. Bone thinning may be so severe that the wall of the sinus may not be perceptible on CT (Figure 10). Although generally benign, mucoceles can have serious complications when they extend to the brain and orbits. M ucoceles are most commonly seen in the frontal and ethmoid sinuses. The signal intensity of the mucocele on MRI will vary with the protein concentration but is frequently bright on T1WIs (Figure 11).

Retention cysts are generally asymptomatic and present as well-circumscribed cysts in the maxillary sinus, although they can occur in any of the paranasal sinuses.

It is presumed that the amount of mucosal hypertrophy demonstrated by CT is a good indicator of disease severity. Unfortunately, the correlation between symptom scores and CT scores is only modest. The Lund-Mackay method (Table 1) is the most commonly used CT scoring system; a score of 0, 1, or 2 is given to each of the five anatomic sites on both sides for normal aeration, partial opacification and complete opacification, respectively. The ostiomeatal unit receives 0 or 2, yielding a maximum score of 12 for one side.

Sinonasal polyposis is a distinct form of CRS. It is much more frequently associated with eosinophilia. On CT and MRI, one can see expansion of the nasal cavity with smooth bony remodeling (Figure 12). In severe cases, expansion of the sinonasal cavity may involve the skull-base and orbits, mimicking a malignant tumor. The MRI signal characteristics of polyposis are quite variable due to varying protein concentration of the polyps and obstructed secretions. When the protein content is too high, polyposis may show no signal mimicking a normally pneumatized sinus, which may lead to underestimation of the extent of disease on MRI. CT, in these cases, is better able to demonstrate the extent of disease and bony changes.

Antrochoanal polyp is an inflammatory mass that arises from the maxillary sinus mucosa and emerges from the sinus via the natural or accessory ostium and extends into the nasopharynx through the choana. The imaging appearance is characteristic (Figure 13). A well-defined mass with smooth remodeling of the maxillary ostium projecting into the nasal cavity or into the nasopharynx is seen.
The role of fungi in the pathogenesis of CRS is under active investigation, and it is believed that at least some forms of fungal sinusitis (FS) and CRS may be within the same spectrum. Nonetheless, there are five clinicopathologically distinct forms of FS in which the direct role of fungi has been established (Table 2). It is important to note that saprophytic colonization of the sinonasal mucosa with fungi is very common in normal populations, and microbiological isolation of fungi from the mucosa is not enough to diagnose FS.

Acute invasive FS targets severely immunocompromised patients and is often fatal despite treatment. Early CT findings are indistinguishable from ordinary rhinosinusitis and consist of mucosal thickening typically involving the nasal cavity. Later, one can see edema in the soft tissues outside the sinuses. Intracranial and intraorbital extension of this process is often catastrophic (Figure 14). A high index of suspicion and biopsy of the middle turbinate are required to diagnose acute invasive FS in the treatable stage.

Chronic invasive FS, either the granulomatous or nongranulomatous form, is seen in patients with mild to moderate immune impairment and has a more protracted course. The radiological hallmarks of chronic invasive FS are bone erosion and intracranial extension of the process in a fashion similar to neoplasms and other mass lesions. Areas of increased CT attenuation within chronic invasive FS are demonstrated in the majority of patients.

Fungus ball, a benign form of FS, is a sinus mass packed with fungal hyphae that afflicts immunocompetent patients. On CT, it is seen as an opacified sinus with multiple foci of increased attenuation in the center of the sinus mass (Figure 15). Bone erosion is rare but expansion of the sinus can occur.
Allergic FS, an immunologically mediated hypersensitivity reaction, is perhaps a subgroup of CRS. The histopathological hallmark of this entity is infiltration of eosinophiles. On CT, a central area of hyperattenuation is almost always seen within the sinus and corresponds to markedly decreased T2 signal on MRI (Figure 16). Expansion of the sinuses with bone remodeling or erosion is common in which case sinonasal tumors would be considered in the differential diagnosis.

Granulomatous Rhinosinusitis

Granulomatous inflammation of the paranasal mucosa is relatively rare, but it must be suspected in cases that are not responsive to therapy for CRS. Wegener granulomatosis (WG) is a systemic vasculitis that affects the kidneys, lungs, and upper respiratory system. It very commonly involves the upper respiratory tract, and approximately half of the patients present with rhinosinusitis before other systemic manifestations are apparent. The radiologic manifestation of WG closely mimics that of CRS in the early stages since small granulomas in the mucosa are not resolved in imaging studies. Extensive osteitis, diffuse mucosal thickening, nasal septum perforation, and erosion of the nasal turbinates are seen in the late stages of WG (Figure 17). Sarcoidosis is another systemic granulomatous disease that can involve the sinonasal cavity and erode the nasal septum. The radiographic appearance is more benign compared to WG and often indistinguishable from CRS since sarcoidosis rarely causes destructive changes. In previous generations, leprosy, tuberculosis, and syphilis would have been more commonly seen causes of granulomatous sinusitis and “saddle nose deformity.”

Exposure to environmental toxins such as beryllium and chromate salts has been implicated in granulomatous sinusitis. Cocaine use may also lead to an erosive nasal septum process.

Cephaloceles and Cerebrospinal Fluid Leaks

Cephaloceles are meningeal or brain hernias that occur through a bony defect present at the skull base. Depending on the location of the defect and cephalocele sac, occipital cephaloceles, frontoethmoid cephaloceles (FECs), and basal cephaloceles (BCs) are defined. The congenital occipital cephaloceles are much more common but they are associated with neural tube closure defects and pathogenetically different from the FEC and BC. FECs are divided into nasofrontal, nasoethmoid, and nasoorbital varieties based on their morphology. Likewise, BCs are described in terms of its relationship to the sphenoid and ethmoid bones. Most FECs are apparent at birth and associated with a myriad of craniofacial deformities. BCs and some FECs may stay asymptomatic for years and present as a sinonasal or nasopharyngeal mass in adulthood. Meningoceles contain only meninges and CSF, whereas, encephaloceles contain brain tissue in addition to dural covering and CSF. Identification of the contents of a cephalocele is critically important since some, particularly BCs, can contain functioning brain tissue such as the optic chiasm and pituitary. In rare cases, vessels can be found in or near the vicinity of the cephalocele sac. The contents of the sac can be best evaluated with MRI, whereas, CT may permit better

Total possible score for one side is 12.

Figure 11: Sphenoid mucocele. Axial T2W (A) and coronal T1W (B) images of the sphenoid sinus show marked expansion of the sinus in this patient with prior history of transsphenoidal pituitary surgery. Characteristic signal changes are seen due to desiccated secretions.

Figure 12: Sinonasal polyposis. Coronal CT images (A and B) show soft tissue attenuation masses in the nasal cavity representing inflammatory polyps. Remodeling of the nasal septum and medial wall of the left maxillary sinus is noted. High attenuation in the central parts of the ethmoid and maxillary sinuses is due to desiccated secretions. This type of high attenuation may be seen in allergic fungal sinusitis but this was histopathologically ruled out.
anatomic classification due to its exquisite ability to demonstrate the three-dimensional anatomy of the skull base (Figure 18).

Acquired cephaloceles can occur as a result of head trauma and surgery. They are now more common than congenital ones because of the marked increase in functional endoscopic sinus surgery and prevalence of head injuries in motor vehicular collisions. These patients typically present with symptoms related to CSF leak and recurrent meningitis. Actual sac formation is rare but the bony defect is demonstrated with high-resolution CT in the majority of patients. CSF leak may be observed during endoscopic evaluation and is augmented if fluorescein is placed intrathecally, although the use of intrathecal fluorescein is not approved in the United States by the Food and Drug Administration. Positive demonstration of a CSF leak from a skull base defect can be accomplished with CT-cisternogram, which involves intrathecal administration of iohexol followed by high resolution CT in the prone position (Figure 19). In nuclear medicine departments, CSF leak can be demonstrated by intrathecal administration of a radionuclide (usually indium diethyleneetriamine pentaacetic acid (DTPA)) and imaging of the skull with a gamma camera. As an adjunct, several pledgets are placed in the nasal cavity before administration of radionuclide and several hours later, radioactivity on these pledgets is counted to predict the approximate location of the leak. While the nuclear medicine method is more sensitive than CT-cisternogram because of its ability to survey the patient over a longer period of time for an intermittent leak, it lacks the spatial resolution needed to accurately localize the leakage site.

Osteomas are common benign bone tumors and are often found incidentally in the paranasal sinuses. They are more frequent in the frontal and ethmoid sinuses and are usually small. They can become symptomatic by obstructing sinus drainage or indenting the extraocular muscles in which case surgical treatment may be warranted and can be accomplished endoscopically in the majority of the cases. Osteomas appear as rounded, bone density mass lesions on CT examination and the diagnosis is straightforward (Figure 20). They appear as signal voids on MRI scans and may simulate an aerated sinus, leading to under diagnosis with MR.13

Fibrous dysplasia is a relatively common tumor-like condition characterized by abnormal proliferation of fibrous tissue and disorganized bone. It most commonly affects the craniofacial bones and is seen as an incidental finding on CT examinations of the sinuses. Symptoms may develop due to sinus obstruction, cranial nerve compromise, and mass effect. CT shows characteristic ground-glass appearance and local bone expansion allowing differentiation from osteoblastic metastasis in most cases (Figure 20). On MRI, fibrous dysplasia may have heterogeneous appearance and show enhancement with gadolinium based contrast material. Ossifying fibroma can present in the nasal cavity and sinuses as a large soft tissue mass with mature bone formation within. Bone remodeling due to expansion of the sinonasal cavity is common.

Papillomas develop from the ectodermally derived Schneiderian mucosa of the sinonasal tract. Three patterns of Schneiderian papilloma are recognized microscopically: fungiform papilloma, cylindrical-cell papilloma, and inverted papilloma (IP). IPs typically arise from the lateral nasal wall, nasal septum, or the maxillary sinus and grow into the nasal cavity. Extension to the skull base and intracranial compartment is not uncommon. High rate of recurrence and malignant transformation or coexistent squamous cell carcinoma are the hallmarks of this tumor and necessitate a total surgical excision. The incidence of malignant transformation is a matter

**Figure 15** Fungus ball. A axial (A) and coronal (B) CT shows an expansile mass in the sphenoid sinus with small calcifications, characteristic of fungus ball.
of debate, but it is apparent that a substantial group of these patients harbor malignancy at first presentation, which escapes diagnosis. Elevated levels of epidermal growth factor receptor and transforming growth factor-alpha have been demonstrated in tumors with IP and squamous cell cancer (SCC) compared to IP. In addition certain histopathologic features such as increase in hyperkeratosis, presence of squamous epithelial hyperplasia, and increase in mitotic index are predictive of recurrence. The presurgical imaging evaluation is crucial and requires both CT and MRI if the tumor is outside the sinonasal cavity. CT, in addition to a sinonasal soft tissue mass, may show calcifications within the tumor and remodeling of the adjacent bones (Figure 21).

On MRI this tumor will show low signal on T2WI and enhancement. Solid "fungiform" and "cerebriform" patterns of enhancement have been described with this entity and may suggest the diagnosis. Due to high rate of recurrence and malignant transformation, careful follow-up is essential and often requires imaging for areas not amenable to endoscopic evaluation.

A myriad of benign tumors including but not limited to schwannoma, neurofibroma, hemangioma, pleomorphic adenoma, plasmocytoma, meningioma, chordoma, giant cell tumor, and giant cell reparative granuloma has been reported to arise from the sinonasal tract. Meningiomas of the olfactory groove and planum sphenoidale involve the anterior skull base. These tumors are usually confined to the intracranial compartment. Extension into the sinuses is not common but occurs (Figure 22). Some of these tumors may be amenable to endoscopic surgery. Meningiomas often cause thickening or blistering or osteolysis of the adjacent bone, which may be reactive in nature or due to intraosseous extension.

Primary malignant tumors of the sinonasal cavity usually present late in the disease course since they do not elicit symptoms in the early stages. Serendipitous diagnosis of an asymptomatic sinonasal cancer is rare. Presenting symptoms are generally secondary to invasion of the skull base, orbit, pterygopalatine fossa (PPF), masticator space, and perineural spread (PNS) and include diplopia, epiphora, malocclusion, trismus, neck mass, and facial numbness.

SCC arising from the sinonasal epithelium accounts for the majority of malignant tumors. Most SCCs of the sinonasal tract arise from the nasal cavity and ethmoid sinuses with frequent secondary involvement of the maxillary sinus. Adenocarcinomas arising from the seromucinous glands interspersed in the sinonasal mucosa are the second most common and make up to 10 to 30% of the malignant tumors of this region. They favor the ethmoid sinuses and have been associated with wood dust exposure. A denocarcinoma arising from the seromucinous glands show low signal on T1WI) and/or hemorrhage. Melanomas are responsible for approximately 5% of the sinonasal malignant tumors and usually develop in the nasal septum, lateral nasal wall, or less frequently in the turbinates. They are readily diagnosed clinically because of their discoloration, but may have a wide variety of signal intensities on MRI scans depending upon the content of melanin (which leads to bright signal on T1WI) and/or hemorrhage.

Olfactory neuroblastoma (ONB) (esthesioneuroblastoma) and sinonasal undifferentiated carcinoma (SNUC) are rare tumors of the sinonasal cavity. SNUCs generally have a dismal prognosis and show a very rapid rate of growth and invade the orbit and skull base whereas ONBs have a much more favorable prognosis. ONBs may be associated with intracranial cysts and preferentially involve the anterior ethmoid/nasal cavity.
region. SNUCs have been reported to have the highest rate of dural/subarachnoid dissemination of sinonasal malignancies. Sarcomas may vary in imaging characteristics depending upon their origin, these tumors show very aggressive features in imaging studies.

Extranodal lymphomas of the nasal cavity and paranasal sinuses are rare in western populations.22 The paranasal sinuses tend to harbor B-cell lymphoma whereas the nasal cavity lymphomas are usually of NK/T-cell variety which has a worse prognosis particularly in the Asian populations.23

Metastasis to the sinonasal cavity is a rare occurrence. Typical primary tumors are renal cell carcinoma, and adenocarcinoma of the gastrointestinal tract. The former may show hemorrhagic features whereas mucinous varieties of the latter may show stippled calcification. In children, neuroblastoma metastases favor the walls of the sinuses near suture lines and may be blastic or lytic.

In the early stages of the malignant tumors, CT findings may be indistinguishable from inflammatory disease. In fact, inflammatory changes are almost always present in association with a neoplasm due to retained secretions. MRI is better able to differentiate inflammatory disease from neoplasm due to the lower signal on T2WI of tumor tissue versus nonhyperproteinaceous secretions and due to the solid enhancement of neoplasms as opposed to the rim enhancement of inflammatory lesions (Figure 23). Detection of erosion and destruction of the thin bones as demonstrated on sinus CT may allow one to diagnose these tumors while they are still in the sinonasal cavity, which requires careful examination of all sinus CT examinations with the possibility of a malignancy in mind. In the late stages of the disease process, there is usually some degree of bone erosion and destruction, which appears different than the bone remodeling secondary to benign processes such as polyposis, mucocele, allergic F5, schwannoma, and papilloma. Differentiation of bone remodeling from more aggressive bone destruction allows the radiologist to offer a reasonable differential diagnosis. It is important to note that some malignant tumors such as melanoma and lymphoma tend to remodel the bone rather than destroying it.

In addition to the histology of the primary tumor, the status of surgical margins and presence/absence of intracranial extent are independent predictors of survival in patients with sinonasal malignant tumors.24 Thus, appropriate treatment of sinonasal tumors requires an accurate depiction of tumor extent preoperatively. Knowledge of pathways of disease spread is important when interpreting these images. In general, CT is more accurate for the evaluation of bone integrity, whereas MRI is much superior to CT in assessing the extent of disease, perineural or meningeal spread, and differentiating the tumor from secondary inflammatory changes (Figure 24). In our practice, most patients are imaged with both MRI and CT before the surgery.
There are two very important questions to answer in preoperative evaluation: (1) Is the periorbita infiltrated? and (2) Is the dura invaded? Most surgeons believe that tumor invasion of the orbital fat requires orbital exenteration. Preoperative determination of invasion of the periorbita is difficult due to the fact that tumor can destroy the bone and indent on the periorbita without infiltrating it (Figure 25). Therefore destruction of the bony orbit does not necessarily imply the need for orbital exenteration for orbital spread. Conversely, subtle invasion of the periorbita may not be apparent on imaging. Infiltration or stranding of the periorbital fat tissue and nodularity of the interface between the tumor and orbital tissue, enlargement and enhancement of the extraocular muscles are reliable signs of periorbital invasion but absence of these findings cannot always rule out tumor involvement (Figure 24). High-resolution fat-saturated T2W and enhanced T1-weighted images are particularly helpful in this assessment. The overall accuracy of imaging for determination of presence or absence of periorbital invasion is about 60 to 70%. It is important to note that this modest accuracy is mainly a reflection of low negative predictive value. Thus, the presence of periorbital invasion is more accurately predicted than the absence of invasion.

Intracranial extension of tumor and dura/brain invasion is important to identify because of their impact on treatment and prognosis. MRI is the modality of choice in this scenario. When there is irregular/nodular thickening and enhancement of the dura or smooth thickening of the dura more than 5 mm, the diagnosis of dural invasion can be made with a 100% positive predictive value (Figures 24 and 25). Difficulty arises when the thickening and enhancement are smooth and thin which can be seen both with dural invasion and reactive changes. As in the periorbital invasion, it is easier to confirm presence of invasion than absence of it.

Lymph node metastasis occurs in 25% of the malignant sinonasal cancers and signifies a poor prognosis. The ipsilateral submandibular and submental level I and high jugular level II chains are the most common sites of nodal metastasis.

PNS is another way by which sinonasal tumors can invade intracranial structures. Imaging can demonstrate PNS of disease before the patient becomes symptomatic, dramatically changing the course of treatment. Detection of perineural metastasis requires detailed knowledge of the skull base anatomy and good quality images. MRI is far superior to CT in this respect. Effacement of the fat pads surrounding the nerves outside the skull is an important clue to PNS of tumor and can be identified with high-resolution T1-weighted images. The authors find contrast enhanced fat-suppressed T1-weighted images extremely helpful for this diagnosis since the enhancing tumor is easily identified against the suppressed background. PNS mostly occurs along the fifth and seventh cranial nerves. The auriculotemporal, vidian, and greater superficial petrosal nerves provide anastomosis between the
seventh and fifth cranial nerves and can act as conduits through which tumor spreads from the fifth to seventh nerve and vice versa. PNS mostly occurs in a centrifugal (from the periphery towards the skull base and brain) fashion but the opposite is also possible. The evaluation of the PPF is particularly important since the tumor, in most cases, first involves the PPF before it infiltrates the inferior orbital fissure, foramen rotundum, foramen ovale, vidian canal, and finally, cavernous sinus and Meckel cave (Figure 26). This region should show only speckles of soft tissue representing vessels and the pterygopalatine ganglion amidst a bright fat background on T1WI. If this fat is obliterated or completely replaced with soft tissue on CT or T1WI, suspect neoplastic infiltration!

Positron emission tomography (PET) is a very robust tool in oncologic imaging in general. Unfortunately, PET and PET-CT have important shortcomings in the evaluation of skull base and sinonasal tumors. Lower resolution compared to CT and MRI is a major disadvantage in this anatomic area where the normal as well as abnormal structures of interest are often very small. PET performs worse than MRI in T staging of untreated patients. Identification of nodal metastasis is slightly more accurate with PET-CT compared to CT or MRI alone, but PET-CT is not sufficiently accurate to direct treatment decisions. For the detection of distant metastases PET has a clear advantage over the other modalities. The most significant advantage of PET-CT is seen in the follow-up of patients who had been treated with surgery or radiotherapy where granulation tissue may obscure “nonphysiologic” imaging.

**NASOPHARYNX AND CENTRAL SKULL BASE**

External examination of the central skull base and nasopharyngeal lesions is either limited or impossible, highlighting the importance of imaging. A high level of anatomic knowledge is a prerequisite to interpretation of imaging studies. The sphenoid bone is the central piece in the central skull base and forms the floor and anterior wall of the middle cranial fossa, houses the sella turcica, supports the cavernous sinuses and separates the orbits and nasopharynx from the intracranial structures. Through a number of bony channels and dehiscences, the nasopharynx and intracranial compartment are contiguous and these channels may serve as a path for disease spread. The nasopharynx is a fibromuscular tube attached to the sphenoid bone. The pharyngeal mucosal space is defined by the pharyngobasilar fascia, which surrounds the mucosa and the superior constrictor muscle and fills the gap between the muscle and the skull base. The eustachian tube pierces through the pharyngobasilar fascia at the sinus of Morgagni, which may allow nasopharyngeal cancer access to the skull base. The fossa of Rosenmüller, torus tubarius, and the orifice of the eustachian canal are on the lateral wall of the nasopharynx. The buccopharyngeal fascia, a part of the middle layer of the deep cervical fascia, separates the pharyngeal mucosal space from the retropharyngeal space. The alar fascia makes the posterior border of the retropharyngeal space and anterior border of the danger space, a potential space between retropharyngeal and perivertebral fascia. The prevertebral fascia separates the danger space from the prevertebral space, which contains the longus colli muscles and extends from the skull base to coccyx.

Nasopharyngeal adenoids can be very prominent and make it difficult to differentiate them from mass lesions particularly in young individuals.
By the third decade of life, most individuals have only a small residual amount of adenoid tissue in the nasopharynx. A symmetric prominence of the adenoids should be regarded with suspicion for an underlying neoplastic process. Immune compromised individuals may show enlargement of this lymphoid tissue.

Tornwaldt, or Thornwaldt, cyst is an embryonic remnant of the pharyngeal bursa occurring at the posterior wall of the nasopharynx in midline and seen in approximately 3% of the population. These submucosal cysts are usually smaller than 1 cm and asymptomatic. They show very bright signal on T2WIs and can be bright or dark on T1WIs depending on the protein content of the fluid. A mild enhancement of the wall is usually seen.

Retention cysts of the nasopharyngeal mucosa are also generally asymptomatic. They can be uni- or multilocular and show similar signal characteristics on MRI to Tornwaldt cysts but occur off midline (Figure 27). Most pathologies of the nasopharynx arise from the pharyngeal mucosal space and extend to the neighboring spaces and skull base.

Most mass lesions in the nasopharynx are malignant. Nasopharyngeal carcinoma (NPC) makes about 70% of the mass lesions in this site and can be seen in a wide range of ages. The incidence begins to rise in the second decade and peaks in the fourth and fifth decades in the United States of America. In Asia, where the prevalence of NPC is 25 times higher in some parts, the peak age of presentation is in the third decade. NPC has three histologic subtypes: squamous cell, nonkeratinizing, and undifferentiated. NPC typically arises in the fossa of Rosenmüller and grows anteriorly to the nasal cavity and orbit, laterally to the parapharyngeal space and infratemporal fossa (ITF) (masticator space), posteriorly to the skull base and intracranial space and anteroinferiorly to the PPF. Once in the ITF and PPF it can extend intracranially via perineural trigeminal neurotropic spread. Imaging is an essential part of staging since parapharyngeal and intracranial extension can only be reliably evaluated by radiologic means. MRI is superior to CT because of the exquisite soft tissue contrast it provides. An added advantage of MRI is its ability to separate tumor from obstructed secretions in the sinuses and to track perineural or meningeal disease intracranially. Involvement of the skull base is also better evaluated with MRI than CT due to the fact that the cancellous part of the bone is “involved” earlier than the cortical bone. Fat in the cancellous part of the bone and signal changes due to replacement of fat are readily visualized on T1WI MRI whereas CT provides a better evaluation of the cortical integrity. It is not known whether these changes in the cancellous part identified on MRI in the absence of cortical erosion truly represent tumor infiltration or merely reactive changes (Figure 28). Regardless, simple bone involvement diagnosed by CT or MRI in the absence of intracranial extension of tumor and cranial nerve palsy does not seem to have an adverse effect on the prognosis.
Lymph node metastasis from NPC can be evaluated by CT or MRI. MRI provides better differentiation of the primary mass from adjacent retropharyngeal nodal metastasis, which may appear as a single mass on CT. Due to abundant lymphatic drainage present in the nasopharynx, nodal metastasis occurs to bilateral retropharyngeal, parapharyngeal, and jugular chain nodes. Five percent of NPC patients will have systemic metastases at the time of diagnosis. Bones, lungs, and liver are the primary targets for hematogenous metastasis. PET-CT is beneficial in staging of patients with T4 disease since these patients have a distinctly higher propensity to have systemic metastases.30

Follow-up of patients after chemo/radiotherapy is best accomplished by PET-CT. While MRI and CT are also very informative, differentiation of viable tumor from posttherapy fibrosis is not consistently possible. Serial cross-sectional imaging is the most useful surveillance technique short of PET.

Lymphoma of the nasopharynx arises from the adenoids and is most commonly of non-Hodgkin variety. B-cell lymphoma is the most frequent type in the western world whereas T-cell lymphoma is more prevalent in Asian populations. Mucosa associated lymphoid tissue, a low-grade lymphoma, is rare in the nasopharynx. In half of the patients with nasopharyngeal lymphoma there is systemic involvement.

The imaging appearance of non-Hodgkin lymphoma of the nasopharynx is not different than that of NPC. Relative lack of bone destruction may be a useful hint for differentiating lymphoma from NPC (Figure 29).

Rare tumors of the nasopharynx include adenocarcinomas, rhabdomyosarcoma, plasmocytoma, and melanoma.

The central skull base mass lesions are much more diverse than the anterior skull base lesions. By far the most common mass lesions in this site are pituitary adenomas. Mucosal adenomas, measuring less than 10 mm, are confined to the sella turcica and pose no diagnostic difficulty when they are visualized on MRI. M acroadenomas, on the other hand, can attain very large sizes and invade the suprasellar region and brain, cavernous sinuses, the sphenoid sinus, and skull base, making it very difficult to differentiate them from other tumors seen in this region. Two imaging findings can help make this distinction: (1) expansion of the sella turcica and (2) visualization of the pituitary gland. Macroadenomas invariably expand the sella whereas most tumors secondarily invading the sella do not expand it to the degree expected from their overall size and extent. Visualization of even a small remnant of the normal pituitary gland implies tumors other than macroadenomas, which typically leave no visible normal pituitary tissue (Figure 30). Macroadenomas may demonstrate variable signal since they can contain varying amounts of cystic and solid areas, hemorrhage, and calcification. Determination of whether a pituitary macroadenoma invades the cavernous sinus is crucial in treatment planning. High-resolution coronal MRI with and without contrast is helpful in this distinction. The likelihood of cavernous sinus (CS) involvement is very high if the tumor extends beyond the line drawn along the lateral margins of the turns of the cavernous carotid artery.31

Rathke cleft cyst arises from remnants of craniohypophyseal canal squamous epithelium in the sella turcica. They are often asymptomatic and found incidentally. The signal intensity on MRI, although usually bright on T1W, may vary depending on the protein content of the cyst but they do not demonstrate any enhancement other than perhaps minimal enhancement of its wall12 (Figure 31). Large Rathke cleft cyst can extend into the suprasellar cistern and become symptomatic by compressing the optic chiasm or the pituitary.

Suprasellar tumors can grow into the sella turcica, sphenoid sinus, and skull base. The most common primary suprasellar tumor is craniopharyngioma, but suprasellar extension of a pituitary adenoma is the most common lesion in this space. Craniopharyngiomas are epithelium derived tumors seen in all age groups but the majority of the cases present at childhood and teens. More than half of the craniopharyngiomas are of adamantinomatous type and present as cystic masses with enhancing solid mural nodules. The amount of cholesterol crystals present in the cyst determines the MRI appearance. Calcification is one of the hallmarks of craniopharyngiomas. The less common papillary type craniopharyngiomas are solid enhancing tumors and typically seen in adults.
Meningiomas of the planum sphenoidale, sphenoid sinus, and diaphragma sella can involve the sella and suprasellar region. Most meningiomas are seen in adults. They are more common in women than men. Meningiomas are typically solid and homogeneous masses and show diffuse, intense enhancement with contrast material (Figure 22). They can have calcifications and occasional cysts. “Dural tail” refers to a smooth and tapered thickening of the dura adjacent to meningioma and is either reactive or due to tumor infiltration. Most meningiomas exhibit this finding, although other dural-based tumors can have a similar dural tail. Hyperostosis, thickening, and sclerosis of the adjacent bone, are helpful in the differential diagnosis, when present.

Tumors of glial origin such as optic/hypothalamic glioma can present as suprasellar mass lesions and involve the sella and skull base. These are generally low-grade astrocytomas, although occasionally one may find a glioblastoma multiforme in the mix. The majority of optic gliomas are pilocytic astrocytomas and seen in children. Gliomas of the chiasm tend to be more aggressive than optic nerve gliomas and adult presentation is associated with higher grade astrocytomas.

Other less common suprasellar masses include germinoma/teratomas and dermoid/epidermoid tumors. Suprasellar germinomas can represent metastasis from other sites such as the pineal region.

The sphenoid sinus may give rise to many central skull base lesions. Because of its proximity to the intracranial compartment acute sphenoid sinusitis should be treated aggressively. Invasive and allergic FS can easily extend from the sphenoid sinus into the intracranial compartment and mimic neoplastic lesions. Mucoceles of the sphenoid sinus are uncommon but they can substantially expand the sphenoid sinus (Figure 11). Primary benign and malignant epithelial tumors of the sphenoid sinus are much less common than the inflammatory/infectious lesions. juvenile nasopharyngeal angiofibroma (JNA) is a disease of male children and teens. It arises from the posterior nasal cavity in the region of the sphenopalatine foramen and grows rather insidiously, invading the PPF, ethmoid and sphenoid sinuses, skull base and orbit. These are very vascular tumors and preoperative embolization is helpful in achieving a comprehensive resection (Figure 32). The most common malignant epithelial tumor of the sphenoid sinus is squamous cell carcinoma.

The sphenoid bone can give rise to a variety of bone tumors. The most frequent mass lesion of the sphenoid bone in adults is metastasis from a remote site (Figure 33). Chordomas derive from remnants of the primitive notochord associated with the sphenoccipital synchondrosis and therefore affect the clivus although some will arise from the petrous apex region. They can be seen at any age group but most patients are young adults. It is more common in men. Clival chordomas are histologically benign tumors but they are locally destructive and have a very high rate of recurrence. High signal on T2WIs is a common feature unless they have a calcified matrix. Chondrosarcomas usually arise from the petroclival fissure and are seen in younger ages than chordomas. Chondrosarcomas tend to invade the skull base through the foramen lacerum and petroclival fissure, reaching to the cavernous sinus, middle cranial fossa and posterior fossa (Figure 34).

Histologically, many chordomas and chondrosarcomas feature areas of hemorrhage, collections of mucin, necrotic regions, calcification, and entrapped bone trabeculae. Both chordomas and chondrosarcomas present as soft tissue masses with lytic destruction of the adjacent bone on CT exams. Due to the varied composition of these tumors MRI shows heterogenous signal intensity, which is predominantly hyperintense on T2W and iso- to hypointense on T1WIs. Enhancement is variable. Both tumors tend to have a lobulated appearance. Although chordomas favor midline and chondrosarcomas favor off-midline location, there is a significant overlap of the site of origin. Furthermore, it becomes impossible to determine the epicenter of a particular skull base mass when it attains a large size. Thus, the CT and MRI appearance of chondrosarcomas is very similar to chordomas rendering a preoperative diagnosis impossible in most cases unless the classic “popcorn-like” calcification of a chondrosarcoma is apparent.

The relationship of the carotid arteries and the optic nerves to a skull base mass is of utmost importance to the surgeon. A ny central skull base mass, regardless of its histology, can come in contact with or invade the carotid artery and preoperative documentation of this is critical in determining the extent of resection and avoiding catastrophic complications. Most benign tumors merely displace or occasionally compress the carotid artery without invading the adventitia, whereas malignant tumors...
the clinicians as printed films. Active participation of radiologists in the care of these patients is crucial. Perhaps the most important clue to the diagnosis of a giant aneurysm mimicking a mass lesion is the failure to identify the tissue of origin of the “mass.” In other words, if one is unable to tell the anatomic and/or tissue origin of a particular tumor, an aneurysm must be suspected.

While the choice of imaging study is determined on an individual basis; however, MRA is generally the most practical and fruitful test in this scenario despite its limited sensitivity for slow flow. CTA has a much superior spatial resolution and affords superb contrast between the vessels and adjacent soft tissues but, sometimes, it may be difficult to differentiate enhancing vessel lumen from other enhancing structures and adjacent bone. An added advantage of CTA is that it can be used to guide surgical navigation. Digital subtraction angiography may be necessary in rare occasions.

Dehiscences of the sphenoid sinus wall can allow protrusion of the internal carotid artery or the optic nerve into the sinus lumen, which can pose a surgical hazard if not recognized preoperatively.

**INFRATEMPORAL FOSSA AND PTERYGOPALATINE FOSSA**

The ITF contains the muscles of mastication, the mandibular nerve and its branches. The outer and inner membranes of the deep cervical fascia separate this space from the adjacent parapharyngeal space. The outer membrane of the superficial layer of the deep cervical fascia is continuous above the zygomatic process and invests the temporalis muscle. Thus, the prefix infra is unsuitable. Yet the term ITF has been used so extensively in the surgical literature that replacing it would not be advisable.

The PPF is bounded by the body of the sphenoid bone superiorly, the pterygoid process posteriorly, the posterior wall of maxillary sinus anteriorly, the inferior orbital fissure supraorbitally, and the perpendicular plate of the palatine bone medially. Laterally, it is contiguous with the ITF through the pterygomaxillary fissure, which is a roughly triangular shaped cleft that houses the maxillary artery, alveolar arteries, veins, and nerves. The posterior openings of the PPF consist of the foramen rotundum suprolaterally and the vidian (pterygoid) canal supramedially. The sphenopalatine foramen, situated on the medial wall of the PPF allows communication between the PPF and nasal cavity. Anteriorly, the PPF is in contiguity with the inferior orbital fissure. The greater and lesser palatine canals connect the palatine/alveolar cavity to the PPF. The PPF contains the pterygopalatine ganglion and its branches, the maxillary nerve and the terminal branches of the internal maxillary artery, which are embedded in fat tissue. Due to its unique CT attenuation and MRI signal fat tissue is easily recognized in imaging studies and replacement of fat tissue by disease process is, thus, relatively easy to diagnose. Nonetheless, the small size of the involved structures and the intricate anatomy of the region pose significant challenges to imagers.

Imaging is essential in assessment of the ITF and PPF. MRI affords excellent visualization of the disease processes in the ITF and PPF. Extension of the disease process into the intracranial compartment and adjacent spaces can best be evaluated by MRA as well. While the involvement of cancellous bone is recognized much earlier with MRA compared to CT, the assessment of the bone cortex is better accomplished with CT.

Biopsy of ITF mass lesions is done using imaging guidance. CT is well suited for this purpose and allows access to virtually all ITF masses. Despite the proximity to vital structures, fine needle aspiration biopsy of ITF mass lesions is performed without significant complication in good hands and with small gauge needles. MR-guided biopsy may be needed for lesions that are not visible on CT and requires special MR-compatible equipment.

Most tumors found in the ITF arise from the mucosal lining of the adjacent spaces such as the nasopharynx, nasal cavity, and paranasal sinuses and represent advanced cancer. Skull base lesions such as chordoma and chondrosarcoma and primarily intracranial tumors such as meningioma and pituitary adenoma can involve the ITF when they are large. SCCs and adenocarcinomas arising from the aerodigestive tract and skin can spread along the nerves to a considerable...
distance from the primary site. Because of its extensive distribution the trigeminal nerve is the most commonly affected cranial nerve by PNS. Involvement of the PPF is usually a turning point in PNS after which, tumor can extend intracranially via the foramen rotundum (maxillary nerve) and vidian canal (vidian nerve), intraorbitally via the infraorbital fissure and along the infraorbital nerve and into the ITF via the pterygomaxillary fissure (Figure 26). Similarly, PNS can occur via the mandibular nerve, which travels through the ITF and foramen ovale. Once reaching the trigeminal ganglion, PNS can occur towards the periphery via the maxillary, mandibular, and V-1 ophthalmic nerve, the latter of which can serve as a source for orbital invasion. PNS signifies a worse prognosis and sometimes can be diagnosed on imaging studies before it becomes symptomatic.

Primary tumors of the ITF are relatively uncommon and include vascular malformations, lipoma, juvenile angiofibroma, salivary gland tumors arising from ectopic salivary tissue, schwannoma, hemangiopericytoma, sarcomas, and lymphoma. The pterygoid venous plexus can be quite prominent and asymmetric mimicking vascular tumors on imaging studies. Pterygoid muscles can have various signal changes on MRI in postoperative patients or in patients with muscle denervation, which may simulate other pathologies. Since most tumors of the ITF originate outside the ITF, it is imperative to carefully evaluate the borders of a mass and its relationship with the surrounding structures before entertaining a primary ITF mass as the diagnosis.

JNA is a rare benign tumor of the PPF and ITF that originates from the superior posterior margin of the sphenopalatine foramen. It is usually very large at presentation and involves the nasopharynx, skull base, and intracranial compartment. JNA almost exclusively afflicts young males. Although histologically benign, JNA is very aggressive locally. Surgical resection and radiotherapy for the residual tumor when present is the standard approach for treatment. Because JNA is very vascular, presurgical embolization is routinely employed to help achieve a comprehensive resection, which is the most important step in curing the disease. Careful evaluation of the extent of disease before surgery and the residual tumor after surgery is critical in planning the surgery and radiotherapy.

Schwannomas limited to the ITF is rare. They appear similar on imaging studies to schwannomas seen elsewhere in the body (Figure 36). Surgical resection is the treatment of choice. Bone tumors arising from the sphenoid bone, mandible, maxilla, or zygoma can present as ITF mass lesions. The level of aggressivity of a bone lesion can usually be predicted in imaging studies by looking at the bone expansion, remodeling and destruction, soft tissue component if present, and transition zone of the tumor. Osteoid and chondroid matrix can occasionally be identified on CT and MRI studies allowing a preoperative diagnosis. Needle biopsy of certain bone lesions,
PART II / Rhinology

while technically feasible, may be misleading due to presence of varying tissues. The age of the patient has a very significant bearing in the differential diagnosis of bone lesions. Osteosarcoma and Ewing sarcoma should be considered in the differential diagnosis of aggressive sphenoid bone lesions in children and teenagers. Chondrosarcoma is typically seen in young adults. A lytic and expansile lesion in an adult should prompt the diagnosis of giant cell tumor while aneurysmal bone cyst or giant cell reparative granuloma should be considered in children.

Soft tissue sarcomas, including hemangio-pericytoma, synovial sarcoma, leiomyosarcoma, and spindle cell sarcoma can arise in the ITF (Figure 37). Rhabdomyosarcoma is a relatively common tumor in children in the head and neck region with a poor prognosis.

Primary tumors of the parapharyngeal space are usually either of MG origin or schwannomas. Pleomorphic adenomas are most common. Nonetheless, the most common neoplastic processes in this space are spread from pharyngeal squamous cell carcinomas or deep lobe parotid masses (again pleomorphic adenomas or carcinomas).

**ORBITS**

The orbital roof is made by the frontal bone. The floor of the orbit is formed by contributions from the orbital plate of maxilla, the palatine bone, and the zygomatic bone. The frontal process of the maxilla and lacrimal bone make the anterior aspect of the medial wall of the orbit. The lamina papyracea forms the mid portion of the medial wall whereas the sphenoid bone contributes to the posterior part of the medial wall. The lateral wall is formed by the zygomatic bone. Three openings at the apex of the orbit allow entry/exit of the neurovascular structures. The superior orbital fissure is between the greater and lesser wings of the sphenoid and houses the oculomotor nerve (III), trochlear nerve (IV), abducens nerve (VI), ophthalmic division of the trigeminal nerve (V-1), and the superior ophthalmic vein. The optic canal is immediately medial to the superior orbital fissure and separated from it by a tiny bone called the optic strut, which is a projection of the anterior clinoid process. The optic nerve and the ophthalmic artery, which are covered by a dural sheet, travel through the optic canal. The inferior orbital fissure carries the inferior ophthalmic vein, infraorbital and zygomatic nerves (both V-2 branches), and branches of the pterygopalatine ganglion and allows communication between the orbit and ITF and PPF.

The bony orbit is lined by a tough fibrous sheath named the periorbita, which serves as a mechanical barrier between the intra- and extraorbital structures. The medial, lateral, superior, and inferior rectus muscles arise from a common tendon, annulus of Zinn, and attach to the globe. The rectus muscles are enveloped by a fibrous membrane that forms the muscle cone and defines the intra- and extraconal spaces. The extraconal space is in between the periorbita and muscle cone and contains fat and the lacrimal
gland superolaterally. The intracanal space contains the extraocular muscles, the optic nerve sheath complex, and other neurovascular structures in addition to fat.

When dealing with an orbital lesion, one should try to identify the anatomic site that the lesion originates from to narrow down the differential diagnosis. Most lesions respect these anatomic boundaries although transspatial involvement is not infrequently seen.

Optic nerve sheath complex mass lesions are meningiomas or gliomas in most cases. Optic nerve meningiomas arise from the dura around the optic nerve and tend to concentrically enlarge about the nerve. On MRI one can generally identify the optic nerve in the central aspect of the mass. Optic nerve meningiomas are generally confined to the orbit but extension to the optic canal and intracranial compartment is possible. The MR signal features of optic meningiomas resemble those of the intracranial meningiomas; isointense to the brain parenchyma on T1 and T2-weighted images with intense and homogenous enhancement with contrast material (Figure 38). The “sandwich sign” refers to enhancement of the optic nerve sheath on either side of the non-enhancing optic nerve in meningiomas of this region. Optic nerve sheath meningiomas arising in the optic canal may become symptomatic when they are very small. The optic canals should be investigated with good quality high resolution MRI to identify such small lesions in patients with unexplained progressive optic neuropathy.

Optic nerve gliomas are usually of low-grade pilocytic astrocytomas and seen in children. One third of patients with optic glioma have neurofibromatosis I. Optic gliomas expand the optic nerve and it is not possible to identify the nerve separate from the tumor (Figure 38). MRI is the imaging study of choice and shows increased signal on T2 and isointense signal on T1-weighted images with variable enhancement on postcontrast images. Lymphoma and leukemia can rarely involve the optic nerve sheath and present as diffuse thickening of the nerve with enhancement on the postcontrast images.

Optic neuritis may show subtle enlargement of the nerve-sheath complex and may affect any part of the nerve. The majority of optic neuropathy in adults is ischemic in nature and can be diagnosed on clinical grounds. Multiple sclerosis is the leading cause of nonischemic optic neuropathy but optic neuritis may also occur in isolation. Eighty percent of patients with multiple sclerosis will have a bout of optic neuritis at some stage in their disease. Scanning the brain may reveal characteristic periventricular plaques. High signal on T2WI and enhancement in the acute setting are characteristic (Figure 38). In the chronic phase, optic atrophy may be present.

A variety of inflammatory and infectious diseases can present with optic neuritis with similar imaging findings. Idiopathic pseudotumor of the orbit is a nongranulomatous inflammatory process involving the orbit. It may present as a mass lesion, hence the name pseudotumor, or as an infiltrative process. It may involve a single structure or the entire orbit. The clinical presentation may be in acute, subacute or chronic form. The acute form is clinically characterized by abrupt onset of pain, redness and swelling of the eyelid. There is generally a quick and lasting response to steroid therapy. Since pseudotumor can involve any structure in the orbit in isolation or combination and present as a mass lesion or infiltrative process, the imaging differential diagnosis includes a number of possibilities from tumors and infection to thyroid ophthalmopathy. The combination of imaging feature and clinical presentation often obviate the need for biopsy, however. The myositic form of idiopathic pseudotumor mimics thyroid ophthalmopathy, whereas the tumor form...
with Valsalva maneuver. Flow voids or pulsation artifacts are typical features on MR. Enhancement is predictable with CT. Thrombi may be variable in signal intensity.

The extradural lesions of the orbit most commonly include the lacrimal gland diseases and direct extension of sinonasal diseases. Infection arising from the sinonasal cavity can gain access to the orbit through the natural bony defects or veins.

The imaging appearance of which may be quite similar and consist of diffuse enlargement of the gland. The primary tumors of the lacrimal gland can often be differentiated from other entities; however, they include epithelial (MGS), lymphoid, and congenital (dermoid/epidermoid) origins.

Vascular lesions of the orbit include caroticocavernous fistula, superior ophthalmic vein thrombosis, cavernous sinus thrombosis, venous varix, and arteriovenous malformations. They are most frequently seen in the orbit. Other sites in the head and neck region include facial soft tissues, paranasal sinuses, skull base (perimeningeal) and ITF. Encephaloceles of the anterior skull base can present as orbital mass lesion, typically in children, and this possibility must be considered when dealing with cystic lesions before any surgical procedure.

Etiology of Infectious Diseases of the Upper Respiratory Tract

David M. Poetker, MD, MA  
Timothy L. Smith, MD, MPH

Infectious diseases of the upper respiratory tract represent a broad topic, involving many different pathogens and targeting many different sites. Many of these result in multiple infections, with overlapping manifestations. In this chapter, we attempt to present an extensive, although not exhaustive, list of the various infectious agents affecting the upper respiratory tract. We have included the bacteria, viruses, fungi, and other pathogens specific to a given anatomical location. In addition, we have included special interest topics related to the upper respiratory tract.

Otitis Media

Otitis media is one of the most commonly diagnosed childhood illnesses. It is estimated that there are about 2.2 million diagnosed episodes per year, at a total cost of about $4.0 billion. It affects more than 90% of children in the preschool years and as many as 60% within the first two years of life. There are several risk factors associated with otitis media. They fall into two categories, the preventable, and the nonpreventable. The preventable include daycare, tobacco smoke exposure, extended pacifier use, and lack of breast-feeding. The nonpreventable risk factors include such things as gender, ethnicity, family history, older siblings, low socioeconomic status, and other health conditions.

Common pathogens isolated from middle ear effusions (MEE) have been well described. Bluestone and colleagues reported their experience and the pathogens isolated from over 7,000 MEE over a 10 year period. They found the most commonly isolated bacteria were the same as in AOM, however the ratios were slightly different. H. influenzae was the most commonly isolated at 15%, followed by M. catarrhalis, isolated from 10% of the cultured effusions, and S. pneumoniae was isolated from 7% of the effusions. Studies have shown much higher identification rates of pathogenic bacteria using more sensitive methods of bacterial identification such as polymerase chain reaction (PCR) techniques. Other explanations for the low rates of bacterial isolation, include the presence of bacterial biofilms.

More recent reports of MEE isolates in chronic otitis media with effusion have shown a decrease in the percent of S. pneumoniae positive cultures. The introduction of Prevnar heptavalent pneumococcal vaccine has been reported to have had a decrease in overall AOM incidence and has been reported to have contributed to a decrease in specific pneumococcal AOM episodes.

Identification of the offending microorganism requires culture of the middle ear fluid. This is relatively straightforward in the case of a perforated tympanic membrane with purulent otorrhea. In the case of an intact tympanic membrane, a tympanocentesis is required. Given the impracticality of performing a tympanocentesis on every child with an intact tympanic membrane, empiric coverage is appropriate. If however the patient fails multiple antibiotic courses, one should consider tympanocentesis to confirm the diagnosis and direct therapy with culture and sensitivity results.

The most recent set of treatment guidelines are from the American Academy of Pediatrics and the American Academy of Family Physicians from 2004. They recommend amoxicillin as the first line therapy for AOM. In those patients with a penicillin allergy, a cephalosporin, azithromycin, or clarithromycin is recommended. Patients that present with a temperature of greater than 39°C, or severe otalgia, amoxicillin/clavulanate is recommended with ceftriaxone for those allergic to penicillin. Those patients that fail the first line therapy should be given amoxicillin/clavulanate with the allergic alternative of ceftriaxone or clindamycin. Patients that present having failed first line therapy and have a temperature of greater than 39°C should be given ceftriaxone or clindamycin. A tympanocentesis should be considered.

Please see Chapters 16, “Otitis Media and Middle-Ear Effusions” and 17, “Chronic Otitis Media and Cholesteatoma” for a more complete discussion of otitis media.

A viral cause for AOM has been linked to such pathogens as the respiratory syncytial virus, influenza viruses, and adenoviruses. Since attempts at culture or identification of these are rarely performed, the incidence of these pathogens is not known. An association is logical, given that many episodes of otitis media follow a viral upper respiratory tract infection. In addition, viral upper respiratory tract infections have similar seasonal patterns as otitis media.

The Common Cold

The common cold represents a syndrome caused by a wide variety of infectious agents. It is usually a benign, self-limited illness of the upper respiratory tract. Despite this, the economic burden caused by the common cold is substantial. It accounts for approximately 20 million days of missed work, and 22 million days of missed school.

Symptoms may present hours to days after inoculation. The most common initial symptom is a sore throat. This is followed by nasal congestion, rhinorrhea, sneezing, and cough. In addition, some patients experience fever, especially children, hoarseness, headache, malaise, lethargy, and myalgia, especially with the influenza virus infection. These symptoms usually last between 7 and 10 days.

The cause of the common cold is almost exclusively viral, although there is overlap with the clinical experience with many bacterial infections (Table 2). The most common of the viral infections is the rhinovirus, estimated to be responsible for 30 to 50% of cases.
than 100 different serotypes of rhinovirus have been identified. The corona viruses account for between 10 and 15% of colds. Influenza viruses are the third most common cause, responsible for 5 to 15% of colds. Although influenza infections can be much more severe than the average cold, there is enough overlap to include influenza. The respiratory syncytial virus and parainfluenza viruses each account for 5%, while adenoviruses and enteroviruses each account for less than 5% of all colds.2 Ten to thirty percent of the cases of the common cold go without identification of the specific agent, although this is likely due to technical issues. The human metapneumovirus is a relatively new respiratory virus identified in children. The percentage of infections due to the metapneumovirus has not yet been established.1

The infectious process begins with the viruses entering the nose. The mucociliary clearance carries them to the adenoid area of the nasopharynx where they enter the epithelial cells via cell receptors such as the intercellular adhesion molecule-1. Once the virus is inside the epithelial cell, replication can occur as quickly as eight hours. Approximately 75% of patients infected will develop symptoms. Virus shedding usually peaks by the second day, but virus can be detected for several weeks.1

The pathophysiology of the manifestations of infection is not clearly understood. Viral infection has been shown to result in vasodilatation and increased vascular permeability. Mucous glands increase secretion due to the cholinergic stimulation. Certain viruses like influenza and adenovirus have been shown to cause extensive damage to the respiratory epithelium, however rhinovirus cause no histopathologic changes to the epithelium. This has led to the belief that inflammatory response to the infection and release of inflammatory mediators cause the symptoms.1 Recent studies have shown that several viruses can infect and replicate in the lower respiratory tract, contributing to the pulmonary symptoms of the common cold, although the exact mechanism of cough development has not been clearly established.12

The gold standard for viral identification involves virus isolation in cell culture. Other identification techniques include antigen detection and PCR. These techniques are of little clinical significance, since most cases can be diagnosed based on patient symptoms. Obviously, patients that are not able to articulate their symptoms make the diagnosis more challenging.11

Many different therapies have been reported for the treatment of the common cold, though few have data to support their use. There are data to support the use of first-generation, however not second-generation, antihistamine/decongestants. These have been shown to help with the nasal congestion and discharge.12 This is thought to be due to their anticholinergic properties, rather than the antihistamine effect. In addition, naproxen was shown to decrease cough, likely due to its anti-inflammatory properties. Other medications such as zinc, echinacea, and vitamin C have had mixed results in clinical trials evaluating efficacy.13

Antiviral medications targeted against influenza viruses have shown that they help to reduce the duration of symptoms by 1 to 2 days if taken within the first 48 hours of symptoms. A manda- dine and rimantadine were first introduced for the treatment of influenza A; however, they showed diminishing returns in the incidence of infections varies, with the incidence decreasing with increased age. Younger children have between six and eight colds per year, while adults have between two and four. Risk factors include daycare attendance, psychological stress, and heavy physical training. Transmission routes include direct contact with viral particles, as well as small-particle and large-particle aerosols. The routes of transmission depend on the specific virus.11

SINUSITIS

A cute and chronic rhinosinusitis are discussed in Chapters 46, “A cute Rhinosinusitis and Its Complications” and 47, “Chronic Rhinosinusitis and Polyps.” It is believed that most acute episodes of sinusitis are caused by viral infections, which lead to mucosal edema and potential obstruction of the paranasal sinuses. These viruses are the same as those that cause the common cold, as outlined above. When the mucosal edema occurs, this provides a favorable environment for the overgrowth of bacteria in the paranasal sinuses leading to acute bacterial sinusitis.14 There exists a progression of infectious agents from acute sinusitis to chronic sinusitis. The aerobic bacteria commonly associated with acute sinusitis are the same as those associated with otitis media, S. pneumoniae, H. influenzae, and M. catarrhals (Table 3). As the acute infection continues, the bacteria consume the available oxygen, thus decreasing the oxygen tension in the sinuses and increasing the acidity, making the environment more hospitable for anaerobic bacteria. The common anaerobic bacteria associated with chronic sinusitis include Fusobacterium nucleatum, Prevotella, Porphyromonas, and Peptostreptococcus species. In addition to the anaerobic bacteria, gram-negative bacteria have been associated with chronic sinusitis.14 These include Pseudomonas aeruginosa, Klebsiella pneumoniae, Proteus mirabilis, Escherichia coli, and Enterobacter species.

The role of fungus in rhinosinusitis is poorly understood. The three major groups of potential pathogens are Zygomycetes, Aspergillus species, and dematiaeous fungi. It has been shown that if looked for carefully enough, fungus can be isolated from almost everyone regardless of sinus disease.15 What is not well understood is why certain individuals may react to the presence of fungi, while others do not. It is also unclear what the precise mechanism is that underlies the pathophysiology of the reaction to the fungi. One theory holds that when individuals are exposed to the fungus, the antigenic trigger, there are type I and III immune reactions and stimulation of an intense eosinophilic response. This response leads to mucosal edema, which then provides an environment that perpetuates the fungal growth. The increased fungal load leads to increased antigen exposure, thus creating a continuous cycle. Other hypotheses include a nonallergic response to the presence of fungus, due to direct fungal stimulation of peripheral monocytes, which results in specific cytokine secretion that promotes eosinophilic response.15 Further investigation will be required to understand this complex interaction fully.

RHINITIS

Bacterial

Rhinoscleroma is caused by the gram-negative, encapsulated bacterium K. rhinoscleromatis. Infection universally involves the nose, and initial infections are believed to occur at mucosal junctions, such as that found in the nasal vestibule. Disease can also involve the nasopharynx, larynx, and trachea.16

Infections are characterized by three distinct and successive phases. Patients typically show rather slow progression through each of the phases. The
initial phase, the catarrhal or rhinitic phase, is characterized by symptoms consistent with the common cold. This includes a “honeycomb” colored discharge with a fetid odor. The second phase is the granulomatous phase, characterized by large, friable, granulomatous masses in the nasal cavity. These granulomas can cause epistaxis, nasal obstruction, and even bony remodeling of the turbinates and the medial maxillary wall. The final phase is the fibrotic or sclerotic phase, during which the cicatrization of the lesions leads to the anatomic distortion of the involved structures with nasal obstruction.

The disease is endemic in areas of Central and South America, Central Europe, East Africa, and the Indian subcontinent and is associated with poor hygiene and overcrowded conditions. An increase in the incidence in the United States is most likely the result of immigration from endemic areas. When histiocytes, or M. ikuliczii cells, are stained with Warthin-Starry or Gram, they can show the gram-negative bacillus within the cytoplasm, thus suggesting the diagnosis. Cultures positive for K. rhinoscleromatis are diagnostic; however, they are only positive in 50 to 60% of cases. Computed tomography characteristically shows homogeneous, nonenhancing nasal masses with well-defined borders. Bone and cartilage involvement may be seen in advanced cases.

Treatment involves long courses of antibiotics for at least 3 months. There is a high relapse rate, requiring multiple antibiotic courses. Tetracycline has been used traditionally; however, given the contraindications in children, other antibiotics including cephalexin, chloramphenicol, chlorotetracycline, rifampin, and trimethoprim-sulfamethoxazole have all been used.

Acinomyces is caused by a gram-positive, anaerobic, or microaerophilic bacterium of the genus Actinomyces. A. israelii is the most common species associated with human disease. Other species include A. naeslundii, A. viscosus, and A. odontolyticus. The bacterium is part of the normal flora of the oral cavity, as well as the respiratory and the digestive tracts. It grows as a hyphae or a filamentous organism, with the initial infection producing microcolonies composed of branching filaments. These develop into tight clusters commonly referred to as sulfur granules.

Acinomyces has been identified throughout the head and neck, including the oral cavity, pharynx, dental plaques, tonsillar crypts, skin of the face, mastoid bone, skull, nasopharynx and paranasal sinuses, and the temporomandibular joint. The clinical course of disease can vary widely, with a typical presentation involving a slowly, progressively enlarging mass in the neck or at the angle of the jaw. Up to 40% of patients have sinuses or fistulas. Involvement in the nasal cavity is relatively rare; however, it has been reported as a slowly enlarging nasal mass.

Diagnosis is based upon clinical examination, culture results, and microscopic analysis of tissue samples including Gram stain, acid-fast staining, and histology, although cultures are difficult to obtain, with only 10 to 20% being positive. The bacterium will be acid-fast negative, and Gram staining demonstrates gram-positive, branching, thin, filamentous-like organisms with the characteristic sulfur granules.

Treatment is both medical and surgical with aggressive surgical debridement followed by a long course of antibiotic therapy to eradicate the infection. Penicillin therapy for up to 12 months is considered first line. Alternatives include doxycycline, ceftriaxone, erythromycin, and chloramphenicol. If the infection recurs, longer courses of antibiotic therapy are required. Some advocate the use of adjunctive hyperbaric oxygen therapy.

Syphilis is caused by the spirochete Treponema pallidum. Involvement of the nose and paranasal sinuses varies, depending on the phase of the infection. Primary syphilis occurs up to 90 days after the initial infection and is characterized by the presence of a painless chancre at the site of initial inoculation. Primary syphilis is rarely associated with the nasal cavity, although it can involve the mucocutaneous junction of the nasal vestibule. Secondary syphilis involves the hematogenous spread of the spirochete, coinciding with regression of the primary chancre. Nasal symptoms of secondary syphilis include irritation of the anterior nares and acute rhinitis with a scant, thick discharge. Mucosal surfaces of the upper aerodigestive tract may develop painless ulcers that are similar in appearance to aphthous ulcers. The disease then enters a latent phase, with approximately one-third of patients maintaining the latent infection, one-third spontaneously clearing the infection, and the final third developing tertiary syphilis. Tertiary syphilis may be manifested by benign, destructive lesions, called gummata, believed to be the result of a robust inflammatory response to spirochetes. These gummata often involve the nasal septum, causing destruction of the cartilage and ultimately a saddle-nose deformity. The gummata have been reported to cause stenosis of the nasopharynx from scarring. Congenital syphilis may be symptomatic in 10 to 75% of infected infants. They most commonly present with watery nasal discharge, which progresses to a thick and purulent, and ultimately bloody discharge. Nasal obstruction leading to feeding difficulties may occur, as well as erosion of the septal cartilage.

There are two types of serologic tests for T. pallidum, the first is the nontreponemal tests. These include the veneral disease research laboratory test slide, the unheated serum reagin, the rapid plasma reagin (RPR) test and the toluidine red untreated serum test. They measure the antibody response to cellular antigens that are released as a result of treponemal infection and are not specific for T. pallidum. They are useful for following the progression of the disease. The RPR is approximately 80% sensitive in primary syphilis, and an RPR titer above 1:32 establishes the diagnosis in secondary syphilis. The second type is the treponemal tests, which detect the antibody response to T. pallidum. These include the fluorescent treponemal antibody absorption and the microhemagglutination-T. pallidum tests. These tests are qualitative not quantitative, remaining positive for life, and are not used to follow disease progression.

Microscopic identification of T. pallidum spirochetes using dark field examination confirms the diagnosis in all phases; however, the spirochetes are abundant only in primary, secondary, and congenital syphilis. Due to maternal antibodies, identification of spirochetes in nasal secretions is the only way to confirm the diagnosis of congenital syphilis. Histological examination of a primary syphilitic chancre reveals central necrotic debris with chronic inflammation at the distal zones. Secondary syphilis demonstrates plasma cells and lymphocytic infiltration of the epithelial lesions.

Penicillin is the treatment of choice for syphilis, based on current Centers for Disease Control and Prevention guidelines. Initial therapy can result in myalgias, fevers, headaches, and other constitutional symptoms; anti-pyretics may help minimize these side effects.

Nasal tuberculosis, caused by the acid- and alcohol-fast bacilli M. cybacterium tuberculosis, is rare. It is speculated to be the result of either inhalation of infectious particles or direct inoculation from a contaminated finger. A typical mycobacterial infections involving the nose or paranasal sinuses are exceedingly rare, although reports of M. kansasii causing a granulomatous infection and perforation of the nasal septum exist.

Nasal tuberculosis infections present with nasal obstruction, anterior and posterior nasal discharge, nasal discomfort, epistaxis, crusting, epiphora, recurrent nasal polyps, and ulceration. The most commonly involved sites are the cartilaginous septum, turbinates, and nasal floor. On anterior rhinoscopy, the mass appears as a bright red, friable mass or as a nodular thickening of the mucosa and may have shallow ulcers. The mass can cause nasal obstruction by mechanical obstruction and/or from crusting around the mass. As the disease progresses, scarring may cause distortion of the nasal tip and vestibule.

The diagnosis is confirmed by microscopic identification of acid-fast bacilli with Ziehl-Neelsen or auramine-rhodamine fluorescent staining. Histology demonstrates both caseating and noncaseating granulomas, with a greater number of epithelioid cells and Langhans giant cells than is seen in other granulomas. Tests, such as PCR, DNA probes, and high-performance liquid chromatography, may become more widely useful in the future.

Nasal tuberculosis treatment follows the same guidelines established for extrapulmonary tuberculosis including rifampin, ethambutol, isoniazid, pyrazinamide, and streptomycin. Therapeutic courses are approximately 6 months, with an initial 2-month course of four antibiotic drugs, followed by 4 months of a two-drug antibiotic course. In addition, nasal flushes have been advocated to clean away crusts and discharge.

Leprosy is caused by M. leprae, an obligate intracellular, acid-fast bacillus that leads to a
chronic granulomatous condition. M. leprae is highly infective, but demonstrates low pathogenicity, low virulence, and has an incubation time that ranges from 3 to 10 years. The most common route of spread is believed to be from nasal discharge. Lepromatous leprosy involves the nasal mucosa in approximately 95% of cases. The earliest signs of the disease include a pale nodular or plaque-like thickening of the mucosa of the anterior end of the inferior turbinate and the anterior part of the nasal septum. This progresses to mechanical obstruction from the tissue mass, ulceration of the mucosa, neural involvement leading to a decrease in sensation, and cartilage involvement leading to septal perforation and saddle nose deformity.

Diagnosis is made by biopsy, which demonstrates scattered neutrophils and a dense infiltrate of lipid-laden histiocytes with intracellular bacilli grouped in clumps as seen on modified acid-fast stains. Treatment involves a multidrug regimen of rifampin, dapson, and clofazamine for 6 to 24 months.

Viral

Viral causes of rhinitis are the same as those that are associated with the common cold. Those include, in order of frequency, rhinoviruses, coronaviruses, and influenza viruses. Other viral causes include the adenoviruses, respiratory syncytial viruses, and parainfluenza viruses.

Fungal

North American blastomycosis is caused by the fungus Blastomyces dermatitidis. Nasal and paranasal sinus involvement is rare, with most cases involving the cutaneous nasal vestibule. There have been relatively few cases of paranasal sinus involvement or cases of blastomycosis as a noncutaneous intranasal mass. The histological appearance shows pseudoepitheliomatous hyperplasia, acanthosis, microabscesses, or giant cells. The use of specific stains, such as periodic acid-Schiff, Comori silver methenamine, or mucicarmine, identify spherical, thick-walled, broad-based yeast. Cultures confirm the diagnosis but require Sabouraud agarose as a growth medium, and may take up to 4 weeks for sufficient growth for positive identification.

Treatment of blastomycosis involves surgical drainage of any abscess if present, followed by systemic antifungals. Amphotericin B therapy is well-established. Although it requires long-term intravenous access and has an extensive side effect profile, it remains the treatment of choice in immunocompromised patients, or in complicated cases. Itraconazole has a lower side effect profile and a high therapeutic efficacy and is the preferred therapy for a 3 to 6 months course.

Coccidioidomycosis is caused by disseminated infections of Coccidioides immitis. Diagnosis is made through serological testing, microbiologic cultures, and tissue staining revealing the fungal agent. Tissue specimens demonstrate double-walled spherules of C. immitis filled with endospores. Fungal cultures can confirm the diagnosis. Treatment includes amphotericin B for severe pulmonary or rapidly progressing disease. Itraconazole and fluconazole are used for most other forms given their lower side effect profile, and good efficacy against C. immitis. Surgery is reserved for cases that require tissue diagnosis, or debridement.

Diagnosis of mucormycosis is made by the septate hyphae on histology and is confirmed by fungal culture. Mucormycosis is most commonly seen in poorly controlled diabetics, as well as individuals with a compromised immune system.

Fungal spores are inhaled by the human host; when the host is unable to phagocytize the spores, germination and hyphae formation occur, leading to invasion of the mucosal tissues. Most patients present with fever, nasal ulcerations with black necrotic tissue in the nose, periorbital or facial edema, visual changes, headache, and facial pain. Computed tomography of the sinuses can demonstrate mucoperiosteal edema with bony destruction. Magnetic resonance imaging is useful to identify intracranial or intraorbital extension.

Diagnosis of mucormycosis is made by the clinical examination and, the presence of nonseptate hyphae on histology and is confirmed by fungal culture. Treatment has included amphotericin B and extensive surgical debridement using frozen-section guidance, allowing for a more thorough debridement of the infected tissues. Hyperbaric oxygen therapy has been used for the beneficial effects of the increased oxygen tension on the host phagocytic cells, the direct fungicidal effects of the hyperbaric oxygen, and the decrease of the local acidosis, which decreases fungal growth.

A. fumigatus and A. flavus cause both the noninvasive form as well as the invasive form of aspergillosis. The noninvasive infections, which do not involve destruction of the surrounding tissues, include allergic fungal sinusitis and aspergillosa. Invasive infections are most commonly found in immunocompromised patients and are characterized by destruction of the sinus mucosa and bony expansion.

Most patients with invasive aspergillosis present with progressive nasal pain or headaches. Computed tomography initially shows a focal soft tissue lesion and may show subtle, focal bony destruction, with focal hypodense areas appearing, which correspond to abscess formation. Diagnosis is based on microscopic analysis and fungal culture from tissue biopsy. On microscopy, Aspergillus characteristically shows haematoxyphilic organisms with 45° branching septate hyphae and can also be demonstrated with methenamine silver and periodic acid Schiff stains. Aspergillus cultures will show growth in 2 to 6 days. It is recommended, that if the initial biopsy is negative, and aspergillosis is suspected, a second biopsy be taken, especially before starting corticosteroids. Treatment involves surgical debridement and amphotericin B, for initial disease control, followed by an oral ketoconazole or itraconazole to ensure eradication. Prolonged treatment is recommended, especially if the patient continues to be immunosuppressed.

Parasitic

Leishmaniasis is caused by the parasites of the Leishmania genus, following a bite from an infected sand fly. Leishmaniasis is seen throughout the world. L. braziliensis or L. panamensis cause the mucocutaneous form of the disease, up to 10 years after the appearance of cutaneous lesions. The mucocutaneous form begins in the nasal septal mucosa, which can become inflamed, ulcerated, and ultimately perforated. The mucosal lesions can spread to involve the oral mucous membranes as well. Malnutrition and pneumonia are the leading causes of death in patients with the mucocutaneous variant of the disease.

The diagnosis of leishmaniasis is mostly clinical; however, histology and culture remain the gold standards. Biopsies show a predominant mononuclear infiltrate consisting of lymphocytes and histiocytes, as well as an abundance of plasma cells, especially in the mucocutaneous form. The histiocytes may be filled with small, oval, encapsulated protozoa with large peripheral nuclei and small, rod-shaped kinetoplast, known as Leishman-Donovan bodies. Biopsies can be cultured on blood agar, with promastigote growth apparent within 2 days to 2 weeks.

Unlike the cutaneous form of the disease, the mucocutaneous lesions will not heal spontaneously and require medical treatment. Amphotericin B has only limited efficacy against the mucocutaneous form of the disease. Antimonials such as sodium stibogluconate and meglumine antimoniate, which seem to inhibit amastigote glycolytic activity and fatty acid oxidation, are the drugs of choice. Both medications must be given parenterally. Currently, there are no effective, oral medications for leishmaniasis.

Infestation of the skin or mucous membranes by developing fly larvae is referred to as myiasis. Most cases of cutaneous myiasis are caused by the human botfly, Dermatobia hominis, whereas the majority of nasal myiasis have been reportedly caused by the green blowfly, Phaenicia sericata. Cutaneous myiasis occurs when the fly eggs are deposited on the mammalian host skin,
allowing for the hatched larvae to descend into the skin to mature. A pruritic papule develops and matures into a boil-like lesion that can become painful, crusted, and purulent. A characteristic feature of the papule is the opening at the top of the boil, allowing oxygen passage. The larvae secure themselves in place with large spines on their torsos and can remain in place for 2 to 3 months. When mature, they leave the skin, drop to the ground, and pupate.29 This can cause extensive necrosis and destruction of tissue, which may be very disfiguring if involving the nose, face, or orbit.28 Myiasis can usually be distinguished from leishmaniasis by the complaints of pain at the site of the wound, a “crawling” sensation, and the ability to visualize the larvae within the lesion.29,31

Nasal myiasis differs in that it involves the flies depositing their larvae in the nasal discharge of patients and does not cause mucosal damage. Treatment involves only nasal lavage and eliminating the fly vector.29 Most cases of myiasis are self-limiting; however, certain types of larvae are able to invade paraanasal sinuses, orbital structures, and even into the cranial vault and brain tissue, thus prompt treatment is indicated.29 Larvae should not be forcibly removed from the wound due to the spines on the body of the larvae. If parts of the larvae remain, a foreign body reaction may occur. Surgical debridement with wide local excision of the larvae is recommended, allowing the wound to granulate. Antiseptic dressings are recommended after removal, with an oral antibiotic to help prevent a secondary infection. Occlusion of the central punctum to cause suffocation and spontaneous emergence of the larvae has been described. Vaccination for Clostridium tetani should be considered with infestation.29

**STomatitis**

**Bacterial**

Stomatitis can result from a wide assortment of bacteria, viruses, fungi, and parasitic infections (Table 4). Most are directly or indirectly the result of poor oral hygiene, either through personal practices or environmental circumstances. A cute necrotizing ulcerative gingivitis is an acute infection of the gingiva that causes gingival bleeding, gingival ulceration, and pain. It has been given many names including necrotizing gingivostomatitis, necrotizing ulcerative gingivitis, trench mouth, and Vincent infection. Vincent angina is an extension of acute necrotizing ulcerative gingivitis, or Vincent infection to involve the tonsils and pharynx. Gangrenous stomatitis, also known as noma and cancrum oris, is an extension of acute necrotizing ulcerative gingivitis, once it involves the surrounding tissues. The infection has been reportedly caused by a mixture of bacteria, including spirochetes (Treponema species), fusobacteria (F. nucleatum), P. intermedia, Veillonella species, and streptococci. It is found most often in underdeveloped countries in Africa, Asia, and South America and has been associated with stress, smoking, and malnutrition, in addition to poor oral hygiene. Patients can develop severe, deep aching pain, along with rapid bone loss from the periodontitis. Treatment depends on antibiotics along with thorough debridement of involved soft tissues. A antibiotic alone will not cure the infection.32

A c tinomycosis is caused by bacteria in the genus Actinomyces, which are normal flora of the oropharyngeal cavity. They are characterized as slow-growing, firm, nontender lesions that may develop multiple abscesses and form sinus tracts. Diagnosis is made by culture of the bacteria and indirect immunofluorescence microscopy. Treatment has been previously discussed.

B acillary angiomatosis results from a bacterium Treponella quintana or henselae infection and can occur in the oral cavities of severely immunocompromised individuals. It poses a diagnostic dilemma due to its gross appearance similar to Kaposi sarcoma, which is also seen in the immunocompromised.32 The lesions are described as bluish or purple macules, pale bluish patches, and erythematous lesions on the gingival, palate, and buccal mucosa. Histologically, they appear as a lobular proliferation of small, round blood vessels with plump endothelial cells protruding into the vascular lumen. Warthin-Starry stains reveal the bacteria.32 Treatment includes antibiotic therapy with a macrolide or doxycycline.32

N eisseria gonorrhoeae is a nonmotile, aero- bacillus. It is found most often in underdeveloped countries in Africa, Asia, and South America and has been associated with stress, smoking, and malnutrition, as well as blood sucking arthropods and insects. It has been reported to occur in the oral cavities of humans following direct contact with infected animals such as dogs, cats, or poultry. Treatment is typically with amoxicillin or a combination of amoxicillin and clavulanic acid.34

The oral and tonsillar manifestations include tonsils that are edematous and erythematous with a grayish exudate. Oral mucosal lesions may be ulcerated, painful, and may be diffusely erythematous and edematous. Diagnosis is by culture and identification, and current treatment guidelines include a third generation cephalosporin.32,33

Oral manifestations of tuberculosis are rare, occurring in less than 1% of all pulmonary cases of tuberculosis. Caused by M. tuberculosis, they present as a chronic, painless, irregular ulcer, with a vegetating surface, and a gray or yellow exudate. Primary oral lesions have been reported in the past, as transmission by infected dentists to patients, prior to the implementation of universal precautions.32 Diagnosis is based on a delayed type reaction to a purified protein derivative skin test or a positive culture demonstrating acid-fast mycobacteria.

Leprosy, caused by M. leprae, may demonstrate oral lesions, depending on the stage of leprosy. The four stages of leprosy are, in increasing severity, indeterminate, tuberculoïd, borderline, and lepromatous. Oral lesions are seen in up to 60% of patients with lepromatous leprosy.32 The lesions start as nodules or lepromas that are filled with M. leprae, and progress to necrosis and ulceration. These ulcers may heal, forming scar tissue, or progress to further tissue destruction. These lesions are seen through the oral cavity. Diagnosis is based on the identification of acid-fast bacilli in smears of the oral lesions. Current treatment guidelines are based on the stage. Intermediate and tuberculoid are treated with dapson and rifampin for approximately 6 months. Patients with the lepromatous and borderline stages are treated with dapson, clofazimine, and rifampin.19

Syphilis may also manifest itself with oral lesions. The primary infection, caused by the spirochete T. pallidum, causes asymptomatic chancres, most commonly on the hard palate, although the soft palate, lips, and tongue may also be involved.33 These chancres are often ulcerated centrally, with a raised indurated border. These usually heal spontaneously within weeks. These are followed by secondary syphilis, which is characterized by generalized symptoms such as fever, malaise, and headache, as well as oral lesions described as a grayish-white, glistening patch on the mucosa of the soft palate, buccal area, or tongue. If left untreated, 30 to 40% of patients will develop tertiary syphilis with oral manifestations of a localized granuloma, or gumma, on the hard palate, soft palate, lips, or tongue.32 Diagnosis and treatment have been discussed above.

Tularemia is caused by Francisella tularensis, a noncapsulated, gram-negative coccobacillus. It can be found in various mammals, as well as blood sucking arthropods and insects. It has been reported to occur in the oral cavities of humans following direct contact with infected animals or animal tissue, ingestion of contaminated water, or inhalation of dust contaminated with infected arthropod feces. There are two...
different biotypes, with varying clinical severities. The F. tularensis biovar tularensis (Jellison type A) is a more serious infection and is more dominant in North America. The F. tularensis biovar palaeaerctica (Jellison Type B) causes milder symptoms and is found in Europe, Asia, and North America. They cannot be differentiated by serological reactions, however the biovar tularensis is able to ferment glycerol, whereas the palaeaerctica is not.33

The incubation period for the disease ranges from 2 to 6 days, with the onset of generalized symptoms including fever, headache, sore throat, malaise, myalgias, cough, and cutaneous lesions. Imaging features are nonspecific, with enlarged lymph nodes, and lymph nodes with central necrosis. The microorganism is poorly grown on culture media, and the diagnosis is largely based on serological tests. These include seroagglutination and microagglutination. Patients will usually develop an antibody titer within 2 weeks of the onset of the disease.33 The bacteria are resistant to beta-lactam antibiotics, however they respond well to aminoglycosides, macrolides, and fluoroquinolones.34

Stomatitis may also be the result of a streptococcal infection. S. viridans, as well as beta-hemolytic streptococci have been implicated. The infection can lead to an acutely inflamed, edematous, and erythematous mucosa and gingiva, with pain, fever, and malaise. It is often preceded by tonsillitis, and the patient is treated with first line penicillins.32

Viral

Viral infections of the oral cavity are numerous, and there exists overlap in the viruses responsible for the common cold, pharyngitis, and stomatitis. The first family of viruses that can cause oral manifestations is the Paramyxoviridae, to which the genus Morbillivirus, the cause of measles (rubella), belongs. Although vaccinations have greatly reduced the incidence of measles, they remain a cause of childhood mortality in developing countries. They are highly infectious, transmitted through aerosolized droplets, and have an incubation period of approximately 2 weeks. The oral manifestation is known as Koplik spots, which are bluish-gray specks on an erythematous base near the molar teeth. These are pathognomonic for measles and appear up to 48 hours before cutaneous lesions. Diagnosis can be confirmed with measles-specific immunoglobulin M identified in oral secretions.32 Treatment is supportive.

There have been important investigations over the years of regarding the roles that the measles virus, as well as another member of the Paramyxoviridae family, the mumps virus, play in sensorineural hearing loss. A serious complication of the measles virus infection, measles encephalitis, occurs in approximately 1 in 1,000 cases. These patients have a mortality rate of approximately 25%, and half of those who survive will have permanent neurological sequelae including deafness.34 In addition, it is been shown that the virus can cause destruction or degeneration of the organ of Corti, the stria, and the cochlear neurons.34 The measles virus has further been linked to otosclerosis, with viral RNA being identified in the foot plates of otosclerosis patients.35 It was estimated that the measles virus was responsible for 5 to 10% of all profound bilateral sensorineural hearing loss before the widespread use of the vaccine.34 Since the vaccination was instituted, the number of cases in the United States has decreased 99%.34 Although the exact reduction in sensorineural hearing loss associated with measles is not yet known, the importance of worldwide vaccinations has been stressed.

The mumps virus has also been linked to sensorineural hearing loss, either through a direct viral invasion of the cochlea and/or the eighth cranial nerve, or an autoimmune reaction against inner ear structures.35 The deafness associated with the mumps virus can often be unilateral, which may go undetected for some time, thus making a correlation to the infection more difficult. It is because of this, and the fact that individuals can still get clinical and subclinical mumps virus infections, that the reduction in hearing loss due to the vaccine is not clearly established.34 The vaccine is believed to have played an important role, and is strongly encouraged.

The rubella (German measles) virus, a member of the Rubivirus genus of the Togaviridae family, can lead to sensorineural hearing loss through infection during pregnancy, leading to the congenital rubella syndrome of which deafness is a major component. Vaccination for rubella where used has virtually eliminated the problem. The measles, mumps, and rubella live virus vaccine is recommended for individuals 12 to 15 months of age or older with revaccination at 4 to 6 years of age.

The family of viruses called Picornaviridae are small RNA viruses, and include the genus Enterovirus. Coxackievirus A and B are included in the genus Enterovirus. Coxackieviruses are responsible for various ulcerative lesions differentiated based on gross appearance and location. Hand, foot, and mouth disease is caused by coxackievirus A5, A10, and A16, and is manifested by ulceration on the buccal mucosa and soft palate, as well as the hands and feet. These are described as rhomboidal vesicles, or square blisters. Although the disease is benign and self-limited, acyclovir has been reported to be effective in the treatment.32

Herpangina is also caused by the coxsackieviruses and leads to clustered petechiae in the soft palate that become shallow ulcers that heal relatively quickly. Patients also experience high fevers, myalgia, and sore throat. Treatment is palliative. Coxsackieviruses are responsible for lymphomonal pharyngitis, which causes orange painful papules on the soft palate, and ulcerative pharyngitis, causing ulcerations on the palate, lips, and tongue.32 The human papillomavirus (HPV) belongs to the genus Papillomavirus, which is a member of the family of DNA viruses Papovaviridae. There are many identified types of the HPV, several of the types have been associated with intraoral lesions. Squamous cell papillomatosis appears as a small, pink, exophytic, cauliflower-like lesion with a narrow base on the oral mucosa. Condyloma acuminatum is similar, with multiple lesions on the mucosa. Both are associated with HPV types 6 and 11.32 These lesions are managed with surgical excision. Verruca vulgaris is associated with HPV types 2 and 57 and can be seen on the gingiva, labial mucosa, oral commissure, hard palate, or tongue. These lesions are firm, sessile, exophytic growths with wide bases. These too are treated surgically. Focal epithelial hyperplasia presents as multiple, plaque-like or papular lesions, of the mucosa, usually in children. They are red to gray to white in color and are found on the oral mucosa exclusively. Other oral lesions have been associated with HPV, including erythromeloblastosis, proliferative verrucous leukoplakia, candidal leukoplakia, squamous cell carcinoma, and lichen planus.32

Herpes simplex viruses are associated with intraoral lesions as well. They belong to the family Herperviridae and the genus Herpesvirus. The intraoral lesions can present as a cluster of small, painful ulcers on the gingiva. They are initially discrete lesions but may coalesce to form a larger lesion. They are self-limiting and usually heal in less than 2 weeks. A cycloprin may speed the healing and prevent further outbreaks.32

Fungal

Fungal infections of the oral cavity are common among the immunocompromised, however, can occur in the immunocompetent as well. The most common oral fungal infection is oral candidiasis, caused by the genus Candida. Although there are more than 100 species of Candida, C. albicans is the most common cause of stomatitis.38 The differentiating feature of C. albicans is the pseudohypha formation found in most of the species. Different types of oral candidiasis exist, the two most common forms are erythematous candidiasis and pseudomembranous candidiasis. The erythematous candidiasis presents as red, macular areas most commonly found on the palate. These can be acute or chronic. Histopathologic analysis reveals epithelial atrophy with loss of rete ridges, connective tissue papillae with epithelial cover of only a few cell layers, an inflammatory infiltrate of lymphocytes in the submucosa with hyperemia, and little or no penetration of hyphae into the epithelium. This responds well to topical antifungals such as nystatin. Pseudomembranous candidiasis is also referred to as thrush and is the most commonly identified form of the disease. The clinical appearance, which is usually diagnostic, includes white or whitish-yellow, curd-like patches that leave a red, bleeding surface when wiped or scraped off. Diagnosis can be confirmed by a wet-preparation of a smear using potassium hydroxide, demonstrating hyphae and mycelia. Histopathologic analysis shows a superficial infection with intraepithelial pseudomycelia which do not penetrate the spinous layer, thickened parakeratin, lymphocytes in the
subepithelial region with fewer lymphocytes than in the erythematous form. Treatment consists of topical antifungals.38

Other forms of oral candidiasis include the hyperplastic, nodular or leukoplaikia, and the plaque-like forms. These are chronic infections that cannot be rubbed off. They can appear translucent to opaque or whitish and are found on the buccal mucosa, the angles of the mouth, and the dorsal of the tongue. Diagnosis is usually clinical. The hyperplastic form can have candidal hyphae invading the parakeratotic layer but not extending into the spinous layer.38

Aspergillosis is a fungal infection caused by the members of the class Ascomycetes, genus Aspergillus. Several species can cause infections including A. fumigatus, the most common, A. niger, A. glaucus, A. terrus, and A. flavus, which seems to be the most virulent. It can present in three different forms, the saprophytic form without invasion, the allergic, and the invasive form which demonstrates extension into viable tissues. The disease is contracted through inhalation of the spores, which tend to germinate in mucus. The invasive form is found almost entirely in immunocompromised individuals. Lesions have been described as yellow to gray to black, necrotic ulcers. Diagnosis and treatment have been discussed under the Section on Rhinitis.

Histoplasmosis is caused by the soil saprophyte Histoplasma capsulatum, which exists in a mycelial form in the environment and a yeast form at body temperature. It is endemic to the Ohio and Mississippi river valleys, as well as Central and South America, Africa, India, East Asia, and Australia. It is the most commonly diagnosed systemic mycosis in the United States. Oral lesions have been reported in up to 60% of patients with disseminated disease and occur throughout the oral cavity. The lesions are nontender, dusky, erythematous granulomas that can appear flat and plaque-like and may ulcerate and be painful. Therapy includes itraconazole for several months. Patients with severe infections or who are immunocompromised are treated with amphotericin B and itraconazole.15

North American blastomycosis is caused by the fungus B. dermatitidis, which is found endemically in the soils of northern Ontario as well as the watershed areas of the Mississippi and Ohio Rivers. It is a thermally dimorphic fungus that exists as a mycelial or mold form in the soil where it produces spores. These spores are inhaled by the host, where it transforms to the yeast form, stimulating a very aggressive inflammatory reaction. South American blastomycosis is caused by Paracoccidioides brasiliensis. It is rarely seen outside of the endemic area in South America, and has been reported to present orally as painful, chronic, irregular ulcers with a granulomatous or vegetating surface. They can occur on the palate, tongue, lips, and gingiva.13,16 If not treated, most presentations of South American blastomycosis are nonspecific with cough, weight loss, fevers, and hemoptysis. Oral lesions are reported as single or multiple ulcerations. Sessile projections and granulomatous or verrucous lesions have been described.38

The epidemiologic profile of South American blastomycosis is largely based on sporadic cases but is believed to have an average age of onset from 30 to 50 years with a male predominance ranging from 2:1 to 15:1 over females. Diagnosis can be made histologically and confirmed with positive fungal cultures. Fine needle aspiration has been shown as a reliable diagnostic tool in the hands of a talented cytopathologist. Histological appearance shows pseudoepitheliomatous hyperplasia, acanthosis, microabscesses, or giant cells. The intense inflammatory reaction may make identification of the microorganisms difficult. The use of specific stains, such as periodic acid-Schiff, Gomori silver methenamine, or mucicarmine, helps to identify spherical, thick-walled, broad-based yeast. Cultures confirm this diagnosis but may take up to 4 weeks to become positive and require Sabouraud agarose as a growth medium.39,40

Treatment of blastomycosis involves surgical drainage if an abscess is present, followed by systemic antifungals. Amphotericin B has been the standard therapy, however requires long-term intravenous access and has an extensive side effect profile. Amphotericin B remains the treatment of choice in immunocompromised patients, or in complicated cases. K. lactis is an effective agent, but has been shown to have high liver toxicity and multiple drug interactions. Itraconazole has a lower side effect profile and a high therapeutic efficacy, and is the preferred therapy for a 3- to 6-month course.39,40

Mucormycosis, caused by members of the order Mucorales, can have oral lesions as well. The microorganisms have broad, nonseptate hyphae, ranging from 6 to 15 µm in width and 100 to 200 µm in length, and the diagnosis can be confirmed by identification of the hyphae histopathologically or by culture on Sabouraud glucose agar. The oral lesions have been described as palatal ulcerations or black, necrotic masses. The palate is the most common site for the original infection. Without proper treatment, the infection can extend, as outlined in the Section on Rhinitis.

Cryptococcosis is an infection that is caused by two forms of the fungus Cryptococcus neoformans. The first type is the neoformans variety and is associated with avian sources and causes the majority of human infections. The second type, the gattii variety, is associated with eucalyptus trees. The majority of infections are pulmonary; however, disseminated disease can be associated with oral cavity lesions. These lesions are described as red, ulcerated areas that have been reported to occur on the palate and tongue. The diagnosis is based on tissue biopsy with identification of the microorganism using Grocott and mucicarmine stains. Therapy includes fluconazole or itraconazole. More severe infections require amphotericin B with or without flucytosine.19

Coccidiodomycosis, caused by C. immittis, is a fungal infection endemic to arid regions of the southwestern United States, and Latin America. Oral lesions have been reported, described as verrucous and necrotic ulcers. Diagnosis is confirmed by histology showing spherules containing endospores, serology, and cultures. Systemic antifungals are used for treatment. The filamentous fungi fusarium species are responsible for fusariosis. This infection can be a local, invasive, or disseminated form. The disseminated form can cause a secondary oral infection. These lesions, found in immunocompromised individuals, are described as black, necrotic ulcers occurring on the palate. The diagnosis is based on histology and culture. The histologic appearance of the microorganism is similar to that of Aspergillus; however, the cultured microorganisms, when grown on medium not containing cyclohexamide, demonstrate distinguishing fusoid macroconidia or microconidia. Superficial infections respond well to local therapy.35

The microorganism Geotrichum candidum has been associated with oral geotrichosis in immunocompromised patients. Clinically, the lesions are a sharply defined, with ulceration. Histologically, the tissue will demonstrate hyphae that segment into rectangular arthrospores with spherical blastospores budding from the hyphae. The fungus will grow flat, white or creamy colonies on Sabouraud glucose agar. Lesions have reportedly responded to 5-fluorocytosine and itraconazole.38

Trichosporonosis, caused by fungi of the genus Trichosporon, and sporotrichosis, caused by Sporothrix schenckii have each been reported to involve the oral cavity. However, the number of cases that have been reported are extremely small.38

Parasites

Parasitic infections of the oral cavity are not common, however must be considered when dealing with patients in developing countries. It is also important to be familiar with these types of infections when treating immigrants from developing countries or world travelers recently returned from endemic areas.

Parasitic tapeworms are commonly found in the intestinal lumen of vertebrate hosts, however they have been known to involve the oral cavity. These parasites belong to the phylum Platyhelminthes, class Cestoda. Teniasis and cysticercosis are two different diseases that can have oral manifestations and are caused by the tapeworms Taenia saginata and T. solium, which are found in beef and pork, respectively. Teniasis occurs when either of the above mentioned tapeworms infects the human small intestine following ingestion of infested and poorly cooked beef or pork. Oral manifestations of teniasis include erythematous, edematous, hyperplastic mucosa with bleeding gingiva and pain. Teniasis is diagnosed by the detection of the worms in the stool. Cysticercosis results from extra-intestinal manifestations of the tapeworm cysts. The human hosts ingest either the cysts or the worms themselves, and penetration of the gastric mucosa by the embryos occurs, giving access to the circulation. The embryos...
Oral or dental myiasis is larval infection of tissues of the oral cavity. Although rare, it continues to be a health concern in developing countries, particularly in Asia. It affects patients of both genders, and of all ages. Risk factors include oral wounds such as extraction sites, severe gingivitis or periodontitis, and a history of mouth breathing. The infection is presumed to occur while the patient is sleeping. Patients present with pain, swelling, bleeding, and an “itchy” feeling at the infection site. Intraoral examination usually reveals an orifice with the presence of active larvae. Treatment involves debridement of the larvae and copious irrigation, followed by treatment of the risk factors.

Leishmaniasis, as described above, is a protozoan parasite which belongs to the genus Leishmania. The sand fly vector can infect the human host and cause either a visceral, cutaneous, or a mucosal disease. Oral leishmaniasis can be a manifestation of both the visceral and the mucosal forms. The lesions of the uvula and palate can appear edematous, red in color, and fissured. Although very rare, oral leishmaniasis must be considered in the differential for oral infections in endemic areas, such as the Mediterranean basin. Diagnosis and treatment are as outlined above.

Other parasitic organisms such as echinococcosis, nematodes, trichinosis, gorgonyeloma, and ascariis have all been reported to have oral manifestations; however, there have been few case reports of each in the literature.

**PHARYNGITIS**

A cute pharyngitis is an extremely common inflammation of the pharynx and tonsils. The exact incidence is not known and is not impacted by the presence or absence of the palatine tonsils.

**Bacterial**

Several different types of bacteria are associated with pharyngitis (Table 5). The most important of these is the group A β-hemolytic Streptococcus (GABHS), the most common microorganism in this group is S. pyogenes. It is responsible for 15 to 30% of cases of pharyngitis in children, and 5 to 10% of cases in adults. It results from direct contact with a person infected. The incubation period is between 2 and 5 days. Antibiotic therapy is indicated for the supplicative complications including peritonsillar and retropharyngeal abscesses, cervical lymphadenitis, sinusitis, otitis media, and the nonsuppurative complications including rheumatic fever. A cute rheumatic fever has been reported to follow 0.5 to 3.0% of ineffectively treated GABHS cases, and occurs because of a rise in streptococcal antibodies. There is no evidence to suggest that treatment will prevent the development of acute glomerulonephritis, also known as poststreptococcal glomerulonephritis, often seen following streptococcal infections. The clinical presentation includes fever, though it may be low grade, sore throat, headache, erythematous pharynx with tonsillar hypertrophy and possibly exudates, submandibular lymphadenopathy, and palatine petechiae. Rhinitis and cough are characteristically absent. A scarlatiniform rash, described as an erythematous, fine, sandpaper-like exanthema is frequently seen. The rash often begins in the axilla and inguinal folds, then spreads. Diagnosis of GABHS pharyngitis is based on rapid antigen testing and throat cultures. The rapid antigen detection tests the presence of group A streptococcal carbohydrate on a throat swab. The results are available within minutes. The specificity is reportedly greater than 95%; however, the sensitivity varies from 80 to 97%. Given the variability of the sensitivity, it is recommended to perform rapid antigen testing in conjunction with throat cultures. Throat cultures grown on sheep-blood agar provide results within 24 to 48 hours. The throat culture is considered the gold standard, with a reported specificity of 99% and sensitivity of 97%. The sensitivity varies depending on the adequacy of specimen collection, which may be difficult in the case of small children. First line therapy for GABHS pharyngitis is penicillin or any β-lactam antibiotic. Alternatives include macrolides, although resistance to macrolides is reportedly increasing.

A additional bacterial causes of pharyngitis include the nongroup A β-hemolytic streptococci, Arcanobacter hemolyticum, N. gonorrhoeae, M. pneumoniae, Chlamydia pneumoniae, and Corynebacterium diphtheriae. Nongroup A β-hemolytic streptococci include groups C and G β-hemolytic streptococci and have many similar features to GABHS. They have been associated with epidemic outbreaks of pharyngitis. Although groups C and G are not associated with the rheumatic fever, they have been linked to glomerulonephritis following infections. The majority of C and G streptococci are sensitive to penicillins, cephalosporins, and erythromycin. A. hemolyticum is an uncommon cause of pharyngitis and is most commonly seen in adolescents and young adults. It can lead to lymphadenopathy, erythema of the pharyngeal seal, exudates and a scarlatiniform rash. It is difficult to culture, and erythromycin is the drug of choice. Pharyngitis caused by N. gonorrhoeae, though rare, should be considered in sexually active adolescents. The presentation ranges from asymptomatic sore throat, to ulcerative pharyngotonsillitis. Diagnosis is based on a positive culture. Gonococcus can be cultured on Thayer-Martin medium, and is treated with either ceftriaxone, or a combination of an oral quinolone and a macrolide or doxycycline. The latter two are given for possible chlamydial coinfections. Both M. pneumoniae and C. pneumoniae can cause pharyngitis, but the frequency is unknown. The diagnosis is largely clinical. Both microorganisms respond to tetracycline or erythromycin.

Diphtheria has become a rare cause of pharyngitis, although cases continue to be reported. Fatality rates for noncutaneous diphtheria have remained constant for the past five decades at 5 to 10%. Currently, it is a disease of the unimmunized or poorly immunized members of disadvantaged socioeconomic groups. Examination reveals a grayish-white membrane extending from the tonsils to the soft palate, and even to the nares, larynx, and tracheobronchial tree. This membrane in the tracheobronchial tree can cause life threatening obstruction. Removal of the membrane reveals bleeding, edematous tissue. Soft tissue edema and lymphadenopathy also occur. The toxin from the bacterium can cause cardiac and neural toxicity. Diagnosis is suspected on clinical examination, and confirmed by culture. Treatment involves equine hyperimmune diphtheria antitoxin and penicillin or erythromycin.

Kawasaki disease is most likely an infectious disease, however the agent is currently not known. Clinical manifestations of the disease include a sore throat, fever, bilateral nonpurulent conjunctivitis, anterior cervical node enlargement, erythematous oral mucosa, and an inflamed pharynx with a strawberry tongue. Additional findings include cracked lips, a generalized rash, edema and erythema of the palms and soles, followed by periangual desquamation, and peeling of the palms. Coronary artery damage resulting from Kawasaki disease is the leading cause of acquired heart disease in children in the developed world. Treatment includes supportive measures, high dose aspirin, corticosteroids, and high dose intravenous immunoglobulin.

of a low-grade fever, acute rhinitis, cough, and mild erythema of the pharynx. In this first group, cervical lymphadenopathy and sore throat may or may not be present. Viruses commonly associated with this presentation include rhinoviruses, coronaviruses, respiratory syncytial viruses, and parainfluenza viruses.41

A second clinical presentation pattern includes viruses such as the adenoviruses, influenza virus A or B, enteroviruses, Epstein-Barr virus, herpes simplex viruses type 1 and 2, and primary infection with the human immunodeficiency virus. The patients infected with one of these viruses present with more severe symptoms including fever, sore throat, malaise, pharyngitis, and cervical adenopathy. A denovirus is the most common cause of this second group, accounting for 15 to 23% of cases. The coxsackievirus A can cause a pharyngitis, which is referred to as herpangina. When ulcers are present on the soft palate, palms, and soles, the disease is called “hand, foot, and mouth disease.”41

Patients infected with the Epstein-Barr virus develop the constellation of symptoms known as infectious mononucleosis. This can also be seen, though much more rarely, with cytomegalovirus infection. Patients develop a viral tonsillitis and pharyngitis, with high fevers and lymphadenopathy. The pharynx becomes erythematous with a thick continuous exudate and palatal petechiae. This usually follows a prodrome of chills, sweats, fevers, and malaise.42 It is commonly seen in patients between 15 and 24 years of age. Up to 50% of cases can develop splenomegaly, and 10 to 15% develop hepatomegaly. Approximately 5% will have a rash of variable form, and approximately 90% will develop a pruritic maculopapular rash if given ampicillin or amoxicillin.42,44 Diagnosis of infectious mononucleosis can be confirmed by the monospot test, as well as by the presence of atypical lymphocytes on a white blood cell count differential. The monospot is approximately 90% will develop a pruritic maculopapular rash if given ampicillin or amoxicillin.42,44

Fungal
Fungal pharyngitis is caused by C. albicans and is often the result of medications that affect the normal oral flora such as antibiotics or corticosteroids. It is also seen in patients with immunosuppression. Examination reveals a diffusely erythematous and edematous pharynx. White plaques of various size are seen throughout the oral cavity and pharyngeal mucosa. Microscopic examination of smears can demonstrate pseudohyphae and fungal spores. Treatment is usually a topical antifungal such as nystatin oritraconazole for several days.19

**EPITROCHLEITIS/SUPRAGLOTTITIS**

Epitrochleitis, or more appropriately supraglottitis, is a rare disease affecting both children and adults. There are many pathogenic microorganisms that can cause supraglottitis, however the most famous is H. influenzae type b (Table 6). This is the microorganism that was most frequently associated with pediatric supraglottitis until the introduction of the H. influenzae type b vaccine.46 The vaccination program has dramatically decreased the pediatric incidence of supraglottitis, however, it has not impacted the incidence of adult supraglottitis; and the disease is now seen more in adults than children.46 The mortality rates associated with the disease have steadily declined since the 1970s for the pediatric population and are now less than 1%. This is largely due to aggressive treatment algorithms for children that present with supraglottitis. The mortality rate in the adult population has held steady for many decades around 6 to 7%, with reports up to 20%. This is believed to be in part related to delays in diagnosis.46 In both pediatrics and adults, there seems to be a male predominance, ranging from 1:9:1 to 4:1.46,47 The incidence of otitis media has not been influenced by the H. influenzae type b vaccine because it is caused by the nontypeable H. influenzae.

An extensive list of pathogens associated with supraglottitis include: H. influenzae type b, nontypeable H. influenzae, H. parainfluenzae, Staphylococcus aureus, β-hemolytic Streptococcus, groups A, B, and C Streptococcus, S. pneumoniae (pneumococcus), S. pyogenes, S. milleri, S. viridans, E. coli, Bacteroides melanogenicus, K. pneumoniae, N. meningitidis, P. aeruginosa, Kingella kingae, Vibrio vulnificus, Serrata marcescens, Pasteurella multocida, Citrobacter diversus, M. catarrhalis, Aspergillus, Mucormyces, C. albicans, Herpes simplex virus, varicella zoster virus, cytomegalovirus, parainfluenza virus, influenza virus type B, and M. tuberculosis.46 Although this is an exhaustive list, many cases of supraglottitis go without identification of the pathologic microorganism.46

Children and adults present similarly with a sore throat, fever, and respiratory distress. Many patients are unable to manage their secretions due to the severe dysphagia and odynophagia. Children will often assume the tripod position, sitting upright with their chins up, mouth open, and bracing themselves on their hands.48,49 The voice is often muffled or hoarse, with stridor being a late sign.48 Progression of the disease and the respiratory distress can occur remarkably fast, with patient usually seeking care within 24 hours of onset of symptoms, although there are reports of onset of symptoms to fatal respiratory arrest in less than 4 hours.47,49

The workup differs between adults and children, with care being taken to avoid unnecessary anxiety in children. The workup includes radiographic imaging in children, if stable, and a direct laryngoscopy using a flexible nasopharyngoscope in adults. The imaging studies will help rule out foreign bodies, retropharyngeal abscess, or croup.48 A lateral neck film shows an enlarged epiglottis with thickening and rounding, referred to as the “thumb sign,” with obliteration of the vallecular air space.46 Direct laryngoscopy will show varying degrees of epiglottic, aryepiglottic fold, and arytenoid edema. The swelling of the epiglottis can be graded based on the amount of the vocal folds visualized, as well as whether or not the extent of the edema involves the arytenoids.43 Blood work, including complete blood counts and blood cultures, should be performed as should bacterial cultures of epiglottic swabs. This may be achieved in the awake adult but is

best done during direct laryngoscopy under anesthesia in the child.

In the pediatric patient, once supraglottitis is suspected, the child should be taken for a direct laryngoscopic and tracheobronchoscopic examination. Once the airway is stabilized, cultures may be taken. The preferred route of airway stabilization is the nasotracheal intubation. Extubation may be considered upon repeat endoscopic examination with improvement or resolution of the edema, and/or development of an air leak. Often times, a flexible endoscopic examination will provide information as to the progress.48

The need for airway intervention in the adult is less certain than in the child. This is due to the larger anatomy of the adult, and the belief that the larger anatomy affords the patient a larger degree of edema before airway compromise.47 A recent report from Japan outlined a series of 96 adults with supraglottitis. Only 8 (8%) of the 96 patients required airway intervention. They elected to perform tracheostomies on the patients requiring intervention due to the concern that failed attempts at intubation would cause more laryngeal edema and risk for further airway compromise. They found that the patients that required airway intervention had a higher rate of stridor and muffled voice, edema involving the arytenoids, and epiglottic swelling that obstructed the view of at least one-half of the true vocal folds.47

Broad spectrum antibiotics are usually started immediately, then the coverage may be tailored to the results of the culture and sensitivities. Coverage should take into account Haemophilus, S. aureus, and Streptococcus species.47,48 The use of corticosteroids in the treatment of epiglottitis is debated, and no controlled trials exist to support or refute their use.46 The study discussed above by Katori and colleagues reported the use of corticosteroids in 83% of their patients.47 They continued to be sporadic outbreaks. The current estimates of the disease are approximately 2.5 cases per 100,000 people in the United States, with the majority of cases occurring in the southeastern region of the country.20 Primary syphilis has been associated with laryngeal chancres. Secondary syphilis manifests itself with laryngitis and hoarseness as it involves the laryngeal mucosa. Tertiary syphilis can lead to gummata of the larynx causing hoarseness or even cicatrix formation in the form of adhesions between the vocal folds, interarytenoid scar, or subglottic stenosis. Recurrent laryngeal nerve dysfunction can occur in neurosyphilis by direct involvement of the nerve or with cardiovascular syphilis in which aortic aneurysms compress the nerve.20 Diagnosis and treatment are as outlined above.

Laryngeal manifestations of K. rhinoscleromatis have also been reported in 15 to 80% of the cases of rhinoscleroma.16,50 These manifestations include hoarseness, eduades, and vocal fold edema in the early, catarrhal-atrophic stage. The second, or granulomatous stage, can lead to airway narrowing with vocal fold motion impairment. The sclerotic stage, is the final stage, and can lead to progressive scarring of the larynx and subglottis, contributing to stridor and airway obstruction.16 Please see the Section on Rhinitis for the diagnosis and treatment of rhinoscleroma. As mentioned previously, diphtheria can extend inferiorly to involve the larynx and even the trachea with the thick exudates, causing airway obstruction in the extreme cases.51 In addition to the diphtheria caused by C. diphtheriae, a second microorganism of the same genus, C. ulcerans can cause a similar disease. C. ulcerans is associated with bovine mastitis and can be transmitted to humans with ingestion of nonpasteurized dairy products. It causes a similar disease process with most of the infections being mild although deaths

**Figure 1** Lateral neck radiograph of a child with bacterial tracheitis. Note hazy pseudomembranes in the tracheal air column. (Courtesy of Stephen F. Conley, M.D.)

**Figure 2** Endoscopic photo of a child with bacterial tracheitis. Note the pseudomembrane on the posterior wall of the trachea. (Courtesy of Stephen F. Conley, M.D.)
The clinical presentation usually involves a several-day history of a viral upper respiratory tract infection. This can then lead to a rapid onset of a high fever and a toxic appearance although usually without drooling or odynophagia. Upon workup, an elevated white cell count is often found, and patients frequently have secondary sites of infection, most commonly pneumonia. Radiographic evaluation usually involves a lateral neck plain radiograph. This will often show a diffusely hazy air column, with areas of lumenal soft tissue irregularities consistent with pseudomembrane detachment (Figure 1).48

Patients that are cooperative enough to tolerate a flexible nasopharyngeal endoscopic examination, should have it performed. If frank pus is visible or if a continued high level of suspicion exists, the children should undergo an open bronchoscopic examination. During the open bronchoscopy, a specimen of the pseudomembrane should be obtained for Gram stain, culture and sensitivity (Figure 2). The pseudomembrane itself should be removed as extensively as possible with suction or forceps. Most patients are then intubated, and left intubated for several days, until the patient has defervesced and tracheal secretions have decreased. Often times, repeat open bronchoscopy is required to debride the pseudomembrane further. Most patients are extubated within 3 to 7 days. Broad spectrum antibiotics are required initially, such as a third generation cephalosporin or ampicillin/subactam. Once the culture and sensitivity results are available, antibiotics should be appropriately tailored, for a total of 2 weeks.48

Viral

Most of the viruses associated with viral pharyngitis can cause a viral laryngitis and/or tracheitis (Table 7). One infection of particular concern is laryngotracheobronchitis, or croup. It is most commonly caused by the parainfluenza virus, types 1 and 2, although it has been associated with the influenza A and B viruses, the respiratory syncytial virus, herpes simplex virus, measles, adenovirus, and varicella. It is most commonly seen in children between 6 months and 3 years of age, and accounts for 90% of infectious airway obstructions. Approximately 5% of children have one episode, of whom 5% will have recurrent episodes. Children with recurrent episodes of croup should be taken, when healthy, for endoscopic evaluation of the subglottic airway for stenosis.48

Children often present with a several-day history of upper respiratory tract symptoms, which progress to a barking cough, hoarseness, and stridor. Patients often have a low-grade fever, and an elevated white blood cell count may be present. The stridor may progress from inspiratory to biphasic. This, along with retractions, tachypnea, and oxygen desaturations, strongly suggests impending airway collapse. Hospitalization and intubation are infrequently necessary, with respective rates ranging from 1.5 to 15% and 1 to 5%.48

The diagnostic evaluation most commonly includes an anterior-posterior radiographic view of the soft tissues of the neck. This will show the classic “steeple sign,” which is narrowing of the subglottic area. This narrowing is often dynamic, being more prominent on inspiration, thus distinguishing it from a fixed subglottic lesion such as stenosis or hemangioma. The anterior-posterior film may be falsely negative in as many as 50% of the patients with laryngotracheobronchitis. A flexible nasopharyngoscopic examination will show edema of the larynx and subglottis; however, it is not commonly performed given the airway instability.48

Laryngotracheobronchitis usually resolves on its own. As mentioned, it infrequently requires hospitalization or intubation. Most argue that this must help soothe the inflamed mucosa and hydrates the secretions, making them easier to clear. Although there is no objective data to support cool or warm mist, enough anecdotal data exist to support its use. Racemic epinephrine is a combination of the epinephrine rotatory isomers, dextro (D) and levo (L). They act to reduce airway edema by their alpha-adrenergic effect on mucosal vasculature and are given as a nebulized solution. Although both isomers have this alpha-adrenergic effect on the mucosa, the o-isomer is more potent and can thus lead to more systemic side effects than the L-isomer, which is why a mixture of the two is used. Of great concern are the cardiovascular side effects of high blood pressure and cardiac arrhythmias. Because of these side effects, caution must be used when administering epinephrine, and it should not be used in children with cardiac abnormalities or tachycardia. In addition, the potential for rebound edema exists with the use of epinephrine. Children should be monitored closely for at least 3 hours, although some still advocate hospital admission after the use of racemic epinephrine.48

The use of corticosteroids in cases of laryngotracheobronchitis is controversial. The reduced edema seen with corticosteroids, as well as the studies that have shown their efficacy are arguments for their use. However, the lack of a complete understanding of their mechanism of action and their potential systemic side effects as well as the risk of bacterial and fungal superinfections argues against their use.48

A mixture of helium and oxygen, heliox, is commonly used for airway narrowing such as laryngotracheobronchitis or severe asthma.48 It decreases the work of breathing by decreasing the airway turbulence and promoting laminar flow. The helium decreases the density of the gas mixture and increases the viscosity, thus increasing the laminar flow.48 The mixture is approximately a 70% helium and 30% oxygen mixture, although exact percentages vary. This is used in addition to medical therapy to help stabilize a patient. It must be used cautiously, for if a patient fails heliox, there is usually little reserve, and the patient will likely require urgent intubation.

When intubation is required, nasotracheal intubation is the favored route. An endotracheal tube that is smaller than the expected size should be used, given the reason for intubation. Patients should remain intubated until an air leak develops around the endotracheal tube, which is usually within 5 to 7 days.48

Although very rare, herpetic laryngitis has also been reported. It can be caused by both the varicella zoster virus and the herpes simplex virus.53,54 The appearance can simulate a laryngeal neoplasm, fungal infection, abscess, or granulomatous disease. A mucosal biopsy is required for the diagnosis. If the histology is consistent with a herpes virus infection, antitherpes medications, such as acyclovir, should be used to treat the patient.53,54

Fungal

Fungal infections of the larynx are commonly seen in the immunocompromised patient, but also occur in the immunocompetent, likely at a rate higher than realized. The most common cause of fungal laryngitis is Candida species, however many other fungi can be the cause, including Blastomyces, Histoplasma, Cryptococcus, and Coccidioides (Table 7).55,56 These most commonly appear secondary to an oral, pharyngeal, or pulmonary infection. In addition to immunocompromise, they are more common when the mucosal barrier is impaired, such as the case with smoking, radiation therapy, or corticosteroid use.

Histopathologic analysis is required for diagnosis; however many argue that empiric treatment is reasonable initially. This point of view is based on the gross appearance similar to epithelial dysplasia of the larynx as well as the similarities seen in fungal colonization. Fungal spores, hyphae, and pseudohyphae are found within the upper layers of the epithelium in fungal infections. Hematoxylin and eosin stains will demonstrate what is known as pseudoepitheliomatous hyperplasia. This specifically refers to epithelial hyperplasia with hyperkeratosis, neutrophils within the upper epithelial layers, lymphocytes, plasma cells, and scarring within the submucosal stroma. Fungal infection may also predispose to dysplasia; therefore, both elements may be present. Fungal colonization differs in that the fungal elements lie on top of the epithelial layer, with no penetration, and no associated hyperkeratosis or neutrophil infiltration.

First line therapy for fungal laryngitis varies among authors, but a topical nystatin is a reasonable first option. A topical corticosteroid for 3 to 4 weeks may be used if the topical is unsuccessful. Refractory cases may be treated with intravenous amphotericin B. If the fungal laryngitis continues to fail to respond, especially when dysplasia is present, a fungal infection secondary to a neoplasia must be considered.

Allergic Rhinitis

Robert M. Naclerio, MD
Asli Sahin-Yilmaz, MD

Allergic rhinitis is defined as a symptomatic disorder of the nose induced by immunoglobulin E (IgE)-mediated inflammation due to exposure to foreign substances, referred to as allergens. It is characterized by 1 or more nasal symptoms of pruritus, sneeze, discharge, and stuffiness. Additionally, the sense of smell and ability to taste can be altered. More than creating symptoms, the disease affects the individual’s quality of life and is associated with comorbidities like asthma, eustachian tube dysfunction, sinusitis, and conjunctivitis.

EPIDEMIOLOGY

It is estimated that more than 20% of the world population suffers from IgE-mediated allergic diseases. In the Western world, allergic diseases have increased two- to threefold over the last 40 years and have reached epidemic proportions.7 Allergic rhinitis is the most common allergic disease. The prevalence of allergic rhinitis varies throughout the world. The prevalence of seasonal allergic rhinitis ranges from 1 to 40%, and the prevalence of perennial allergic rhinitis varies from 1 to 18%.7 Overall, allergic rhinitis affects 20 to 40 million people in the United States.8 In an otolaryngologist’s practice, the prevalence of allergic rhinitis in patients coming to the office exceeds that of the general population and is in the range of 50%.

Although it is a benign but chronic disease of the upper airway, quality-of-life studies demonstrate that allergic rhinitis has a great impact on the patients’ well-being. It causes a significant decrease in energy, general health perception, and social function.8 In the United States, the estimates of the annual cost of allergic rhinitis range from 2 to 5 billion dollars.9 The decreased quality of life not only leads to absenteeism but also contributes to “presenteeism” or decreased productivity at work. The economic impact of work productivity losses due to allergic rhinitis was found to be $593 per year per employee, higher than that due to other common conditions like stress, migraine, depression, and respiratory infections.9

Allergic rhinitis in children results in a variety of problems that may affect their quality of life, such as learning impairment, inability to integrate with peers, anxiety, and family dysfunction. Diminished functional capacity in children due to allergic rhinitis alone causes the loss of 2 million school days each year.9 These numbers are augmented when one considers related disorders such as asthma and sinusitis, which are thought to be affected by allergic rhinitis. Treatment-related side effects, such as sedation, can increase the negative impact of allergic rhinitis.

Evidence suggests that there has been an increase in the incidence of allergic rhinitis. The prevalence of self-reported allergic rhinitis was 16.5% in Norwegian school children in 1985 and increased to 24.7% by 1995, and to 29.6% by 2000.10 Similar trends have been observed in other studies.9,11 In a study from US-population-based National Health and Nutrition Examination Survey, data of the years 1976 to 1980 were compared to the data of 1988 to 1994. The prevalence of a positive test response to 6 common allergens observed in the latter survey was 2.1 to 5.5 times higher than in the former.10 The cause of the increasing prevalence of allergic rhinitis is not clear.

Risk Factors Associated with the Disease

Genetics and Family History. A study of twins confirmed the hereditary transmission of allergic rhinitis. The concordance of allergic rhinitis in identical twins was higher than that in fraternal twins.11 Several investigators have conducted genome-wide screens in a variety of populations in the search for susceptibility genes involved in allergic diseases, primarily asthma.12-14 Evidence of linkage to allergic rhinitis and/or asthma for 2 chromosome regions (1p31 and 2q32) was shown in a genome screen from France. No region detected had evidence for linkage to asthma without also being linked to allergic rhinitis.14 In another study from Denmark, significant evidence for linkage to chromosome segment 3q13.31 for allergic rhinitis was shown.15 Heterogeneity of phenotype, gene environment interaction, complexity of molecular mechanisms, an unknown mode of inheritance, and the possibility of small effects of a number of genes complicate these approaches. This remains an area of intense interest and will likely accelerate in the near future.

Early Life Exposures. According to the hygiene hypothesis, infections in early life protect from the development of allergic diseases later in life. This hypothesis is based on observations that show a higher prevalence of allergic diseases in individuals brought up in smaller and wealthier families, particularly in children and young adults in developed nations. The lower prevalence of early childhood infections can be explained by a lowered risk of exposure to infectious agents early in life as a result of improved sanitary conditions and smaller family size. High exposure to acute respiratory infection between pregnancy and age 1 year has also been found to be associated with overall reduced odds for allergic diseases, the most effective period for protection being the first 9 months of life.16

It has been suggested that a decrease in exposure to infectious agents results in a skew in the balance between T-cell subpopulations from T helper 1 (Th1)-cell responses toward atopic Th2-cell responses, including increased production of IgE (Figure 1). Supporting the hygiene theory are studies demonstrating an inverse relationship between the frequency of allergic disorders and serologic evidence for acquisition of certain infections, mainly food-borne and orofecal infections.16,17 Recently, it has become clear that innate responses to microbes are mediated in large part by the toll-like receptors (TLRs), a series of 13 cell surface receptors located on epithelial cells, and various cells of the immune system.18 These receptors are known to recognize the ligands produced by viruses, bacteria, and fungi. Stimulation of the innate immune system causes the release of chemokines, cytokines, and growth factors that can drive the adaptive immune system in a specific direction that may decrease the likelihood of the individual being atopic. More studies are required for developing an understanding of the influence of TLR exposures on the maturation of the immune system and the risk for allergies.

Exposure to allergen is suggested to be a risk factor for the development and persistence of allergic rhinitis. Outdoor allergens appear to constitute a greater risk for seasonal allergic rhinitis than do indoor allergens.2 New hypotheses on the effect of allergenic exposure on allergic rhinitis are controversial. It is suggested that early exposures to indoor allergens like pet dander may have a protective effect on the development of allergic rhinitis.19 In primary intervention studies, in children of atopic parents, avoidance of house dust mites or similar indoor allergens resulted in a reduction of the incidence of sensitization during the first year of life.20 However, continuing mite avoidance measures did not make any difference for allergy development in children at 4 years of age.21

43
In developing nations, rural locales were found to have lower rates of allergic diseases than did urban locales. Close animal contact and exclusive breast-feeding in the families living in rural areas are shown to be associated with lower atopic sensitization. The beneficial effect of growing up on a farm against sensitization and development of allergic diseases in childhood has been reported in several other studies. Most consistently, the "protective" farm effect was related to livestock farming and most likely was due to microbial exposure. A dose-dependent inverse relationship between exposure of children to endotoxin in the mattress dust and the occurrence of atopic diseases was shown in rural environments in Europe. In addition, the blood cells of farmers' children were shown to express higher amounts of innate-immunity receptors. Toll-like receptor 4 (TLR4) is the principal receptor for bacterial endotoxin recognition and plays a critical role in the innate immune response to gram-negative pathogens and respiratory syncytial viruses. The evidence that exposure to endotoxin during early life is protective against development of atopy resulted in studies searching for a relationship between early solid feeding and atopy-related phenotypes. A systematic review of available evidence demonstrated that early feeding of solids may increase the risk of eczema, however, the data supporting an association between early solid feeding and other allergic conditions, including allergic rhinitis, are limited. Many other factors have been implicated in hypotheses and speculations on the possible cause-effect relationship in the development of allergic rhinitis. Some of these factors seem to be significant, such as mode of delivery, birth weight, day care outside the home, and socioeconomic status, but more prospective studies are needed for confirmation of the results.

**Pollution.** The impact of pollution on allergic rhinitis is controversial. Pollution is suggested to cause an increase in nasal responsiveness to environmental allergens. Common outdoor pollutants include sulfur dioxide (SO2), nitrogen dioxide (NO2), and ozone, whereas indoor pollutants include side-stream cigarette smoke.

Persistent exposure to outdoor pollution, especially particulate matter from motor vehicles, has been suggested as one of the factors responsible for the increase in the prevalence of allergic rhinitis. Some studies have shown that exposure to diesel exhaust particles alter the nasal immune network by increasing IgE production, directing cytokine gene expression toward a Th2 profile as well as altering responses to allergen challenges. However, results of other research provided a more complex picture. Outdoor pollution was found to be a poor predictor of physician visits for allergic rhinitis among adult patients. A study on a different chemical content of diesel exhaust particles failed to show any differences in nasal total cell numbers or mediators compared to placebo. The evidence for the effect of pollution on nasal allergies remains an area of further investigation.

Studies in children showed positive associations between atopic allergic rhinitis and passive smoking. A birth cohort study showed that infants exposed to 20 or more cigarettes per day compared with nonexposed infants are 3 times more likely to have allergic rhinitis at age 1. Estimates of daily exposure of children to environmental tobacco smoke in the home range as high as 40 to 60%. Environmental tobacco smoke is known to exacerbate allergic responses by promoting the production of allergen-specific IgE, the induction of a Th2 cytokine nasal milieu, and an increase in histamine after nasal allergen challenge.

**NATURAL HISTORY**

Symptoms of allergic rhinitis can begin at any age, but are most frequently first reported in adolescence or young adulthood. The prevalence in females was found to be slightly higher than that in males, but no racial or ethnic variations have been reported. The incidence of developing an allergic diathesis is higher in children whose parents suffer from allergic rhinitis. If 1 parent has allergies, the chances of the child having rhinitis are 20 to 30% and increase to 40 to 50% when both parents have the disease. The cumulative decrease in the rate of loss of allergic rhinitis symptoms has been estimated to be about 10%, and this occurs mostly in patients with the mildest form of the disease.

Allergic rhinitis is highly related to asthma. The Tucson Epidemiologic Study of Obstructive Lung Diseases confirmed that rhinitis is a significant risk factor for adult-onset asthma. Allergic rhinitis or asthma or both are related to a combination of environmental and genetic factors, some of which affect either the upper or lower airways.

**CLINICAL SIGNIFICANCE**

A part of the clinical importance of allergic rhinitis lies in its association with complications related to chronic nasal obstruction. Total nasal obstruction, regardless of etiology, can cause sleep disturbances. Whether interference with sleep or the effects of systemically released mediators contribute to the fatigue associated with the disease is unknown. Evidence for a role of the nervous system is a new and exciting area of investigation. The prevalence of smell and taste problems in patients with allergic rhinitis is 21.4 and 31.2%, respectively. Studies report a high prevalence of sensitization to inhalant allergens both in acute and chronic rhinosinusitis. In animal studies, it has been shown that an ongoing allergic response in the nose augments acute bacterial sinus infection.

Whether nasal polyps result from allergic rhinitis remains an open question. In an allergy
All subjects with allergic asthma had allergic rhinitis and exposed to allergen ex vivo, showed that class switching of B cells to IgE occurs locally in the nasal mucosa.

**PATHOPHYSIOLOGY**

**Sensitization and IgE**

The distinguishing characteristic of allergic rhinitis is the involvement of IgE immunoglobulins. IgE itself constitutes a small fraction of the human serum; however, the biological activities of IgE are enhanced by the activities of specific cell surface receptors to which it binds. The impact of anti-IgE antibody on the symptoms of allergic rhinitis has proven the role of IgE in the pathophysiology of allergic rhinitis. In an individual with a susceptibility for developing allergic disease, an initial contact with allergen leads to the production of specific IgE molecules, a process termed sensitization. This begins when macrophages and other antigen-presenting cells process the allergen before presenting it to T-helper cells, which then interact with B lymphocytes, leading to their differentiation (isotype switching) into IgE-producing plasma cells, a process involving Th2 cytokines [interleukin (IL)-4 and IL-13] and newly synthesized mediators (prostaglandins [PGDs], cysteinyl leukotrienes [CysLTs], platelet activating factor, bradykinin, tumor necrosis factor-α [TNF-α], and granulocyte-macrophage colony-stimulating factor) follows. Plasma exudation results in edema and swelling in the nasal mucosa. The edematous state allows additional mediators and enzymes including kinins, albumin, proinflammatory mediators, and activated complement fractions to appear in nasal secretions. The early-phase reaction also includes the activation of epithelial cells and release of neuropeptides like substance P (SP).

For ascertaining the importance of any mediator in the pathophysiology of allergic rhinitis, 3 criteria should be satisfied: (1) the mediator should be present during the allergic reaction; (2) instilling the mediator in the nasal cavity should mimic part of the pathophysiology or symptoms of the disease; and (3) a mediator antagonist must at least partially attenuate disease expression. To establish the importance of different mediators in allergic rhinitis, several investigators have attempted to satisfy 1 or more of these criteria. Multiple mediators have been recovered at increased levels in nasal secretions after allergen challenge; these include histamine, kinins, plasma and glandular kallikrein, mast cell tryptase, PGD_2_, and LTB_4_. Furthermore, several of these mediators have been used to challenge the nasal mucosa and observe resultant responses. Histamine provocation, for example, produces rhinorrhea, congestion, pruritus, and sneezing by stimulating receptors on sensory nerves and blood vessels. Instillation of serotonin produces sneezing, whereas prostaglandin D_2_ and kinins all produce nasal congestion. The other approach to establishing the importance of a mediator involves the use of antagonists; the best example of these is H_1_ antihistamines: the clinical utility of H_1_ receptor antagonists serves to demonstrate the importance of this inflammatory mediator.

Whereas mast-cell degranulation and the released inflammatory mediators mimic most of the symptoms of allergic disease, the short duration of these events, as opposed to the prolonged symptoms of clinical disease, suggests that additional inflammatory processes are probably important in clinical disease. Furthermore, increased responsiveness and mucosal cellular changes that accompany chronic exposure to allergen cannot be explained by this mechanism alone. Many of these phenomena relate to the cellular infiltration that is a hallmark of the inflammatory response.

**Late Response**

Various techniques of experimental nasal allergen provocation, in addition to being useful for an understanding of the early response, assist investigators in understanding subsequent inflammatory events. Following challenge, there is an increase in symptoms and mediator levels characteristic of the early allergic reaction, which soon return toward baseline. If one continues to monitor the response for several hours, symptoms recur, associated with an elevation of levels of inflammatory mediators in approximately 50% of the patients, referred to as the late-phase response. During the late-phase response, subjects have a recurrence of sneezing, rhinorrhea, and congestion, with congestion predominating.
As in clinical disease, a striking characteristic of the late-phase response is cellular inflammation (Figure 3). Mediators released during the early phase reaction stimulate the production, maturation, and infiltration of inflammatory cells, including basophils, eosinophils, neutrophils, and mononuclear cells in nasal secretions, as recovered by nasal lavage. Nasal mucosal biopsies, performed 24 hours after topical allergen provocations, show increases in the number of inflammatory cells, but, in contrast to the nasal secretions, in which eosinophils and neutrophils account for the majority of recovered cells, mononuclear cells predominate. These are mostly of the T-helper category, as evidenced by positive staining with antibodies against CD4, and a portion of them are activated, as documented by IL2 receptor expression (CD25). These T lymphocytes are shown to express messenger RNA for Th2-type cytokines.

The cellular changes observed after allergen provocation are similar to observations of nasal cytology during seasonal disease. In separately conducted studies, Bryan and Bryan, and Okuda and Otsuka observed basophilic cells in nasal secretions during seasonal exposure of allergic individuals to pollen. In contrast to nasal secretions, which represent the most superficial compartment of the nasal mucosa, examination of nasal mucosal scrapings, nasal mucosal biopsies, or biopsies from nonallergic control subjects showed that the majority of metachromatic cells in these compartments were mast cells. These are mostly of the T-helper category, as evidenced by positive staining with antibodies against CD4, and a portion of them are activated, as documented by IL2 receptor expression (CD25). These T lymphocytes are shown to express messenger RNA for Th2-type cytokines.

Cytokines and Chemokines

In addition to the role of inflammatory mediators in allergic disease, cytokines are increasingly recognized as important mediators of allergic inflammation and have been shown to have proinflammatory effects in vitro. The proinflammatory cytokines include IL-1, TNF, IL-6, and IL-18. These cytokines are involved in the recruitment and activation of inflammatory cells of the late phase.

Adhesion Molecules

Cellular adhesion molecules play a critical role in recruiting circulating leukocytes to the vascular endothelium at sites of inflammation. Studies have demonstrated increases in

![Figure 3](image-url)
endothelial adhesion molecules, namely, vascular cell adhesion molecule-1 (VCAM-1) in nasal biopsies obtained from allergic subjects 24 hours after nasal allergen challenge. This molecule is expressed on the surface of vascular endothelial cells and interacts with a counterligand, very late antigen-4 (VLA-4), which is present on the surface of several leukocytes, including lymphocytes, monocytes, eosinophils, and basophils, but not neutrophils. The VLA-4/VCAM-1 adhesion pathway has been suggested as a mechanism for specific eosinophil, as opposed to neutrophil, migration from the circulation into allergic inflammatory sites. However, in asthmatic patients, studies using an inhaled VLA antagonist did not result in any protection against allergen-induced airway responses.

Other adhesion molecules thought to be important in the recruitment of inflammatory cells from the intravascular compartment into tissue sites of allergic inflammation are intercellular adhesion molecule 1 (ICAM-1), which is constitutively expressed in the nasal mucosa, and E-selectin, which is modestly upregulated 24 hours after allergen provocation. ICAM-1, a ligand for the β2 integrin molecules CD11a/CD18 (leukocyte function associated antigen-1) and CD11b/CD18 (Mac-1), is present on the surface of leukocytes, mediates the attachment of all classes of leukocytes to endothelial cells, and E-selectin binds to sialyl Lewis X expressed on the surface of leukocytes. The expression of the adhesion molecules VCAM-1 and E-selectin was shown to be enhanced 24 hours after local allergen challenge. Similarly, ICAM-1 and leukocyte function associated antigen-1 are increased in nasal epithelial cells of patients with seasonal and perennial rhinitis. It has recently been shown that the expression of adhesion molecules correlates with the severity of airway diseases. ICAM expression has been shown to be suppressed by H1 antihistamines (terfenadine and cetirizine), which is modestly upregulated 24 hours after antigen challenge. The response to histamine challenge returned to baseline 10 days later, suggesting that increased responsiveness to histamine was reversible. Other studies showed a positive correlation between the number of eosinophils 24 hours after antigen challenge and the magnitude of the responsiveness to histamine, and this hyperresponsiveness was inhibited by pretreatment with topical corticosteroids.

Cysteinyl Leukotrienes

CysLTs are synthesized by mast cells during the early-phase response and by eosinophils, basophils, and macrophages during the late-phase response of allergic rhinitis. The CysLTs include LTC4, LTD4, and LTE4. The enzymes for the production and release of CysLTs are already present in inflammatory cells, unlike cytokines which require transcription and synthesis. CysLTs stimulate mucous glands, which results in rhinorrhea, and they also have the ability to increase microvascular permeability and blood flow, which results in tissue edema. In addition to these local responses, CysLTs participate in the systemic immune response to allergens.

The use of leukotriene modifiers is an important therapeutic advance in the management of allergic diseases. Even though the role of leukotriene receptor antagonists has been more extensively established in asthma, studies on the effects of these drugs on the upper airways have shown that these drugs represent a useful approach to the treatment of seasonal and perennial allergic rhinitis.

Nasal Reactivity

Besides the development of recurrent symptoms within hours after a nasal challenge, the inflammatory cellular influx is accompanied by increased nasal reactivity. In the 1960s, John Connell coined the term "priming" to refer to increased antigen responsiveness. Priming may explain why patients become more symptomatic to the same amounts of pollen in the environment later during the allergic season. Nonspecific reactivity implies increased responsiveness to nonallergenic substances and has been studied by provocation of individuals with methacholine, histamine, cold, dry air, or bradykinin. Like priming, nonspecific reactivity is not obligatorily linked to the appearance of a late reaction. Walden and colleagues found increased sensitivity to histamine 24 hours after antigen challenge. The response to histamine challenge returned to baseline 10 days later, suggesting that increased responsiveness to histamine was reversible. Other studies showed a positive correlation between the number of eosinophils 24 hours after antigen challenge and the magnitude of the responsiveness to histamine, and this hyperresponsiveness was inhibited by pretreatment with topical corticosteroids.

Neural Reflexes

Nasal reflexes are involved in the pathophysiology of allergic rhinitis. For example, sneezing and itching clearly involve the nervous system. Kanno and Togawa and others demonstrated the importance of neural reflexes in patients with allergic rhinitis by showing that stimulating 1 nasal cavity with histamine led to bilateral nasal secretions. Unilateral intranasal challenge with antigen in subjects with allergic rhinitis led to an increase in sneezes, rhinorrhea, nasal secretions, histamine, nasal airway resistance, and PGD2 on the side of the challenge. Contra-lateral to the challenge, rhinorrhea and secretion weights increased significantly, as did PGD2. The contralateral secretory response was rich in the glandular markers, lactotransferin and lysozyme, and was inhibited by atropine, an anticholinergic, suggesting that the efferent limb was cholinergically mediated. The muscarinic receptors that mediate the actions of acetylcholine in the human nasal mucosa are of both the M1 and M3 receptor subtypes and coexist at high densities in the submucosal glands.

Immunohistochemical studies have established the presence of several neuropeptides in addition to sympathetic and parasympathetic nerves and their transmitters in the nasal mucosa. These neuropeptides are secreted by unmyelinated nociceptive C fibers (tachykinins, calcitonin gene-related peptide (CGRP), neurokinin A, and gastrin-releasing peptide), parasympathetic nerve endings (vasoactive intestinal peptide, peptide histidine methionine), and sympathetic nerve endings (neuropeptide Y). SP, a member of the tachykinin family, is often found as a cotransmitter with neurokinin A and CGRP and has been found in high density in arterial vessels and, to some extent, in veins, gland acini, and the epithelium of the nasal mucosa. In addition to the identification of these neuropeptides in the nasal mucosa, Okamot showed that incubation of nasal biopsy specimens of perennial rhinitic subjects and nonallergic rhinitic subjects with SP or mite allergen resulted in significant increases in mRNA for IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, TNF-α, and interferon gamma (IFN-γ) in specimens from allergic subjects but not in those from nonallergic controls. In nasal challenge studies in allergic subjects, Mosimann and colleagues showed that levels of SP, CGRP, and vasoactive intestinal peptide all increased significantly immediately after antigen challenge, with...
The balance between Th1 and Th2 cells can be influenced by regulatory T cells (Treg). Treg cells have been shown to suppress Th1 and Th2 responses and to promote Th3 and Th0 responses. Treg cells express high levels of CD25 and are defined by the expression of the transcription factor FoxP3. These cells play a crucial role in maintaining peripheral tolerance and preventing autoimmune disease.

**Summary of Pathophysiology**

One can summarize the pathophysiology of allergic rhinitis as follows: after sensitization of the nasal mucosa to an allergen, subsequent exposure to that same allergen leads to cross-linking of specific IgE receptors on mast cells and their resultant degranulation, with the release of host inflammatory mediators that are responsible for allergic nasal symptoms (Figure 3). Proinflammatory substances produced by other inflammatory cells are also generated after antigen exposure, most prominent among eosinophil products and cytokines. Cytokines are thought to be generated, in part, by lymphocytes, which are found in abundance in both resting and stimulated nasal mucosa. Recent evidence also points to an important role for mast cells in the storage and probable production and secretion of cytokines. Cytokines can upregulate adhesion molecules on the vascular endothelium and possibly on interacting cells, leading to migration of these cells into tissues. Other cytokines also promote chemotaxis and survival of recruited inflammatory cells. A further important player is the nervous system, which amplifies the allergic reaction by both central and peripheral reflexes that result in changes at sites distant from those of antigen deposition. All of these changes lower the threshold of mucosal responsiveness and amplify it to a variety of specific and non-specific stimuli, making allergic individuals more responsive than nonallergic individuals to stimuli to which they are exposed in daily life.

**COMORBIDITIES OF ALLERGIC RHINITIS**

Multiple lines of evidence support the observation that allergic rhinitis and sinusitis are closely associated disease entities; however, controlled studies of the incidence of rhinosinusitis in patients with allergic rhinitis have not been conducted. In a retrospective review of 200 chronic sinusitis patients who underwent endoscopic sinus surgery, Emanuel and Shah have shown that 84% of the patients tested positive for allergies, with a predominance of perennial allergens. Friedman reported an incidence of atopy in 94% of patients undergoing sphenoidomeotomies. Holzmann and colleagues reported an increased prevalence of allergic rhinitis in children who had orbital complications of acute rhinosinusitis, and these complications occurred especially during pollinating seasons. In a study involving 8,723 children, Chen and colleagues found the prevalence of sinusitis to be significantly higher in children with allergic rhinosinusitis than in children without allergies. Comparison of otolaryngologic disqualifying events in naval flight personnel with and without allergic rhinitis revealed a significantly increased risk of having chronic sinusitis and the need for sinus surgery in the personnel with allergic rhinitis. The risk for the development of barotraumas and nasal polyps was also higher in this group.

Complementing the above data that allergic rhinitis occurs frequently in patients with chronic sinusitis are data showing a high prevalence of sinus disease in patients with allergic rhinitis. Sinus radiographs are abnormal in more than 60% of adults who have perennial allergic rhinitis. MRI scans demonstrate increased evidence of sinus mucosal abnormalities during major pollinating seasons. A study of subjects with ragweed rhinitis during the pollen season showed that 60% of the subjects had sinus mucosal abnormalities on computed tomography (CT) imaging. Subjects with allergic rhinitis were also shown to have more severe paranasal sinus changes in CT scans than did nonallergic subjects during viral colds.

Multiple mechanisms are postulated to explain these relationships. In 1 study of subjects with seasonal allergic rhinitis outside their season, the nose was challenged with allergen, and nasal and ipsilateral maxillary-sinus responses were monitored by use of lavage. There was a late increase in total cell count (the percentage of eosinophils and total eosinophils) within the sinus cavity in the allergen-challenged subjects but not in the control experiments. There were
significantly more total cells after allergen challenge than in controls, as well as a higher number of total eosinophils. This study highlights that important relationships exist between the nose and other organs. A relationship between pulmonary disease such as asthma and allergic rhinitis has long been observed. Allergic rhinitis is present in up to 75% of patients with asthma; and, in a longitudinal follow-up study, patients with allergic rhinitis were 3 times more likely to develop asthma than were subjects without allergic rhinitis. A beneficial influence of treatment with intranasal corticosteroids on bronchial hyperresponsiveness in patients with seasonal allergic rhinitis has been observed, although other studies have failed to confirm this finding.

Treatment with orally inhaled corticosteroids not only prevented development of increased bronchial hyperresponsiveness to methacholine but also reduced nasal symptoms, eosinophils from nasal brushings, markers of eosinophil activation in nasal lavage fluid, and peripheral-blood eosinophilia. A study by Braunstahl and colleagues demonstrated that segmental provocation with allergen in the lungs produced allergic inflammation in the nose in atopic patients. In a study on the ability of the nose to condition cold, dry air, asthmatics had a reduced ability to warm and humidify cold, dry air as compared to normal subjects; subjects with seasonal allergic rhinitis also had a reduced ability to condition air, with possible adverse implications for the lower airways. In a follow-up study, treatment of nasal inflammation with intranasal corticosteroids further decreased the ability of subjects with asthma to condition the inspired air, suggesting that allergic inflammation has a beneficial effect on nasal air conditioning. This was supported by other studies which showed an increase in nasal conditioning by either seasonal exposure or allergen challenge.

Studies on the effect of nasal challenge on bronchi in adults and children with allergic rhinitis have shown correlations between allergen induced nasal changes and bronchial hyperreactivity. Cochrane analysis of the use of intranasal corticosteroids on asthma control showed that it tends to improve asthma symptoms and forced expiratory volume in 1 second; however, these results did not reach statistical significance. Pathophysiological connections between the nose and lungs are still not entirely understood and remain an active area of investigation. The above data, however, support the presence of important physiologic and pathophysiologic connections between contiguous areas of the respiratory tract.

Nasal inflammation with an allergic or infectious cause may be a factor involved in the development of otitis media and pathologic tube dysfunction. Studies of the pathogenesis of otitis media have identified interactions among infection, allergic reactions, and eustachian tube dysfunction. Nguyen and colleagues demonstrated that middle-ear fluid of atopic patients who had otitis media with effusion contained more eosinophils and IL-4 and IL-5 mRNA-positive cells than those in nonatopic patients with otitis media with effusion. In the presence of allergic rhinitis, treatment may improve symptom resolution and therapeutic response. The inflammation found in allergic rhinitis is thought to promote eustachian tube dysfunction and supports the development of otitis through mediators and cytokines.

Studies on adults and adolescents with allergic rhinitis have shown disrupted sleep, difficulty concentrating, daytime fatigue, and a related significant decrease in quality of life parameters. Ocular symptoms are observed in a large percentage of patients with seasonal allergies.

**ALLERGENS**

Allergens are foreign substances capable of provoking an IgE-mediated response. Most allergens are between 5 and 20 µm in diameter, a size that permits their complete removal by the nose. They are proteins with molecular weights between 10 and 40 kDa. No distinguishing surface characteristics appear to differentiate allergens from non-allergenic substances.

According to the third National Health and Nutrition Examination Survey, the prevalences of positive skin test responses in the US population were as follows: 54.3% of the population had positive test responses to one or more allergens. Prevalences were 27.5% for dust mite, 26.9% for perennial rye, 26.2% for short ragweed, 26.1% for German cockroach, 18.1% for Bermuda grass, 17.0% for cat, 15.2% for Russian thistle, 13.2% for white oak, 12.9% for A. aestivalis, and 8.6% for peanut.

We often categorize allergens into indoor and outdoor types. In general, outdoor allergens are responsible for seasonal allergic rhinitis, whereas indoor allergens usually cause perennial rhinitis. Pollens causing allergy in temperate climates are released into the air from plants, trees, weeds, and grasses and are carried over great distances. Thus, cutting down trees around a suburban home in an effort to reduce the amount of pollen has little effect. Trees clearly have geographic variations; for example, Western red cedar is limited to the Northwest. Grasses are diverse and include timothy grass, often used for feeding horses, Kentucky bluegrass, widely used in lawn grass mixtures, orchard grass, ryegrass, and English plantain. Common short ragweed is present in up to 75% of patients with asthma; the region is ragweed-free. In the Northwest coastal region, trees and grass pollen are present, but the region is ragweed-free. In the traditionally arid Southwest, previously a haven for allergy sufferers, increased urbanization and irrigation have contributed to increasing the pollen load because humans tend to bring their allergens with them.

Global climate changes, driven by the increased concentrations of gases such as carbon dioxide, have been shown to stimulate opportunistic weeds and trees including ragweed, maples, birches, and poplars to produce more pollen. The increase in temperature also encourages growth of molds and fungi, which may result in important allergen loads for individuals who have asthma and allergic rhinitis. Recent studies have shown that pollen grains, apart from their function as allergen carriers, are also a rich source of lipid mediators, which may contribute to the generation of local inflammation.

The most frequent perennial allergens are animal danders, dust mites, cockroaches, and molds. Dust mites are microscopic, eight-legged organisms of the genus Dermatophagoides, including *D. pteronyssinus*, *D. farinae*, and *Euroglyphus maynei*. They are the major allergens in “house dust.” Dust mites are found throughout the world, with the exception of regions with extremely dry climates such as northern Sweden, central Canada, and areas at elevations above 10,000 feet. These mites feed on human epithelial scales and thrive in warm, humid environments (60 to 70% relative humidity, temperature 65 to 80°F). Bedding provides an ideal environment for proliferation of dust mites. Other sites for mite accumulation are upholstered furniture, carpets, and stuffed toys.

Animal danders are an important source of indoor allergens. Cat and dog dander are the most frequent, but mice, guinea pigs, and horses can all...
be responsible for allergic symptoms. Laboratory workers can become allergic to animals at work. In most cases, the allergen is found in secretions. In cats, Fel d 1 is the principal allergen secreted in saliva. It dries on fur and is spread to furniture, bedding, and carpets. When these reservoirs are disturbed, the allergen becomes airborne and can provoke symptoms. Cat dander is “sticky,” and children with cats can carry enough of it to school to cause symptoms in cat-allergic children who have no cats in their homes.

Cockroaches are an important source of allergen in inner-city populations. Both the American (Periplaneta americana) and German cockroach (Blatella germanica) have been identified as important allergens in asthma. Allergenicity occurs to body parts and to feces. M olds, although less well-studied, are sources of allergens, particularly in warm, humid environments. They tend to be found inside older homes in areas of decreased ventilation or increased dampness. Although a phenotypical variety of molds exists, alternaria and cladosporium are principally responsible for symptoms due to outdoor exposure, and aspergillus and penicillium are most prevalent indoors.

The patient’s work environment may be a source of allergens. Symptoms occurring only at work and subsiding on days off may reflect an occupational disorder. At risk are flour handlers, workers in paint and plastic industries, woodworkers, fish and shellfish processors, and animal handlers. Unfortunately, few specific tests exist for the diagnosis of these disorders.

Allergic reactions to natural-rubber latex have increased, especially in health-care workers who have high exposure by direct skin contact and inhalation of latex particles from powdered gloves. Latex allergy is observed in about 4% of health-care workers and is significantly associated with asthma and allergic rhinitis. Eliminating powdered natural rubber latex from the work place and using latex-free material resulted in a decrease in markers of sensitization and symptoms in health-care workers.

**CLASSIFICATION OF ALLERGIC RHINITIS**

Allergic rhinitis has always been subdivided, based on the time of occurrence during the year, into seasonal and perennial disease. Seasonal allergy is related to outdoor allergens such as pollens or molds. Perennial allergic rhinitis is related to indoor allergens such as dust mites, molds, cockroaches, and animal danders. This subdivision is not entirely satisfactory for the following reasons: (1) seasonal allergens in one region can occur throughout the year and cause perennial symptoms, and (2) patients with perennial allergies could present symptoms only during a short time of the year.

For these reasons, the allergic rhinitis and its impact on asthma workshop has changed the definition of the chronology of allergic rhinitis and subdivided the disease into “intermittent” and “persistent” categories. This classification has been validated. The new classification of allergic rhinitis is shown in Table 1. It is designed as a system to initiate treatment guidelines, whereas “seasonal” and “perennial” is a system for identifying the allergens. Recently, a modification of this method of assessment was suggested. The questions used for assessing the severity of allergic rhinitis have been decreased to 2, 1 of them addressing sleep disturbance and the other, impairment of daily personal and/or professional life. If the answer to both questions is “no,” the disease would be classified as mild, if the answer to 1 of the questions is “yes,” as moderate, and if the answer is “yes” to both questions, the disease would be classified as severe. This proposed modification has not yet been validated.

**CLINICAL PRESENTATION**

**History**

An antigen exposure causes itching within seconds, which is soon followed by sneezing. Rhinorrhea ensues, and within about 15 minutes nasal congestion peaks. Besides nasal symptoms, patients often complain about ocular pruritus, tearing, pharyngeal itching, throat clearing, cough, and ear popping. Other commonly reported symptoms include postnasal drip, increased lacrimation, dry cough, red eyes, headaches (pressure) over the paranasal sinus areas, and loss of smell or taste. These symptoms are nonspecific and have significant clinical overlap with other disorders. Itching of mucous membranes and repetitive sneezing, however, are the symptoms most suggestive of allergic disease. The relative importance of each symptom may vary among individuals, but nasal congestion tends to be the most bothersome. Each symptom is usually present, at least to some degree.

When obtaining the history, the physician should attempt to link exposure to allergens temporally with the occurrence of symptoms. This temporal correlation is the hallmark of allergic rhinitis. Patients with seasonal allergies complain of recurrent symptoms only at specific times of each year that coincide with pollination periods. In contrast, a history of year-around symptoms may indicate sensitivity to a perennial allergen or to multiple seasonal allergens. Symptoms immediately following exposure to a potential source of allergen, such as a cat, strongly suggest an allergy to that source. Exposures to perennial allergens tend to be accentuated in winter in colder climates, where ventilation is reduced. Symptoms occurring only at work or during the workweek and subsiding on weekends may reflect an occupation-related disorder. The presence of domestic pets (including birds) and whether these sleep in the patient’s bedroom must be determined.

Additional considerations in history-taking include the response to prior therapy and evidence of complications. For example, nasal obstruction may lead to mouth breathing. In children, this may be manifested as adenoid facies with a high palatal arch, and abnormal dental development. In adults, nasal obstruction may contribute to snoring and sleep-disordered breathing. Sinusitis may be present and contributing to symptoms. A contribution of allergic rhinitis to middle ear disease has also been shown.

Obtaining a general medical history remains important. The medical history may document systemic disorders that affect the nose, such as hypothyroidism. Pregnancy can produce nasal congestion and may require modification of treatment strategies. The presence of pulmonary disease such as asthma should be sought. Indeed, a significant percentage of patients with allergic rhinitis have asthma. Between 5 and 10% of asthmatic subjects may have intolerance to aspirin and nonsteroidal anti-inflammatory drugs. The frequency of aspirin tolerance in patients with nasal polyposis is about 23%. A family history of allergic rhinitis increases the chances of the patient having an allergic disorder. Nasal symptoms might also be due to intake of medications such as β blockers, which may contribute to nasal congestion through interference with the adrenergic mechanism. Tricyclic antidepressants may produce dryness of the nasal mucosa by virtue of their anticholinergic effects. A ngiotensin-converting enzyme inhibitors can produce a chronic cough. Birth control pills can cause nasal congestion, and topical eye drops can induce nasal symptoms. Overuse of topical decongestants may result in rhinitis medicamentosa.

**Examination**

A tentative history-taking and physical examination, combined with appropriate diagnostic tests, are required for establishing the correct diagnosis, because allergic rhinitis shares features of other nasal disease entities. The classical description of allergic facies includes mouth breathing, allergic “shiners” (resulting from periorbital venous stasis from chronic nasal obstruction), and a transverse supratip nasal crease from long-term rubbing of the nose upward to relieve itching. These classic
representations occur especially often in children, but absence of these signs does not exclude the disease.

Physical examination must be complete. Ocular examination may demonstrate injection of the conjunctiva or swelling of the eyelids. Examination of the nose begins with observing the external appearance for gross deformities such as a deviation suggesting previous trauma, or expansion of the nasal bridge suggestive of nasal polyps. A nasal speculum permits evaluation of the anterior third of the internal nasal architecture and the character of the nasal mucosa. Structural anomalies providing an anatomic basis for obstruction or recurrent infections such as septal deviations or spurs should be sought. The character and consistency of nasal secretions should be noted. These can vary from thin and clear to thick and whitish. The nasal mucosa may be swollen and pale-bluish, although these signs are not pathognomonic of the disease as previously thought. The results of examination of allergic individuals often appear normal, and the primary importance of the physical examination is to rule out other causes of or contributors to the symptoms.

Decongestion of a swollen nasal mucosa with a topical decongestant improves visualization and allows the differentiation of reversible from irreversible changes. Combining the vasoconstrictor with a topical anesthetic allows complete examination with an endoscope. The choanae and the nasopharynx may be visualized in this manner. The region of the middle meatus should also be examined carefully because secretions there might be suggestive of acute or chronic sinusitis. Nasal polyps that were not visualized by anterior rhinoscopy may be seen during a careful endoscopic examination. Nasal polyps are infrequent in allergic rhinitis (<2%), but are found in up to 20% of patients with cystic fibrosis. The presence of nasal polyps in children suggests a diagnosis of cystic fibrosis. Children with polyps should undergo sweat or genetic testing for cystic fibrosis.

**DIAGNOSIS**

The identification of allergen(s) responsible for the patient’s symptoms is important both for establishing the diagnosis and for the institution of avoidance measures. Symptoms occurring in temporal relation to allergen exposure suggest sensitization but are not diagnostic. Sensitization implies the presence of elevated levels of IgE directed against a specific allergen and can be demonstrated by a wheal and flare response to skin testing with allergen extracts or by measurement of the level of antigen-specific IgE antibodies in the serum. However, individuals can show evidence of sensitization by a positive skin test or elevated specific antibody levels in the serum without having evidence of clinical disease. This emphasizes the importance of obtaining a good history in the evaluation of patients with suspected allergic disorders. In patients with a positive history, the magnitude of skin responses often corresponds to the severity of symptoms.

**Skin Testing**

Skin testing furnishes an excellent in vivo method for demonstrating sensitivity to a given allergen. This test evaluates the presence of specific IgE antibodies on skin mast cells, thereactivity of these cells, and the reaction of the end organ to releaseds mediators. Its advantages include great sensitivity, the rapidity with which results can be obtained, and low cost. Like all diagnostic tests, skin testing also has disadvantages, which include the inability to perform the test in patients with dermatologic problems such as dermatitis and acute eczema, poor tolerance of many children for multiple needle pricks, the inhibitory effect of certain ingested drugs such as antihistamines on skin test reactivity, the need to maintain the potency of the allergen extracts, and the possibility of systemic reactions.

Skin testing often begins with puncture testing, which produces a low-dose allergen exposure. A small drop of concentrated allergen is placed on the skin (usually on the volar surface of the forearm or on the back), and a minute quantity is introduced into the dermis with a sharp object. Skin puncture tests with various devices have been introduced that decrease the variability in the tests. Positive responses occur within 10 to 15 minutes and produce a characteristic raised central area of induration (wheat), with a surrounding zone of erythema (flare). The response is graded in comparison with a positive histamine or codeine response, and a negative control with the diluent for the allergen extracts is included as control for nonspecific reactivity to the vehicle. The positive control ensures that the patient can mount a cutaneous reaction to histamine, and the absence of a reaction can unmask interference by medications, decreased skin reactivity, or technical problems with the procedure. Skin testing is valid in infants and young children, but here the criteria for a positive reaction need to be adjusted because the reactions are smaller. Measurement of serum-specific IgE levels is also valid in this younger age group. It is important, however, to test with only relevant antigens. Infants are more likely than adults to be allergic to foods, and children are more likely to be allergic to perennial rather than to seasonal allergens.

Negative puncture tests are usually confirmed by intradermal tests, which are more sensitive. In an intradermal test, a small (0.01 to 0.05 mL) quantity of dilute allergen is injected into the superficial dermis, and the same wheal and flare responses are observed and graded in comparison with a positive histamine or codeine control. Because antihistamines can interfere with the results of skin testing, most H1 receptor antagonists are withheld for 2 days before the test. Tri cyclic antidepressants suppress responses for several weeks, as can tranquilizers and antiemetics of the phenothiazine class through intrinsic anti-H1 activity. Short-term oral corticosteroid and antileukotrienel treatment has no effect on skin test reactivity. Testing with extracts that are standardized (ragweed, grass pollens) is more reliable than testing for nonstandardized antigens such as foods and molds.

**In Vitro IgE Measurements**

Drawing blood for the measurement of specific IgE can circumvent some of the disadvantages of skin testing. False-positive results may occur if patients have elevated IgE levels in their sera because of nonspecific binding. False-negative results may also occur from inhibition by IgG antibodies with affinities similar to those in patients receiving immunotherapy. Data from clinical studies comparing results of skin testing and in vitro tests for specific IgE determination in allergic subjects suggest a good correlation between the 2, with a higher sensitivity for skin testing. Therefore, both determinations of specific IgE levels and skin testing are useful in the diagnosis of allergic disorders, but their results should always be interpreted in the context of clinical symptoms. Disadvantages in vitro testing include cost, slightly lower sensitivity, and the time delay between drawing blood and obtaining the results.

**Other Diagnostic Tests**

Peripheral eosinophilia, although nonspecific, may indicate the presence of atopic diseases. Nasal cytologic examination allows the identification of eosinophils and other inflammatory cells in nasal secretions and may be helpful in differentiating an infectious from an allergic cause during a clinical exacerbation of symptoms. In normal individuals, smears show the presence of epithelial cells, including some ciliated and goblet cells, with few eosinophils, neutrophils, basophils, or bacteria. In subjects with an infection, neutrophils increase in nasal secretions, and in symptomatic allergic subjects, the percentage of eosinophils increases. A value greater than 10% for eosinophils is suggestive of allergic disease; however, they may also be present in the absence of IgE-mediated disease. Approximately 25% of patients with chronic rhinitis and negative skin tests demonstrate eosinophilia on nasal cytologic study, and this entity is known as the nonallergic rhinitis with eosinophilia syndrome.

Soft-tissue radiography of the neck can be used for evaluating adenoid size, a major consideration in the differential diagnosis of rhinitis in children, especially when the predominant symptom is nasal obstruction. Sinus disease often complicates perennial allergic rhinitis and may need to be considered in the differential diagnosis. CT is now standard for evaluation of the presence and extent of sinus abnormalities. The common association of upper and lower airway disease makes tests of pulmonary function a useful adjuvant. This statement applies to such diverse disorders as cystic fibrosis, asthma, and bronchopulmonary aspergillosis.
E
ter the increase in the prevalence of asthma and allergic diseases highlights the need for developing effective preventive strategies. The large number of potential environmental risk factors and the inability accurately to predict the development of asthma and allergy resulted in conflicting data from recent prevention studies. Environmental modifications consist of removal of specific antigen and the removal of irritants. The most important example of the latter is tobacco smoke. A avoidance of exposure to environmental tobacco smoke can be recommended safely for the whole population, not only for prevention of allergy but also for other known benefits. A through perfectly logical, the advantage of other avoidance measurements in the presence of good pharmacotherapy has been questioned.166

The most potent treatments cannot eliminate symptoms in the face of an overwhelming allergen load. Complete avoidance of the allergen(s) to which the patient is sensitive eliminates symptoms of the disease. Thus, measures aimed at reducing the allergen load from the patient’s environment are effective in reducing symptoms. Although many methods of environmental control (removal of a pet, restriction of activities, home renovations) are difficult to execute, particularly with children, simple measures can be very effective. In seasonal allergic rhinitis, patients can reduce exposure by keeping windows closed on days when pollen counts are high and limiting physical activity outdoors in the early morning and evening when pollen counts are at their peak. A ir conditioning can help, and the addition of special filters can prevent pollen grains and mold spores from entering the home. Pollen counts are often given during daily weather reports, and the previous day’s pollen counts are the best predictor of the next day’s counts. Rain, however, profoundly reduces the levels of outdoor pollen.

Measures to reduce exposure to dust mites concentrate on bedding. These include replacing feather pillows and bedspreads with synthetic ones that can be washed in hot water (hotter than 130°F) and covering mattresses with commercially available impermeable covers (pores <10 µm). A study showed that washing clothing with detergent plus bleach removes a significant portion of mites, and repeated washing is suggested to reduce the mites further.167 Removing carpets and frequent vacuuming with a vacuum cleaner designed to trap allergen particles also help. Where carpets cannot be removed, acaricidal products can directly kill mites. Stuffed toys can be placed in the freezer for 2 days for reducing the number of dust mites. Mite-proof covers can significantly reduce the level of exposure to mite allergens. Despite a decrease in mite exposure, intervention studies failed to show a clinical benefit of this single avoidance measure.168

In subjects with allergies to animal dander, removal of a domestic pet is the best step. Reduction in the allergen load after pet removal may take up to 6 months, however, and thus symptoms may persist. Furthermore, complete removal of a pet may be difficult, but eliminating the animal from the bedroom, where we spend an average of 8 hours per day, is considered a helpful alternative. In the case of cats, regular washing of the animal may decrease the allergen load; however, this decrease is short-lived, and it is unlikely that one will obtain a meaningful symptomatic improvement with this measure.169 Studies show that cat allergens are ubiquitous in the environment, including schools. This "second-hand" exposure to cats in the school environment increases the risk of cat sensitization in school children who have no regular contact with cats and can trigger symptoms in cat-sensitive subjects. It is most likely that cat dander is carried into classrooms on the clothes of a cat owner.170

Humidifiers must be cleaned regularly so that they do not become a source of mold allergens, which thrive in moist environments. The humidity should not exceed 40 to 45% because higher levels encourage the growth of dust mites and molds. The use of high-efficiency particulate air filters and of electrostatic filters effectively removes particulates larger than 1 µm in diameter. Particles, however, must be airborne for removal, for example pollen, whereas heavy particles that settle from the air rapidly, such as dust mites, are not eliminated by these measures.171 High-efficiency particulate air filters are preferred to electrostatic ones, as they filter out particulate matter without generating ozone, an irritant.

General household changes may also be helpful. Repair of any plumbing or drainage problem areas in the house must be undertaken for eliminating mold. Decontamination of surfaces contaminated with mold by use of diluted bleach and elimination of soiled organic materials are useful. A appropriate packaging of garbage, as well as pesticide application, are necessary for eliminating cockroaches. Use of well-fitting, semi-rigid masks when vacuuming or using vacuum cleaners designed to trap allergens offers useful protection from airborne allergens such as dust mites.

Pharmacologic Therapy
Management of allergic rhinitis should encompass educating the patient to increase adherence to the treatment plan. Pharmacologic management should take into account efficacy, safety, the severity of the disease, patient’s preference, and cost-effectiveness.172 Interestingly, increasing the co-pay by $10 of antihistamines decreases the number of refills, suggesting financial considerations are important to patients. This type of change in drug benefits has resulted in the decreased use of antihistamines. This reduction may cause short- or long-term clinical consequences in patients with allergic rhinitis.173

Antihistamines. Four receptors exist for histamine. H1 receptors are found on blood vessels, on sensory nerves, on smooth muscles of the respiratory and digestive tracts, and in the central nervous system. Stimulation of these receptors leads to vasodilatation, increased vascular permeability, sneezing, pruritus, glandular secretion, and increased intestinal motility. H2 receptors have a distribution similar to that of H1 receptors but are principally involved in the regulation of gastric acid secretion. H3 receptors are located primarily in the brain and seem to be involved in the regulation of histamine synthesis and release. H4 receptors are expressed in various cells of the immune system, including mast cells, T lymphocytes, dendritic cells, and basophils. It has been suggested that H4 receptors are involved in inducing chemotaxis of eosinophils and mast cells and in the control of IL-16 release from lymphocytes.174 The contribution of histamine to the early allergic response, largely mediated by the H1 receptor, has long been recognized and is the rationale for the large number of H1 antagonists in clinical use. H1 antihistamines have been classified as first-generation, or sedating, and second-generation, or non-sedating, antihistamines. The first-generation antihistamines are effective in the relief of symptoms of allergic rhinitis. Some studies showed a better improvement in symptoms with diphenhydramine compared to the second-generation antihistamine desloratadine.175,176 However, first-generation antihistamines have some undesirable side effects because of their lack of selectivity and the resulting nonspecific stimulation of other receptors. Among these side effects are sedation, anticholinergic effects, functional and performance impairment, and gastrointestinal distress. When applied topically, some act as local anesthetics. The most important of the side effects is sedation. In 1 study, diphenhydramine caused worse impairment to driving than does consuming alcohol to the level of being legally drunk.177 In this study, the performance after a second-generation agent was similar to that after a placebo. Meta-analysis of other performance impairment trials failed to show a clear and consistent distinction between the sedating antihistamine diphenhydramine and non-sedating antihistamines including acrivastine, astemizole, cetirizine, fexofenadine, loratadine, and terfenadine.178 Although the results of the analyzed studies varied in sample size, most of them tended toward more cognitive dysfunction with diphenhydramine than with placebo and second-generation antihistamines.175,178

Second-generation antihistamines are less lipophilic than first-generation H1 antihistamines and do not penetrate the blood–brain barrier. Therefore, they produce no more somnolence than does placebo. Their greater receptor selectivity also reduces the incidence of anticholinergic side effects. In addition to antagonizing histamine at the H1 receptor, some antihistamines, such as azatadine, of the piperidine class, and terfenadine, a non-sedating antihistamine, inhibit histamine release after intranasal antigen challenge.179,180 Treatment with some antihistamines also reduces the production of leukotrienes and kinins, which are mediators with proinflammatory effects, as well as the allergen-induced
increased responsiveness to methacholine.\(^{181}\) Similarly, the topical antihistamine antagonist azelastine has shown a significant inhibitory effect on the methacholine response, whereas it failed to affect the early- and late-phase mediators.\(^{182}\) Other described effects of antihistamines are reduction of soluble ICAM-1 levels in nasal secretions (loratadine and cetirizine),\(^{183}\) modulation of the cytokine pattern by reducing IL-4 and IL-8 levels (levocetirizine),\(^{184}\) and reduction of nasal neurogenic inflammation by modulating the release of SP (cetirizine).\(^{185}\) Oral antihistamines are readily absorbed. Their onset of action is rapid, usually within 60 minutes, and the maximum benefit occurs within hours. Metabolism of most antihistamines occurs primarily through the hepatic cytochrome P-450 system. Drugs that interfere with this system, such as antifungal agents, can lead to the accumulation of antihistamines to toxic levels. One exception is cetirizine, which is primarily excreted in the urine and does not depend on the cytochrome P-450 system. The clinical effectiveness of antihistamines exceeds the duration of measurable serum levels, perhaps due to the presence of active metabolites. Another explanation for the prolonged efficacy of H\(_1\) receptor antagonists beyond their measurable serum levels relates to extended tissue levels. P-glycoprotein (a multidrug resistance 1 [MDR1] gene product) is a drug transporter that has been shown to contribute to the disposition of some drugs, including fexofenadine. Polymorphisms of the MDR1 gene have been reported to be associated with alterations in the disposition kinetics of fexofenadine.\(^{186}\) Further studies on genetic variations of P-glycoprotein will be important for explaining the factors affecting the peripheral response to antihistamine. In the United States, the following second-generation antihistamines are in clinical use: azelastine, cetirizine, fexofenadine, loratadine, and desloratadine. Levocetirizine has been approved for use in allergic rhinitis in Europe. This drug has been shown to have a duration of action exceeding 24 hours in adults.\(^{187}\) Loratadine, one of the major second-generation antihistamines, has taken on a non-prescription status in the United States. Azelastine, a pthalazinone derivative, is an intranasal preparation with efficacy comparable to that of other antihistamines.\(^{188}\) It can be effective within 20 minutes of administration. Although it does not cause somnolence, a sensation of altered taste immediately after use is observed in 10% of patients.\(^{189}\) Another H\(_1\) antihistamine under development in a nasal spray formulation is olopatadine hydrochloride. It has been shown to elicit significant improvements in allergic rhinitis symptoms compared to placebo.\(^{190}\) Cardiac arrhythmias, fatal ventricular tachycardia, or prolongation of the QT interval associated with concomitant administration of agents that interfere with the cytochrome P-450 system have been reported with two older second-generation antihistamines, terfenadine and astemizole. These agents are no longer available in the United States. Fexofenadine, a metabolite of terfenadine, does not possess these cardiac risks. Second-generation agents have been shown to be effective. Cetirizine, fexofenadine, and desloratadine have been demonstrated to improve quality of life, as measured by generic and disease-specific tools.\(^ {190-192}\) They cause little or no somnolence, do not affect performance, and have no anticholinergic effects. Azelastine and fexofenadine are approved for children older than 5 and 6 years, respectively. Loratadine and cetirizine are approved for children older than 2 years, and desloratadine is approved for children older than 6 months.

All antihistamines are effective in the treatment of allergic rhinitis and differ principally in their side effects, duration of action, and cost. In equipotent doses, they are equally effective in suppressing histamine-induced skin wheals. H\(_1\) receptor antagonists are most effective in treating sneezing, nasal and ocular pruritus, and rhinorhea associated with allergic rhinitis but have little or no effect on nasal congestion. Thus, they are often combined with an oral decongestant. Some clinicians have tried to circumvent the sedation caused by first-generation antihistamines by directing that they be taken before bedtime, when somnolence is not a problem. The next day, prolonged tissue levels provide continued efficacy without the undesirable side effect of drowsiness.\(^{193}\) Some studies, however, suggest that performance is impaired despite the lack of drowsiness. It is therefore important to warn patients receiving these drugs about their effect on daily activities, such as driving or operating heavy machinery. Patients who lack medical insurance or formulary coverage often use first-generation agents despite their significant side effects. This poses considerable public-health concerns, given recent studies demonstrating the marked performance impairment associated with their use.

**Decongestants.** Decongestants exert their effect through stimulation of \(\alpha_1\) or \(\alpha_2\) adrenergic receptors. These receptors are present on resistance vessels, where they control blood flow, and on capacitance vessels, where they control blood volume. In capacitance vessels, \(\alpha_2\) outnumbers \(\alpha_1\) receptors. In resting conditions, sympathetic nervous activity regulates nasal patency by maintaining the sinusoids contracted to approximately half their maximal capacity. The resting state is affected by the nasal cycle, a periodic, reciprocal alteration of nasal-cavity congestion and decongestion that affects about 80% of normal individuals. Increased sympathetic stimulation, such as occurs during exercise, reduces nasal congestion. Oral decongestants exert their effects directly and by stimulating release of norepinephrine. The 2 major decongestants are pseudoephedrine and phenylephrine, which can be prescribed separately or in combination with antihistamines. Oral medications including pseudoephedrine are now placed behind the counter because of their illegal use in the manufacture of methamphetamine. Use of phenylpropanolamine in diet medication has been associated with rare hemorrhagic stroke and has been withdrawn from the US market. Because oral decongestants also stimulate adrenergic receptors other than those in the nasal vasculature, overdosage has been associated with hypertensive crisis. When given in prescribed doses, however, they do not induce hypertension in normotensive patients, nor do they alter the pharmacologic control of blood pressure in stable hypertensive patients. Current recommendations suggest that decongestants should not be used in patients with uncontrolled hypertension, in those with severe coronary artery disease, or in patients receiving monoamine oxidase inhibitors. Decongestants should be prescribed with caution in patients with diabetes, hyperthyroidism, closed-angle glaucoma, coronary artery disease, cardiac insufficiency, prostatic hypertrophy, or urinary retention. Their major side effect is insomnia, which occurs in approximately 25% of patients.

**Topical Intranasal Corticosteroids.** Topical intranasal glucocorticosteroids are potent medications for the treatment of allergic rhinitis. These agents profoundly reduce multiple aspects of the inflammatory response to allergen. Corticosteroids pass into the interior of the cell, where they are bound by a glucocorticoid receptor in the cytoplasm. The glucocorticoid receptor inhibits inflammation by genomic or nongenomic mechanisms (Figure 5). A genomic mechanism occurs within the nucleus and involves direct (induction of annexin 1 and mitogen-activated protein kinases) or indirect effects (nuclear factor-kB) on gene expression. The nongenomic pathway involves rapid effects on inflammation by second-messenger cascades (endothelial nitric oxide synthetase and phosphatidylinositol-3-hydroxykina) which do not require changes in gene expression.\(^{194}\) Many of the anti-inflammatory effects of glucocorticoids occur by suppression of a host of proinflammatory proteins with potential anti-inflammatory activity (such as annexin 1, IL-10, mitogen protein kinase) and proteins with potential proinflammatory activity (such as chemokine receptors, complements, IL-1 and IL-8 receptors, IFN-\(\gamma\) receptors, TNF, and TLR 2 and 4).\(^{195}\)
Studies on the unchallenged nasal mucosa showed that 4 weeks of intranasal corticosteroid administration leads to a significant reduction in symptoms and in levels of recovered inflammatory mediators in nasal secretions. Pretreatment with topical corticosteroids effectively suppresses the response to allergen provocation (Figure 6). In contrast to treatment with systemic corticosteroids, pretreatment with topical corticosteroids reduces the acute nasal response to allergen challenge, as shown by a reduction in nasal symptoms and in levels of recovered inflammatory mediators in nasal secretions. Pretreatment in epithelial Langerhans cells, macrophages, mast cells, T cells, and eosinophils. These agents inhibit hyperresponsiveness to non-allergenic stimuli such as histamine. Topical corticosteroids also prevent the increase in mast cells and inflammatory cells seen during seasonal exposure to allergens. Furthermore, they result in suppression of the seasonal increase in specific IgE antibodies during the ragweed season.

Currently used topical forms of corticosteroids include flunisolide, beclomethasone dipropionate, triamcinolone, budesonide, mometasone, and fluticasone. Although differences in the potency and strength of receptor binding among these molecules can be demonstrated in vitro and in certain in vivo models, none of these variations has been shown to translate into major clinical differences. Their onset of action has been reported to be as short as 7 to 8 hours after dosing, with most preparations having a peak effect between 3 days and 2 weeks. Previous studies suggested that these medications work best with continued usage, as opposed to intermittent, as-needed use. However, they are also effective when used intermittently. A large clinical trial compared the efficacy of intranasal fluticasone and placebo nasal sprays used as needed in patients with seasonal allergic rhinitis and showed that as-needed use of the intranasal corticosteroid led to significant improvement in symptoms and quality of life scores compared to placebo. Additionally, data indicate that the as-needed use of intranasal corticosteroids is more effective for perennial allergic rhinitis than is a second-generation antihistamine.

Side effects of intranasal corticosteroids are relatively rare. The most frequent is nasal irritation, which occurs in approximately 10% of patients. This is manifested as a nasal burning sensation or sneezing. Two percent of patients have blood-tinged secretions either because of the medication or because of the delivery system. Although septal perforations have been reported, they are extremely rare. Nasal biopsies after prolonged use of these agents have not shown thinning of the nasal epithelium or abnormalities in the nasal mucosa. Mucosal superinfection with Candida albicans, occasionally found with the use of topical, orally inhaled corticosteroids in the treatment of asthma, has not been a significant problem in the nose.

Systemic side effects have long been a matter of concern. Preparations now available on the market have lower systemic absorption than did older preparations; and, at the standard doses used for the treatment of allergic rhinitis, no detectable effects on the hypothalamic-pituitary-adrenal axis have been found. A reduction in bone growth in children has concerned pediatricians. This problem has been studied best in asthmatic children, in whom the majority of studies suggest no effect and in whom they are confounded by the effect of asthma itself on growth. Therefore, for long-term use, a topical corticosteroid with low bioavailability, administered in the lowest dose necessary to provide relief of symptoms, seems advisable and safe. In children, the rate of growth was reduced slightly in those regularly treated twice a day with intranasal beclomethasone over 1 year. No such effect was observed in 1-year follow-up studies of children.
Evidence suggests that intranasal corticosteroids help reduce ocular symptoms of allergic rhinitis. This approach may have advantages regarding compliance and cost.212,213

Studies on intranasal corticosteroids have shown that the properties of individual product may influence the preference of the patients. A multicenter study has shown that, compared with fluticasone and mometasone (original formulation), triamcinolone acetonide aqueous was associated with better product attributes, higher preference, and better compliance.214 Melzler and colleagues reported that scent-free mometasone furoate nasal spray (current formulation) was preferred over fluticasone propionate nasal spray by patients based on the sensory attributes that were tested.215

**Systemic Corticosteroids.** Clinical practice suggests that oral corticosteroids reduce symptoms during seasonal allergies, but this has not been documented in patients with allergic rhinitis in placebo-controlled trials.216 In a placebo controlled trial of patients with nasal polyposis and atopy, clinically significant improvement was observed in patients who received oral corticosteroids for 2 weeks and no significant adverse events were observed.217

These agents are usually administered to patients during severe exacerbations of allergic symptoms, when total nasal obstruction prevents the introduction of a topical intranasal corticosteroid. Furthermore, these agents are used successfully in combination with antibiotics for treatment of sinus infections complicating allergic rhinitis. Depot injections of corticosteroids have efficacy comparable with that of short-term oral prednisone therapy but have a longer duration of action and enjoy some popularity in Europe, including Scandinavia.218

**Cromolyn Sodium.** Cromolyn, which is available over the counter as a 4% solution for intranasal use, has been shown to be clinically effective in the treatment of allergic rhinitis. It exerts a protective effect on the allergic response when given 4 to 6 times daily beginning before the development of symptoms. Although it was initially thought to prevent mast cell degranulation, the exact mechanism of action of this agent is unknown. Like antihistamines, cromolyn is more helpful in treating rhinorrhea and nasal itching than for nasal congestion. Its safety profile, however, makes it an attractive treatment, especially in children and pregnant women.219 When effective, the potency of this agent parallels that of antihistamines but is less than that of intranasal corticosteroids.220

**Anticholinergics.** Ipratropium bromide is the only anticholinergic agent available for topical use in the United States. Anticholinergic agents inhibit parasympathetic stimulation of glandular secretion by competing for muscarinic receptors on glands. They are highly effective in reducing rhinorrhea, but they have no effect on the other symptoms of allergic rhinitis. The clinical benefit of anticholinergic agents is primarily limited to the treatment of patients with rhinitis in whom rhinorrhea is the predominant complaint. This could occur in a variety of nasal conditions such as allergic and nonallergic rhinitis, as well as the rhinorrhea precipitated by exposure to cold, windy environments, often referred to as “skiers’ nose.”221 The dosage should be titrated to avoid excessive drying of the nasal mucosa and epistaxis, which are the most frequent side effects. This agent serves as a useful adjuvant therapy in combination with topical corticosteroids and antihistamines for control of rhinorrhea. It is also
Leukotriene Modifiers. Recognition of the importance of leukotrienes in the pathogenesis of asthma has led to the development of leukotriene modifiers. Controlled clinical trials with the 4 currently used leukotriene modifiers (montelukast, zafirlukast, and zileuton in the United States and pranlukast in Japan) have established their efficacy in improving pulmonary function, reducing symptoms, decreasing night-time awakenings, and decreasing the need for rescue medications in patients with asthma.

A mong the many mediators in the nose, leukotrienes were detected both in the early and late phase of an allergic reaction. Leukotrienes stimulate mucous glands, which result in rhinorrhea, and they also have the ability to increase microvascular permeability and blood flow that result in tissue edema and subsequent congestion. Introduction of leukotriene modifiers increased the therapeutic options for patients who have allergic rhinitis without asthma.

Montelukast is the only leukotriene modifier that has been approved in the United States to be used for the symptoms of seasonal and perennial allergic rhinitis. Montelukast is a cySLT1 receptor antagonist that inhibits the physiologic actions of LTD4. It is rapidly absorbed after oral administration. The mean plasma concentration is achieved in 3 hours. The drug dose should be 10 mg, taken once daily. Montelukast is a safe and well-tolerated drug with adverse effect profiles similar to those of placebo.

The efficacy of montelukast for the treatment of allergic rhinitis has been evaluated in several randomized double-blind trials. Montelukast significantly improved night-time symptoms (difficulty going to sleep, night-time awakenings, and congestion on awakening), as well as daytime symptoms (congestion, rhinorrhea, pruritus, and sneezing), compared with placebo in patients with allergies. A meta-analysis of randomized controlled trials revealed that leukotriene receptor antagonists are modestly better than placebo, as effective as antihistamines, but less effective than nasal corticosteroids in improving symptoms and quality of life in patients with seasonal allergic rhinitis.

In a comparative study, pseudoephedrine showed an efficacy equivalent to that of montelukast in decreasing symptom scores and increasing nasal airflow in subjects with seasonal allergic rhinitis. A recent study in children between 2 and 6 years of age revealed that montelukast is as effective as cetirizine in quality of life symptom scores. For night sleep quality, montelukast was superior to cetirizine.

Combined montelukast and cetirizine treatment started 6 weeks before the pollen season was effective in preventing symptoms of allergic rhinitis, and it reduced the allergic inflammation in the nasal mucosa during allergen exposure. Comparison of the effectiveness of intranasal corticosteroid treatment with that of the combination of an antihistamine and leukotriene inhibitor in the treatment of seasonal allergic rhinitis showed that in the intranasal-corticosteroid group, symptom relief was better. A study comparing the fexofenadine-pseudoephedrine combination with that of loratadine-montelukast showed comparable efficacy in improving symptoms, quality of life scores, and nasal obstruction in subjects with seasonal allergic rhinitis. The effects of fexofenadine alone or a combination of fexofenadine with montelukast were significantly better than placebo; however, combination therapy conferred no additional benefit. A randomized clinical trial comparing the clinical efficacy of fluticasone propionate nasal spray administered alone with fluticasone plus cetirizine or fluticasone plus montelukast showed that fluticasone is highly effective in the treatment of patients with allergic rhinitis, with efficacy exceeding that of cetirizine plus montelukast in combined therapy. Thus, the combined therapy of fluticasone with cetirizine or montelukast has not offered any substantial advantage over fluticasone in monotherapy.

Ophthalnic Preparations. Treatment of ocular symptoms of allergy employs a regimen of medications similar to those used for nasal manifestations. After avoidance of allergens, pharmacotherapy includes the use of topical decongestants, antihistamines, mast-cell stabilizing agents, and anti-inflammatory preparations. Topical decongestants such as phenylephrine and tetrahydrozoline decrease vascular congestion and eyelid edema through α-adrenergic receptors. Several over-the-counter topical antihistamines are available, some in combination with a decongestant. Recently, second-generation topical antihistamines have become available. Levocabastine is a long-lasting topical antihistamine with rapid onset of action that has been shown to be effective for ocular allergies. Azelastine is approved for the treatment of allergic conjunctivitis. Emepastine and olopatadine are topical agents which have also been shown to be effective. Ophthalmic formulations of ketotifen fumarate, premasturtor potassium, olopatadine, and nedocromil sodium are agents with mast-cell-stabilizing properties. Ketotilarol, a nonsteroidal anti-inflammatory agent, diminishes ocular itching and hyperemia and is the only agent in this class approved by the FDA for treatment of allergic conjunctivitis. M lid topical corticosteroids can be utilized in patients who continue to have symptoms despite treatment with the aforementioned agents, but these can cause local complications.

Immunotherapy. Allergen-specific immunotherapy is a very effective method of treatment in carefully selected patients with allergic rhinitis. The treatment is the only treatment that can lead to a life-long tolerance. The mechanisms underlying the success of immunotherapy are slowly becoming elucidated. Immunotherapy mechanisms, circulating antibody responses were examined. Immunotherapy with inhalant allergens is associated with increases in serum allergen-specific IgE, IgG4, and IgA levels.

Immunotherapy with inhalant allergens is associated with increases in serum allergen-specific IgE, IgG4, and IgA levels. More recently, the focus has been on T-cell responses. Studies show that this treatment acts on T cells to modify peripheral and mucosal Th2 responses to allergen in favor of Th1 responses.

Peripheral T-cell tolerance is crucial for a healthy immune response and successful treatment of allergic disorders. The tolerant state of specific cells results from increased IL-10 secretion. IL-10 has been shown to have numerous potential anti-allergic properties against mast cells, T cells, and eosinophils. It also promotes the production of IgG4 by B cells. The cellular origin of IL-10 was demonstrated to be Treg cells. Treg cells also produce transforming growth factor beta (TGF-β), a suppressant cytokine. Immunotherapy has been shown to reduce the development of asthma and new sensitizations in children with seasonal allergies.

Indications for immunotherapy have not been established by experimental studies but rather have evolved over years of clinical experience. The primary indication is that of symptoms not adequately controlled by avoidance measures and pharmacotherapy. Patients with perennial symptoms may prefer immunotherapy to year-long daily medication. In making their selection, patients must be advised that immunotherapy offers control of symptoms but is slow in onset and, unlike pharmacotherapy, is effective only for the allergens for which the patient is being treated. Whether successful therapy cure the patient of the disease after discontinuation of immunotherapy is an important but unanswered question. However, 1 study suggested that improvement in rhinitis symptoms persists for several years after the end of treatment.

Immunotherapy begins with low-dose injections of allergen extracts and builds to a maintenance dose. Injections usually begin at weekly intervals and are reduced in frequency when maintenance doses are reached. The choice of allergens for treatment must be made after a careful diagnostic workup so that the probability of treatment being started with extracts from all of the allergens responsible for symptoms is high. Treatment should not be given if skin or serum testing cannot confirm evidence of an IgE-mediated mechanism. Whereas excellent relief can be expected with pollen allergens, dust mites, and some animal danders, treatment with molds is less reliable. Immunotherapy with too many allergens is impractical; usually, treatment with no more than six to ten allergens is attempted. Enzymes from some allergens can destroy other antigens, reducing the expected potency of the treatment. Furthermore, combining allergens of different clinical sensitivities may interfere with reaching adequate maintenance doses for all allergens. Patients who are taking β-blockers should not receive immunotherapy because, if anaphylaxis occurs, patients cannot be resuscitated. Immunotherapy of symptomatic asthmatic patients should be administered with extreme caution because these patients have the greatest
Allergen injections should be administered under the supervision of a qualified medical practitioner, and patients should be observed for at least 30 minutes after every injection. Local reactions at the site of injection are frequent with effective dosages and require no therapy. Repeated strong reactions (e.g., swelling greater than 4 cm in diameter) persisting for 24 hours should lead to consideration of dose reduction. Proper resuscitative equipment should be present because anaphylactic reactions can occur at any time during treatment, even in patients receiving maintenance doses. Factors that seem to contribute to increased complications, including fatalities, seem to be labile, corticosteroid-dependent asthma that has required prior hospitalizations, high sensitivity to allergen (as demonstrated by serum-specific IgE tests or skin tests), and a history of prior systemic reactions. Therefore, although death from immunotherapy is uncommon, special precautions need to be taken with asthma, and a waiting period of at least 20 minutes after administration of the injection is recommended for all patients, with longer intervals (30 minutes) appropriate for high-risk patients. Results of a survey from the United States showed that fatal reactions occurred with 1 per 2.5 million injections, with an average of 3.4 deaths per year. Sixty percent of fatal reactions occurred during maintenance. The vast majority of patients were asthmatics. Twenty percent of fatal reactions occurred in a medically unsupervised setting. None of the fatal cases were receiving β-blockers. An e-mail survey of allergists regarding incorrect allergy injections (wrong patient or wrong dose) revealed that 58% of allergists observed an event in which a patient received an injection meant for another patient, and 74% of allergists reported that patients had received an incorrect amount of vaccine. The effect of these mistakes on patients resulted in 1 fatality and underscores the need for care while using this form of treatment.

**Sublingual Immunotherapy.** Sublingual administration of allergen extracts has been shown to be a well-tolerated and efficacious approach to treatment of allergic rhinitis. In the last few years, reports on the safety and efficacy of this treatment have grown enormously. In a recent meta-analysis encompassing 22 clinical studies evaluating sublingual immunotherapy (SLIT), it was concluded that this method reduces both symptoms and medication requirements. The immunologic mechanisms of SLIT are less well established. An increase in IgG4 and induction of allergen-specific IgA without a change in IgE values has been reported with SLIT. The evidence on the changes in Th1/Th2/Treg activity induced by SLIT should be confirmed. SLIT requires more allergen (at least 50 to 100 times) than does subcutaneous immunotherapy. It is rather unclear whether a dose-response relationship exists. The allergen is kept under the tongue for one to two minutes and then swallowed. If the vaccine is swallowed immediately, the clinical efficacy decreases substantially. It is now widely accepted that SLIT is much safer than subcutaneous immunotherapy, with no evidence of anaphylactic shock recorded after more than 500 million doses administered to human subjects. Adverse events are reported to be local (oral itching, swelling, and irritation) and self-resolving. Immunotherapy has to be continued for at least 3 years.

**Anti-IgE.** Omalizumab is a recombinant humanized monoclonal antibody that binds selectively to IgE. It lowers free IgE levels in the circulation. Several studies have shown that omalizumab, in addition to reducing the free IgE level in serum, is associated with an anti-inflammatory effect on cellular markers in blood and nasal tissue. It inhibits allergen-induced seasonal increases in circulating and tissue eosinophils and reduces the expression of FcεR1 on the mast cells and dendritic cells. This medication is currently available in the United States. It is indicated for patients older than 12 years who have moderate to severe asthma, who have a positive skin or in vitro test to a perennial allergen, and whose symptoms are inadequately controlled with inhaled corticosteroids. It is not approved for use in patients with allergic rhinitis.

Omalizumab is administered subcutaneously every 2 to 4 weeks. The doses and dosing...
frequency are determined by the patient’s body weight and the pretreatment serum IgE level. It has a low incidence of side effects, such as reaction at the injection site, viral infection, headache, and upper respiratory tract infection. The most serious adverse reactions reported are malignancies (0.5%) and anaphylaxis (0.1%). Omalizumab reaches a peak concentration within 7 to 8 days after subcutaneous administration and has a half-life of approximately 26 days.

In a large clinical trial on subjects with seasonal allergic rhinitis, omalizumab decreased serum-free IgE levels and provided clinical benefit in a dose-dependent fashion. It has been shown to decrease nasal symptoms and quality-of-life scores in adolescents and adults who have outdoor allergies. The efficiency of this drug compared to H1 antihistamines and intranasal corticosteroids remains to be established.

A recent study suggested that pretreatment with omalizumab increases the safety of rush immunotherapy in patients with allergic rhinitis. Co-seasonal application of omalizumab after preseasonal specific immunotherapy resulted in decreases in nasal and ocular symptoms of children who had seasonal allergies.

**Future Therapies.** As understanding of the complex immunologic pathophysiology of allergic rhinitis has developed, new targets have been surfacing for pharmacologic development. Drugs targeting several cytokines and chemokines known to play a role in the inflammatory process are being developed and tested. Classes of investigational agents that target other molecules thought to be important in the inflammatory processes of allergic rhinitis include tryptase inhibitors, phosphodiesterase-4 inhibitors, chemokine inhibitors, and adhesion receptor antagonists. A perhaps more elegant therapeutic strategy would be to effect long-lasting changes in immune responses away from an allergic phenotype. Such a strategy might alter the natural course of the disease and allow discontinuation of medication. The identification of Treg cells as key regulators of the immunologic processes involved in the peripheral tolerance to allergens has opened an important era in this regard. A crucial area for future studies is the identification of drugs, cytokines, or costimulatory molecules that induce in vivo growth of Treg cells while preserving their suppressor function.

Recombinant DNA technology has enabled the cloning of many allergens, thus facilitating investigations aimed at improving the efficacy and safety of immunotherapy. Future prospects for allergen-specific immunotherapy include reconstitution of extracts by use of recombinant allergens, reconstitution of several major allergens in 1 protein as a T-cell-directed vaccine, and peptide immunotherapy. These therapies will require further study, but ultimately may prove useful in expanding the armamentarium available against allergic rhinitis.

**Special Considerations.** Several patient populations require careful attention in the treatment of allergic rhinitis. In the case of elite athletes, preventive therapy must be initiated so that effects on peak performance can be avoided. The Olympic Committee bans pseudoephedrine-containing agents. Similarly, care must be taken in the treatment of elderly patients with respect to side effects, clearance of drugs and drug interactions. Treatment of rhinitis during pregnancy poses special problems. Rhinitis and nasal congestion frequently occur during pregnancy (30%) and are related to hormonal changes.

Pregnant patients require careful consideration in the choice of therapy. Ideally, no medication should be used, particularly during the first trimester. A avoidance measures should be implemented first. If symptoms of rhinitis interfere with maternal well-being, pharmacologic management is considered. The patient must be advised that no drug can be regarded as absolutely safe, because most drugs cross the placenta and can be measured in fetal blood.

The American College of Obstetricians and Gynecologists and The American College of Allergy, Asthma and Immunology make the following recommendations: medical treatment of allergic rhinitis should start with first-generation antihistamines. In patients who do not tolerate chlorpheniramine and tripelennamine and who fail other therapies, use of cetirizine and loratadine could be considered. Sodium cromoglycate is a safe drug during pregnancy and should be considered in the treatment of allergic rhinitis before corticosteroids. Maternal exposure to orally inhaled budesonide during pregnancy was not associated with an increased risk of congenital malformations or other adverse fetal outcomes. Data on pregnancy outcomes after maternal exposure to intranasal budesonide are limited, but the totality of evidence indicates that its safety profile is at least comparable with that of orally inhaled budesonide. Budesonide is the only intranasal corticosteroid that carries a pregnancy category B rating. Other agents such as leukotriene modifiers may be considered in women who exhibited a good response to these agents before pregnancy. Maintenance immunotherapy may be continued safely during pregnancy for patients who are not prone to systemic reactions. However, because of the increased risk of systemic reactions, immunotherapy should not be initiated during pregnancy.

**Toward a Rational Choice of Therapy.**

Pharmacotherapy remains the mainstay of the treatment of allergic rhinitis (Figure 8). If allergen exposure can be reduced, this should be a part of any long-term management. Short-term avoidance does not result in an instant resolution of symptoms and is rarely completely achievable.

Pharmacotherapy provides the fastest relief. Oral antihistamines begin to take effect within 1 hour and traditionally constitute the first line of intervention. Topical antihistamines have an even
faster onset of action. They are excellent for the treatment of sneezing and watery rhinorrhea. When cost is not an issue, nonsedating antihistamines should always be prescribed. Decongestants can be added to antihistamines in fixed combinations or as separate agents for relief of nasal congestion. Cromolyn sodium is an alternative to antihistamines as an initial treatment, but the need for frequent dosing, with the resultant reduction in compliance, should be kept in mind. Leukotriene modifiers may be utilized for effects against congestion in asthmatic or refractory patients and may be used in combination with antihistamines for patients who do not tolerate other therapies.

A according to recent guidelines, intranasal glucocorticoids are regarded as a highly effective first-line treatment for patients suffering from allergic rhinitis with moderate to severe and/or persistent symptoms. They are highly effective in reducing all of the nasal symptoms of allergic rhinitis, including congestion. They are non-sedating, have few side effects, and are well-tolerated by patients. Topical corticosteroids are given initially at the dose recommended in the Physicians’ Desk Reference. Patients should be seen 2 weeks after initiation of therapy for monitoring for the development of local side effects. Superficial septal erosions can occur secondary to trauma from the nozzle, and the application technique should be reviewed carefully with these patients. The dose is adjusted depending on the response: if a patient is doing better, but continues to have breakthrough symptoms, the frequency of administration is increased; if excellent control is achieved, the frequency or the dose should be reduced. In those doing better, but still having symptoms, other agents can be added to the intranasal corticosteroids.

Furthermore, periods of exacerbations can be predicted, based on a patient’s pattern of allergies; and, therefore, the medication dosage can be varied accordingly. Ocular symptoms may be controlled only minimally by intranasal corticosteroids and thus adding an ophthalmic preparation or an oral antihistamine may be necessary.

As children, the long-term use of certain topical corticosteroids is approved in patients as young as age 2 years or older. For most topical corticosteroids, it is recommended to give half the adult dose in young children. Because of the slight possibility that intranasal corticosteroids could interfere with growth, these medications should always be given in the lowest effective dose. Growth should be monitored carefully and regularly.

Treatment with topical corticosteroids requires patient education. The physician must often reassure patients as to the safety of intranasal corticosteroids, compared with oral preparations.

Initiation of immunotherapy depends on patient preference and the response to pharmacotherapy. It has the potential to alter the natural history of the disease.

Surgical management of nasal obstruction is presented in Chapter 45, “Acute and Chronic Nasal Disorders,” and Chapter 53, “Rhinoplasty and Septoplasty.” Septal deviations may need to be corrected because they may interfere with the delivery of intranasal medications or contribute to symptoms. Similarly, turbinate reduction by means of submucous resection, resurfacing with the laser, electrocautery, or radiofrequency ablation may be advantageous procedures in patients with allergic rhinitis but cannot often find use in the management of nonallergic rhinitis. Functional endoscopic sinus surgery, covered in Chapter 49, “Primary Paranasal Sinus Surgery” can be used for the treatment of chronic rhinosinusitis, which frequently complicates perennial rhinitis.

Epistaxis

Thomas A. Tami, MD
James A. Merrell, MD

Epistaxis is one of the most common otolaryngologic emergencies. Although the lifetime incidence of epistaxis is approximately 60%, only about 6% require formal medical intervention. Of these episodes of epistaxis, 10% can be serious and even life threatening. The nature and causes of the epistaxis vary with age. Since epistaxis may be a symptom of systemic disorders, all patients with epistaxis should undergo a careful medical evaluation.

ETIOLOGY

The causes of epistaxis are varied (Table 1), and both local and systemic factors may contribute. Several factors which have been shown to correlate strongly with epistaxis include: the season of year (winter being most common); sex (more common in males); age (epistaxis in the younger patient tends to be anterior and more minor whereas the more severe posterior epistaxis tends to be seen in those greater than 50 years of age). Hypertension is common in the older population, and while it has been associated with epistaxis, no causal relationship has been proven.1

RELEVANT ANATOMY

The nasal cavity is supplied by several arteries with extensive anastomotic connections. The primary sources include the external carotid artery with the branches being the facial artery giving off the lateral nasal and septal branches and the internal maxillary artery (IMA) giving off the sphenopalatine and lateral nasal and septal branches. There are also contributions from the posterior pharyngeal and greater palatine arteries of the external carotid system. The internal carotid artery supplies much of the superior portion of the nasal cavity via the anterior and posterior ethmoid arteries, which most often are terminal branches of the ophthalmic artery. There are 2 main areas in the nose where there are well-recognized confluences of anastomotic connections. These include the area on the anteroinferior part of the septum, “Little area” or “Kieselbach plexus,” and “Woodruff plexus” in the posterior part of the nasal cavity.

Little was an American physician who, in 1879, described 4 cases of epistaxis in which there was “an ulcer on the septum half an inch from the lower edge of the middle of the columnella.” Subsequent anatomical studies have clarified the anatomic detail of the anterior part of the nasal septum. Clearly demonstrating that in most cases there were 3 dominant arteries supplying this region forming an anastomotic triangle of large thin-walled vessels as a dominant arterial arcade in the anterior part of the septum. The feeding arteries were found to be the middle septal branch of the sphenopalatine artery (SPA) posteriorly, the anterior ethmoidal artery from above and the superior labial branch of the facial artery anteriorly. The anastomotic vessels of the anterior septal triangle also seemed to be thinner-walled compared to the feeding arteries2 (Figure 1).

Posteriorly on the lateral nasal wall is the area known as Woodruff plexus at the posterior end of the inferior turbinate where the sphenopalatine and posterior pharyngeal arteries anastomose. Ninety percent of the nasal mucosa receives its blood supply via the SPA.3 The SPA enters the nasal cavity through the sphenopalatine foramen located on the lateral nasal wall within the superior meatus, usually, between the middle turbinate and the posterior horizontal end of the lamella of the superior turbinate (Figure 2). Generally this is just above the posterior end of the horizontal lamella of the middle turbinate and just posterior to the ethmoid crest off the perpendicular plate of the palatine bone. The sphenopalatine foramen is bordered superiorly by the body of the sphenoid, the anterior border is the orbital process of the palatine bone, the sphenoidal process of the palatine bone forms the posterior border, and the inferior border is the perpendicular plate of the palatine bone. In most cases the SPA divides into 2 major branches. These 2 major branches are the nasal septal branch and the posterior lateral nasal artery. The nasal septal artery crosses the lower portion of the anterior wall of the sphenoid sinus and runs toward the septum within the mucosa. It then supplies most of the posterior septum. This artery may cause profuse arterial bleeding if it is damaged when performing a sphenoidotomy since it usually lies just inferior to the sphenoid ostium. The posterior lateral nasal artery supplies the majority of the mucosa of the lateral nasal wall. It courses downward on the perpendicular plate of the palatine bone giving off major branches to the inferior and middle turbinates. Occasionally, the branch to the superior turbinate arises from the septal artery.4,5

The nasal cavity also receives blood supply via the anterior and posterior ethmoid arteries. These are branches of the opthalmic artery of the internal carotid system. The anterior ethmoid supplies much of the anterior portion of the nasal cavity including both the septum as well as the anterior part of the lateral nasal wall. The posterior ethmoid supplies part of the superior turbinate as well as portions of the septum. Both arteries anastomose with end branches of the SPA and with the sublabial artery arising from the facial artery. The anterior and posterior ethmoid arteries are terminal branches of the ophthalmic artery. They exit the orbit medially at the superior portion of the lamina papyracea at the level of the cribiform plate through foramina in the frontoethmoid suture. There is

variation in the exact locations of the foramina; however, the anterior ethmoid artery is generally found approximately 13 to 18 mm posterior to the frontomaxillolacrimal suture, and the posterior ethmoid artery is another 10 to 13 mm posterior to the anterior and is only about 4 to 7 mm anterior to the optic nerve. The ethmoid arteries then traverse the superior portion of the ethmoid air cells along the roof and supply the superior portion of the nasal cavity.

**CLINICAL AND LABORATORY EVALUATIONS**

The approach to the patient with epistaxis begins with the initial evaluation. If bleeding has been profuse, the patient may present in a state of shock and will require resuscitation according to well-established principles for the treatment of hemorrhagic shock. With the patient stable, it is important to first elicit the nature and history of the epistaxis. Essential historical information includes: when it began, duration of bleeding, frequency, inciting factors, and previous attempts, whether successful or not, at control of the bleeding. A thorough history should be obtained to detect the presence of comorbid conditions such as coronary artery disease, diabetes, and hypertension. Patient medications can also have an impact on the etiology and successful epistaxis management. Not only prescribed medications, for example, coumadin, nonsteroidal anti-inflammatory agents, or antiplatelet drugs, but some over-the-counter and herbal preparations can also impact clotting, for example, ginkgo, garlic, ginseng, high-dose vitamins A and E, and high doses of fish oil and flaxseed oil. It is also essential to obtain a family history as certain inheritable conditions may predispose to epistaxis such as the hemophilias and related coagulopathies, and hereditary hemorrhagic telangiectasia (HHT). A social history may lead to important clues, especially such findings as alcohol or intranasal drug usage.

Once a thorough history has been obtained, a full head and neck examination is essential as it would be unwise to be so focused on the nasal examination as to miss such things as a neck mass or a unilateral tympanic membrane retraction or hemotympanum. The nasal examination should be undertaken with prior preparation. It would be wise to be prepared to intervene prior to beginning the examination. Table 2 provides a list of supplies which might be useful (Figure 3).

Nasal evaluation should begin by observing the external nose. Important signs found here might include evidence of trauma and side of anterior bleeding. Anterior rhinoscopy with a nasal speculum and headlight will commonly reveal a bleeding source on the anterior nasal septum, evidence of anterior septal trauma (as after digital manipulation), an eschar, a nasal septal perforation, or dilated vessels. Many studies recently have highlighted and demonstrated the importance of endoscopy in accurate diagnosis since the most important factor in determining and effectively treating epistaxis is visualization of the offending vessels. Thorough intranasal endoscopic evaluation is best performed following adequate local anesthesia and the topical application of a vasoconstrictive agent such as oxymetazoline. An additional maneuver which assists to anesthetize the nasal cavity and may also be therapeutic is transoral greater palatine nerve block by injecting 1 to 2 mL of local anesthetic containing epinephrine through the greater palatine foramen in the roof of the hard palate into the pterygopalatine fossa. In addition to providing anesthesia to the posterior nasal cavity and septum, it also serves to tamponade the IMA. As many as 20% of nosebleeds are from a posterior origin where the use of nasal endoscopy is particularly important. Epistaxis from a posterior source is more likely

Treatment can be classified from least invasive to most invasive. As a part of the physical examination, the source of the bleeding should have been identified. This step is clearly the most important aspect of determining the most proper treatment.

Medical management consists of nasal pressure initially, having the patient hold the nose putting pressure on the anterior septum. A frequently useful adjunct procedure is to add oxymetazoline or phenylephrine as a vasoconstricting agent. By the time they have come to the attention of an otolaryngologist, this has usually already failed to stop the acute hemorrhagic process or the problem has become recurrent or chronic in nature.

**Medical Management**

For the chronic recurrent epistaxis, the most commonly used medical management is the application of a moisturizing or humidifying agent to prevent desiccation. A recent study in the pediatric population showed that when patients were treated with nasal emollients alone, 61% of those who used the emollients had resolution by the first follow-up appointment. Commonly used agents include nasal saline mist, nasal saline gels, irrigation, foam, petrolatum-based ointments, use of room humidifiers, and essential oil emollients. By definition, when these conservative measures fail, a patient is said to have intractable epistaxis. At this point, it is likely that another, more invasive step will need to be undertaken.

For the acute hemorrhagic process, the initial step will be to identify the bleeding vessel as described above. If the bleeding cannot be controlled adequately to identify the source of bleeding, measures will be needed to tamponade the bleeding. This generally means some form of nasal packing. Traditional methods of nasal packing include use of an inflated Foley catheter or gauze roll in the nasopharynx for a posterior pack with layered petroleum, based ointment, coated gauze packed anteriorly. Other methods of anterior-posterior packing include inflatable premade fabricated balloon devices with separate anterior and posterior inflation chambers. The Merocel nasal pack (Medtronic ENT, Jacksonville, FL) is a hydroxylate polyvinyl acetate material which expands when it comes in contact with water. Merocel has become quite popular as an easy to use, readily available product and has become readily available in most emergency departments.

While nasal packing has traditionally been considered noninvasive, conservative therapy, this has recently been challenged. A posterior-posterior packing carries significant risks and a high failure rate. Risks have been well-documented in the literature. First of all, the procedure itself is extremely uncomfortable and is accompanied by nasal obstruction, gagging, pain, and dysphagia. Nasal packs have traditionally been felt to be associated with the nasal pulmonary reflex which decreases pulmonary ventilation causing hypoxia as well as possibly arrhythmia, hypoxemia, and death. While most otolaryngologists still consider this to be a risk of posterior nasal packing, recent evidence questions the validity of this phenomenon.

A major risk is septum perforation, and minor risks include alar necrosis, serous otitis media, local infections, acute sinusitis, and septal perforation. A side from the risks, the success rate is generally poorer than for the more invasive techniques, with a failure rate approaching 40%. When the cost of keeping a patient in the hospital for several days in a monitored bed is compared to surgery or embolization, it has also been found to not be cost effective.

A further potential complication of nasal packing is toxic shock syndrome (TSS). TSS is caused by a toxin which is released by either coagulase-positive staphylococci (Staphylococcus aureus) or group A beta-hemolytic streptococci (Streptococcus pyogenes). Although TSS has traditionally been associated with use of super-absorbent tampons in menstruating women, it has also been described with nasal packing. The typical presentation for TSS includes: fever and chills, diffuse watery diarrhea with abdominal pain, light-headedness and syncope, myalgias and arthralgias, pharyngitis, headache, and confusion. Physical findings may include: fever (>102°F), hypotension (systolic BP <90 mmHg), diffuse rash appearing on trunk, spreading to arms and legs involving palms and soles with subsequent desquamation 1 to 2 weeks later. Multorgan involvement may include ventricular arrhythmias, renal or hepatic failure, disseminated intravascular coagulation, and acute respiratory distress syndrome.

Treatment includes parenteral antistaphylococcal and antistreptococcal antibiotics, removal of offending packing and intensive supportive care, often in a critical care setting so that aggressive fluid resuscitation, monitoring, and specific treatment for affected organ systems can be provided.

**Hemostatic Agents.** Various hemostatic compounds have also been used in an attempt to avoid the discomfort and morbidity associated with nasal packing. A nontitibrolinatory agents such as epsilon amino caproic acid and tranexamic acid have both been shown to be somewhat effective, especially in HHT; however, their use (both systemically and topically) has not been widespread. More recently, biodegradable hemostatic sealant compounds have been introduced as hemostatics. One of these, Floseal (Baxter Health Care Corp, Deerfield, IL) is composed of collagen particles and topical bovine thrombin applied as a high viscosity gel. This easy to apply material has recently been shown to compare quite favorably with nasal packing in terms of efficacy and was much better tolerated by the patients. Treatment using this agent was, however, much more expensive than either merocel or petroleum gauze.

**Surgical Treatment and Embolization**

When conservative measures fail to control epistaxis, more invasive means are then usually undertaken. Where available, embolization of...
the offending arteries by means of interventional radiology can be effective. Comparisons of embolization versus surgery show success rates of embolization to be 71 to 100% with an average of 88% and for surgical treatment approximately 87 to 100% averaging about 90% in various reports. However, this expertise and associated equipment is not universally available. In one study, only 11% of otoaryngologists in nonurban regions in Ohio had access to interventional radiology.  

Cost effectiveness has also been looked at and seems to vary by institution. The cost of embolization has been found to be higher in some institutions than surgery, whereas it is lower in others.

While embolization may be both efficacious and cost effective, serious complications have been reported during these endovascular procedures. These include internal carotid artery intimal injury requiring anticoagulation, soft tissue necrosis, facial paralysis, myocardial infarction, blindness, and stroke.

Traditionally, surgical treatment has consisted of ligature of the ethmoid, internal maxillary or the external carotid arteries. More recently endoscopic approaches have been successful. Even before ligation of the SPA is considered, endoscopic examination of the nasal cavity, usually under general anesthesia, can allow the surgeon to locate the exact site of bleeding (usually the lateral nasal wall or posterior nasal septum) and selectively cauterize these areas (bipolar diathermy or monopolar suction cautery). This can be a highly effective approach and essentially applies the same principles previously available for anterior epistaxis to the otherwise more challenging and refractory posterior bleeding.

When the bleeding continues despite conservative measures, more invasive surgical approaches may be necessary. The traditional surgical approach is ligation of the internal maxillary and the anterior and posterior ethmoid arteries. The IMA is traditionally managed via a sublabial transantral approach. By accessing the pterygomaxillary space through the posterior wall of the maxillary sinus, the IMA can be identified, dissected and ligated with vascular clips. Recurrent bleeding following IMA ligation is usually attributed to failure to ligate all of the distal branches of the IMA. The more proximally the vessel is ligated, the more likely there will be unrecognized collateral branches that can contribute to continued bleeding. Thus, arterial ligation closer to the actual site of bleeding will produce a better likelihood for success. This is 1 reason that SPA ligation has come to be favored as a surgical approach for refractory posterior epistaxis. The endoscopic approach to this vessel has become a preferred surgical technique and is quickly becoming the standard surgical treatment forrecalcitrant posterior epistaxis.

The procedure begins with decongestion and local anesthesia as routinely performed prior to functional endoscopic sinus surgery. Next a middle-meatal antrostomy can be performed, but is usually not necessary. A mucosal incision is made on the lateral nasal wall beginning just above the posterior part of the attachment of the inferior turbinate and extending anterior and superior just anterior to the attachment of the middle turbinate. Using this incision, a mucoperiosteal flap is elevated on the lateral nasal wall and continued until the crista ethmoidalis is encountered. The SPA is immediately posterior to this landmark as it exits the pterygopalatine fossa through the sphenopalatine foramen (Figure 4). A fer carefully identifying and dissecting this vessel, it should be ligated using surgical clips and then divided. Dissection posterior to this vessel will often reveal a second branch of the SPA which may exit through a separate foramen. Since this usually gives rise to the posterior nasal artery, it should be bipolar cauterized. Mobilizing and surgically clipping this artery is often quite difficult.

Ethmoid artery ligation may also be necessary, particularly for those with continued bleeding despite IMA or SPA ligation, or those with a bleeding site identified in the superior nasal cavity, whether on the septum or lateral nasal wall superior to the middle turbinate. This is usually performed through a standard external medial canthal Lynch incision. The anterior ethmoid artery is difficult to access safely through an endoscopic approach.

**HEREDITARY HEMORRHAGIC TELANGIECTASIA**

HHT, also known as Osler-Weber-Rendu syndrome is an autosomal dominant disease characterized by localized angiodysplasia, often manifested as dermal, mucosal, visceral, pulmonary, and cerebral arteriovenous malformations (AVM's). The prevalence has been found to be from 1 in 5,000 to 1 in 10,000. The penetrance also increases with age more than ninety percent being symptomatic by the age of 21 years. It is incurable and progressive. Epistaxis is the most common presenting symptom, and it occurs in over 90% of individuals with HHT and becomes more frequent with increasing age. The vessels affected by this disorder are characterized as being thin-walled, dilated, postcapillary venules in the submucosa. They are frequently 1 to 2 mm in diameter and are characterized by a loss of elastic membrane in arterioles without a complete muscular layer. As the disease progresses, the capillaries become dilated and the arterioles become involved, arteriovenous shunts develop (Figures 5 and 6).

Genes which have been found to be mutated in HHT include **Endoglin (ENG)** and **Alk1**, which have been localized to chromosomal loci 9q33 and 12q11 respectively. Other genes which have also associated with HHT include **MADH4** on 18q21, **BMPRII** on 2q33, and a third locus on 5q31. A common feature of HHT mutations is an endoglin deficiency in endothelial cells. These genes appear to play a role in transforming growth factor-beta signaling pathways which affect endothelial cell proliferation and migration.
leading to dysregulation in the organization of the capillary network, disorganized cytoskeletons which are prone to cell breaking with changes in shear stress and blood pressure.18

Currently, the clinical diagnosis of HHT is made by the Curação criteria (Table 3). A definitive diagnosis requires at least 3 of these 4 criteria. A suspected diagnosis based on having at least 2 of the 4 symptoms of the Curação criteria, should prompt further investigation searching for pulmonary, cerebral, and gastrointestinal vascular malformations.19 Pulmonary AVMs may occur in up to 33% of patients and cerebral AVMs in 11%. Although any AVM can present with hemorrhage, the presentation for most pulmonary AVMs results from blood shunting through these abnormal vessels and causing transient ischemic attacks, embolic strokes, or cerebral hemorrhage. Cerebral AVMs may present with anything from seizure to cerebrovascular accidents, or cerebral hemorrhage.20 All patients with HHT, as well as their first-degree relatives, should be routinely screened for pulmonary AVMs using chest computed tomography scans, and for intracranial AVMs using brain magnetic resonance imaging with and without gadolinium.

Treatment is primarily focused on prevention and treatment of the recurrent epistaxis. Conservative measures begin with regular nasal mucosal care using nasal saline and emollient preparations. The second line and mainstay of treatment is endonasal Nd:YAG or KTP laser treatments at regular intervals as needed based on bleeding frequency. A regular schedule of laser treatments along with meticulous nasal care can dramatically reduce the frequency of epistaxis. Kühnel and colleagues were able to improve their patients in this manner from at least daily epistaxis to an average of every 7 to 14 days.21

When these treatments fail, there are a number of surgical options. Septodermoplasty has previously been the treatment of choice. This was first described in 1960 by Saunders as a method for permanent control of epistaxis.22 This involves removal of nasal mucosa, usually including the inferior turbinates, and replacing it with epidermal grafts. While this generally works well, vascular ingrowth and nasal drying can often result in recurrence of bleeding. The ultimate procedure for control of epistaxis is to permanently close the nasal cavities, the so called Y oung, or modified Young procedure.23 This procedure does appear to be effective; however, it has the obvious disadvantage of loss of the nasal pathway, which is especially problematic during sleep. An interesting recent study examining quality of life following various treatment protocols for HHT suggested that the modified Young procedure has a high degree of acceptance by patients so treated.24

Acute and Chronic Nasal Disorders

Valerie J. Lund, MS, FRCS, FRCS(Ed)

There is a wide range of acute and chronic conditions which may affect the nose, either arising locally or occurring as part of systemic disease. These may broadly be divided into allergic and nonallergic, and there are a number of etiologic factors and differential diagnoses which should be considered (Tables 1 and 2). This chapter will consider some of the infectious conditions, the nonallergic, noninfectious diseases, and a number of other conditions which enter into the differential diagnosis of patients presenting with nasal symptoms. From an anatomical and physiological perspective, the nose is rarely affected in isolation, and the majority of conditions impact on the adjacent paranasal sinuses to a greater or lesser extent. Thus the term “rhinosinusitis” has been agreed as the term to describe these conditions. Secondary symptoms related to nasal symptoms such as headache and/or facial pain. However, a careful history will usually suggest the diagnosis. A thorough general medical history should be followed by questions specific to rhinoologic symptoms including information on environmental and occupational factors and family history. The frequency, duration, and severity of symptoms should also be discussed and a visual analogue score can be used to semiquantify severity by simply asking the patients to mark on a 10 cm line where they feel they lie for a particular symptom during the last week. This method can be repeated on each subsequent visit with the patients acting as their own controls. Consistent obstruction on the same side suggests a polyp, structural problem or more rarely a tumor or even a congenital unilateral choanal atresia. Hyposmia and anosmia are most often associated with nasal polyps or more severe disease such as Wegener granulomatosis or sarcoid. Secondary symptoms related to blockage of the airways include frequent sore throats, dryness of the mouth, and oropharynx, a hyponasal quality to the voice and snoring. A full drug history may also give a clue to the source of the problem. Symptoms specific to particular conditions are discussed in the relevant sections.

Investigation

A considerable number of tests and procedures are now available for the investigation of sinonasal disease (Table 3). However, not all are routinely available nor indeed applicable to each individual patient, and their selection will depend upon clinical indicators and local factors.

The quantity and quality of secretion should be noted, both the viscosity and color and specimens may be taken for a nasal smear. Similarly under endoscopic control, a swab may be taken from the middle meatus which provides a reasonable correlation with the bacteriology of the dependent sinuses.

The appearance of the mucosa rarely alters in a way that is pathognomonic for a particular disease. However, it is usually reddened in acute infections and overuse of topical medications, whereas a typical allergic mucosa appears pale and swollen. In granulomatous conditions such as Wegener granulomatosis and sarcoid, the mucosa is generally reddened, friable, and associated with crusting and evidence of previous epistaxis. A careful examination of the nasal cavity should reveal polyps, tumor, foreign bodies, or septal deflections, although it is important that the unwary examine beyond the deflection wherever possible as secondary pathology may be present and go unnoticed. The presence of a septal perforation should raise the possibility of cocaine abuse, previous surgery, or one of the systemic granulomatous diseases, although most often is “idiopathic” resulting from minor or repeated trauma.

Physical examination should not be confined to the nose alone and should be accompanied by a full otorhinolaryngologic examination, posterior rhinoscopy, indirect laryngoscopy, and palpation of the neck in selected cases. It should also be remembered that many conditions affecting the nose and sinuses also affect the lower respiratory tract which may be revealed by appropriate examination. Detailed information regarding imaging can be found in Chapter 41, “Imaging of the Nasal Cavities, Paranasal Sinuses, Nasopharynx, Orbits, Infratemporal Fossa, Pterygomaxillary Fissure, and Base of Skull,” and allergy in Chapter 43, “Allergic Rhinitis.”

MUCOCILIARY FUNCTION

Nasal Mucociliary Clearance

A simple test of mucociliary function can be performed by placing a 0.5 mm piece of saccharin on the anterior end of the inferior turbinate approximately 1 cm from the end to avoid areas of squamous metaplasia. The time taken to taste something sweet in the mouth is measured which normally takes 30 minutes or less. If longer than an hour has elapsed, it is worth repeating the test in case the particle has fallen out and checking that the patient is capable of tasting saccharin.

Ciliary Beat Frequency

When the saccharin test is prolonged or if specific ciliary abnormalities are suspected, it is possible to examine the cilia directly by taking a sample with a small disposable cupped spatula (Rhino-probe, Arlington Scientific, Arlington, TX) and observing cilia activity under a phase-contrast microscope with photometric cell. The frequency can be measured with a real time analyzer and expressed in hertz, the normal range from the inferior turbinate being 12 to 15 Hz. However, this technique is not available in every center.

Electron Microscopy

If the nasomucociliary clearance time and ciliary beat frequency are abnormal, samples may be obtained with the spatula or via biopsy for electron microscopy studies to diagnose conditions such as primary ciliary dyskinesia (PCD).

Nitric Oxide

Nitric oxide (NO) is found in the upper and lower respiratory tract and is a sensitive indicator of inflammation and ciliary function. The majority of NO is made in the sinuses (chest <20 ppb [parts per billion], nose 400 to 900 ppb, sinuses 20 to 25 ppm [parts per million]). In PCD the NO is much reduced to double figures or less in the nose and to single figures from the chest. However, as NO is predominantly produced in the sinuses, conditions such as nasal polyposis which obstruct gas exchange from these areas can also result in a low reading from the nasal gases. The level is commensurately elevated in the presence of inflammation and may be improved by medical and surgical therapy.

NASAL AIRWAY ASSESSMENT

Nasal Expiratory or Inspiratory Peak Flow

Nasal expiratory or inspiratory peak flow (NIPF) is a technique which uses a peak flow meter and has the advantage of being inexpensive, quick and easy to perform. It is useful for repeated examinations and compares well with active anterior rhinomanometry. Of the two methods, forced inspiration is preferred although it can produce significant vestibular collapse in some individuals. Forced expiration inflates the eustachian tube, which may be uncomfortable and may also produce an unpleasant quantity of mucus in the mask.

Rhinomanometry

Rhinomanometry attempts to measure nasal airflow resistance by making quantitative measurement of nasal flow and pressure. It employs the principle that air will only flow through a tube when there is a pressure differential passing from areas of high to low air pressure. When the nasal mucosa is decongested, the reproducibility of rhinomanometry is good, but it requires some expertise to produce consistent results and has therefore remained primarily a research tool. A ctive anterior rhinomanometry is more commonly used as the posterior technique cannot be used in 20 to 25% of individuals due to an inability to relax the soft palate.

Acoustic Rhinometry

With the acoustic rhinometry technique an audible sound pulse is electronically generated and is passed into the nose where it is altered by variations in the cross-sectional area. The reflected signal is picked up by a microphone and analyzed allowing determination of the area within the nasal cavity as a function of distance. From this, volumes may be derived, thus providing topographical information rather than a measure of airflow. It appears to be more reproducible and to have greater applicability than rhinomanometry but is still being evaluated as a clinical tool. Nasal airflow measurements are discussed in greater detail in Chapter 40, “Assessment of Nasal Function.”

OLFACTION

Olfactory Thresholds

Estimation of olfactory thresholds may be established by presentation of serial dilutions of pure odorants such as PM-carbinol (phenylethyl methyl ethyl carbinol, Olfacto-Labs, El Cerrito, CA). The patient is presented with two bottles, one containing only the diluent solution as the control, the other the odorant in progressively increasing or decreasing concentrations. Each is sniffed in turn until a point is reached when the patient cannot distinguish between the control and test bottle. This indicates the minimum detectable odor.

Scratch and Sniff Tests. The scratch and sniff tests use patches impregnated with microencapsulated odorants. The patient is forced to choose between a number of options after scratching the patch to release the odor. The results are well validated for age and sex and take into account answers guessed correctly as well as giving an indication of malingering.

Alternative identification tests include the Zurich Smell Test in which eight odorants must be correctly identified. The test choices are offered pictorially as well as in English. The “Sniff ‘n’ Sticks” combine both a qualitative and quantitative assessment of olfaction. Testing of the sense of smell is discussed in greater detail in Chapter 38, “Olfaction and Gustation.”

BLOOD TESTS

A wide range of haematological investigations may be appropriate given the suspected differential diagnosis, for example, thyroid dysfunction, Wegener granulomatosis, sarcoid, and immune deficiency.

INFECTIOUS RHINITIS

The separation of infections in the nose from those in the paranasal sinuses is now recognized as incorrect, and it is generally accepted that the term “rhinosinusitis” better encompasses infections in this region, although one area may be affected to a greater or lesser extent. This was supported by the work of Gwaltney and colleagues who have demonstrated with computed tomography (CT) scanning that during a simple
uncomplicated viral cold, the majority of subjects have some involvement of the paranasal sinuses. A long list of causative agents can produce infection in this region (Table 4) (see Chapter 42, “Etiology of Infectious Diseases of the Upper Respiratory Tract,” for more information on infectious agents).

Etiologic Factors

A number of congenital conditions may predispose patients to infection of the respiratory tract.

Primary Ciliary Dyskinesia. Some individuals are born with a congenital abnormality of the cilia which affects their motility, and this is termed PCD. Electron microscopic examination reveals disorganized microtubules and the absence of dynein arms. In addition to nasal problems, patients usually exhibit lower respiratory tract infection, serous otitis media, and infertility problems. In the full blown Kartagener syndrome patients have bronchiectasis, sinus infection, and situs inversus in approximately 50% of cases.

Cystic Fibrosis. Cystic fibrosis is an autosomal recessive disease, the most common inherited fatal disease of Caucasian children, caused by a defective mucosal chloride transport gene. In its most severe form, it presents with malabsorption and progressive obstructive pulmonary disease; and approximately one-third of children and one-half of adults suffer from multiple bilateral nasal polyps and the majority of patients have a chronic pansinusitis (Figure 1). The polyps have been attributed to an abnormality of sodium and water transport across membranes, and the histology of the polyps differ significantly from those in other conditions having less eosinophils and more lymphocytes and plasma cells. Pseudomonas aeruginosa is commonly found in association with the sinus disease and may be targeted specifically with appropriate antibiotics such as the quinolones. The majority of patients are managed by a combination of medical therapies with intranasal corticosteroids and surgery. The results of surgery are compromised by the condition but are still regarded as worthwhile by patients. Other medical therapies have included intranasal furosemide and/or amiloride.

Viral Infections

The most obvious and frequently occurring example of infection is the common cold. A number of viruses are associated with upper respiratory tract infections of varying degrees of severity including over 100 different types of rhinovirus. This combined with the ability of viruses for mutation has so far confounded attempts at prophylactic immunization. Most young adults suffer from 2 to 3 colds each year, and it is estimated that 0.5 to 2% of these become bacterially infected. Predisposing factors such as climatic and environmental changes, fatigue, and stress have all been implicated but, the huge variety of viruses make it unlikely that there is preexisting immunity and as a consequence most individuals are susceptible most of the time. The virus is normally transported into the nose by direct contact with the fingers rather than by air-borne contamination; and, once the virus gains access to the respiratory epithelium, it will produce ciliary stasis and damage to the cilia. The condition is characterized by edema, increased secretion and desquamation of respiratory epithelium.

Clinically after 1 to 3 days incubation, a prodromal or “dry” phase follows. The subject feels unwell and shivery with a headache, myalgias, and loss of appetite while the nose feels irritated and sneezing occurs. The catarrhal phase follows after a few hours accompanied by profuse watery secretion, nasal obstruction, reduced sense of smell, and an increase in constitutional symptoms. The infection then enters a mucous phase in which symptoms improve or may continue after 5 days due to secondary bacterial infection with a progressively mucopurulent discharge. Other areas of the upper respiratory tract may be affected including the pharynx, middle ear, and tonsils.

From a practical point of view, symptomatic relief with decongestants and antipyretics are generally the mainstay of treatment. However, studies have suggested that a combination of oral chlorpheniramine and intranasal ipratropium bromide (Atrovent, Boehringer-Ingelheim) may be effective in reducing symptoms, if taken early in the prodromal phase. Antibiotics should be reserved for secondary bacterial infection although there are several trials supporting the use of topical nasal corticosteroids in acute rhinosinusitis prior to bacterial infection. Decreasing symptoms after 5 days or near resolution of symptoms by 10 days suggests a viral “common” cold in contrast to those patients with increasing symptoms after 5 days or persistent problems after 10 days, which suggests progression to bacterial infection.

Influenza in its many forms constitutes a more specific and potentially serious viral upper respiratory tract infection resulting in pandemics with significant morbidity and mortality in susceptible populations. Damage to the ciliated epithelium is more profound, facilitating secondary bacterial colonization, and the olfactory epithelium may be permanently damaged leading to anosmia. Vaccines have been developed and are increasingly used as prophylactics in vulnerable populations but their usefulness is again limited by the potential for viral mutation.

Bacterial Infections

Folliculitis and Vestibulitis. Specific bacterial infections can occur in the nasal vestibule when Staphylococcus aureus invades a pilosebaceous follicle to produce an extremely painful indurated area known as folliculitis. This will spontaneously burst and discharge its purulent contents after 4 to 5 days. The condition is exquisitely painful as the vestibular skin is tightly bound to the underlying cartilages providing little room for swelling. Local cleaning and systemic antibiotics which including flucloxacillin should be given, taking into account local bacterial resistance patterns. If the abscess is localized and fluctuant it

In its many forms constitutes a more specific and potentially serious viral upper respiratory tract infection resulting in pandemics with significant morbidity and mortality in susceptible populations. Damage to the ciliated epithelium is more profound, facilitating secondary bacterial colonization, and the olfactory epithelium may be permanently damaged leading to anosmia. Vaccines have been developed and are increasingly used as prophylactics in vulnerable populations but their usefulness is again limited by the potential for viral mutation.

Bacterial Infections

Folliculitis and Vestibulitis. Specific bacterial infections can occur in the nasal vestibule when Staphylococcus aureus invades a pilosebaceous follicle to produce an extremely painful indurated area known as folliculitis. This will spontaneously burst and discharge its purulent contents after 4 to 5 days. The condition is exquisitely painful as the vestibular skin is tightly bound to the underlying cartilages providing little room for swelling. Local cleaning and systemic antibiotics which including flucloxacillin should be given, taking into account local bacterial resistance patterns. If the abscess is localized and fluctuant it
may be incised, but the condition should always be treated seriously as it is associated with the potential complication of cavernous sinus thrombosis caused by retrograde spread of infection along the angular and superior ophthalmic veins.

The cavernous sinuses lie on either side of the sphenoid bone. Each cavernous sinus is broken up by trabeculae into many venous cavernous spaces through which the third and fourth cranial nerves and the first two divisions of the fifth cranial nerve, sixth cranial nerve, and internal carotid artery pass. It is connected by an extensive valveless venous system to the nose, adjacent face, nasopharynx, pharynx, orbit, and paranasal sinuses allowing retrograde spread of infection from any of these areas. Cavernous sinus thrombosis carries a serious morbidity, often with bilateral blindness and mortality. It is a complication predominantly of the young with two-thirds being under 20 years of age.16 The patient complains of headache and painful paresthesia in the distribution of the trigeminal nerve following which other cranial nerves related to the cavernous sinus become involved affecting extraocular movement and resulting in ophthalmoplegia. The sudden development of bilateral orbital signs should alert the clinician to this complication. Prior to antibiotics, cavernous sinus thrombosis carried a 50% mortality which nevertheless still stands at a significant 10 to 27%.17 CT and magnetic resonance imaging confirm the diagnosis and high dose broad spectrum intravenous systemic antibiotic therapy should be given, together with anticoagulation in selected cases.

The increase of asymptomatic carriage of methicillin resistant S. aureus in the nasal vestibule is a source of considerable concern as it is implicated in nosocomial infection with serious consequences for debilitated patients. Despite vigorous eradication programs the incidence of methicillin resistant S. aureus appears to be increasing worldwide.

A mild form of nonspecific infective vestibulitis is often encountered producing mild irritation, small fissures, or pustules. The application of white petroleum jelly, triamcinolone acetonide 0.1%, or antibiotic ointments such as chlorotetracycline hydrochloride 3% may be used.

Erysipelas. Erysipelas is an acute beta hemolytic streptococcus intradermal infection following a cut or surgical incision. The onset is usually abrupt with fever, redness, tenderness, and induration of the involved skin. On the face the infection frequently displays a butterfly pattern across the nose, adjacent cheeks, and upper lip. The infection generally responds well to penicillin or erythromycin and should be distinguished from cellulitis which is a more generalized deep infection of the skin and subcutaneous tissues also caused by Staphylococcus or Streptococcus.

A variety of other specific infections may occur in this region including diphtheria, rhinoscleroma, leprosy, tuberculosis, and syphilis (see Chapter 42, “Etiology of Infectious Diseases of the Upper Respiratory Tract”).

NONALLERGIC, NONINFECTIOUS RHINITIS

Idiopathic (Vasomotor) Rhinitis

The term idiopathic rhinitis relates to any inflammation of the nose where the etiology is unknown. It is the diagnosis of exclusion as underlying causative or contributory factors can often be found if carefully sought. Patients are generally manifesting an upper respiratory hyperresponsiveness or reactivity which is simply an exaggeration of normal defense mechanisms to nonspecific environmental triggers such as changes in temperature and humidity or exposure to irritants, for example, cigarette smoke or strong odors. A very extreme example of a normal physiologic response can be seen in “skier’s nose” in reaction to cold dry air.18 The commonly used term “vasomotor rhinitis” is less satisfactory as it suggests a known pathophysiologic mechanism for the condition which is far from proven.19

Cigarette smoke is known to affect mucociliary clearance9 and has been shown to cause an eosinophilic inflammation in the nasal mucosa of nonatopic children.20 Challenge of smoke-sensitive individuals produces rhinorrhea and obstruction; and, in smokers, eye irritation and hoarseness are more common than in nonsmokers. It has also been shown that the more people smoke, the more they experience the symptoms of chronic rhinitis.21

In nonallergic, noninfectious rhinitis, symptoms vary in intensity but consist of nasal blockage, anterior rhinorrhea, and postnasal discharge, sometimes with sneezing. There is no characteristic seasonal variation and ocular symptoms are almost always missing. Skin prick tests are negative or do not correlate with the symptoms, that is, may be positive to grass pollen.

Therapy may encompass avoidance of obvious triggers, but most patients require medication, the mainstay of which is topical corticosteroids, which are safe for long-term usage. If watery rhinorrhea is the most significant or only symptom, a topical anticholinergic agent such as ipratropium bromide (Atrovent) may be helpful. Topical decongestants are best avoided because of their long-term side effects; and although oral decongestants are popular, their effect is variable and not without systemic cardiovascular and neurologic effects. Topical capsaicin has been investigated for intractable nonallergic rhinitis22 as it produces a short-term neuronal defunctionalization but the effects are short-lived and accompanied by an unpleasant burning sensation so its role remains undetermined.

Surgery has a limited role to play in vasomotor rhinitis. Vidian neurectomy has had a vogue but has been largely abandoned as the effects are unpredictable and at best short-lived. Correction of septal deformity and/or turbinate hypertrophy is occasionally indicated if medication fails.

Occupational/Environmental Rhinitis

Airborne agents present in the workplace may affect the upper respiratory tract, producing either an allergic reaction or a nonallergic hyperresponsiveness. Chemicals such as acid anhydrides, platinum salts, glues, and solvents as well as dusts from grain and wood may act as irritants.23 Considerable controversy now surrounds the adverse effect of environmental pollutants such as ozone, sulphur dioxide, nitric dioxide, particulate matter, volatile organic compounds, and formaldehyde. Some contradictory evidence should be clarified by carefully constructed epidemiological studies which may ultimately support present concerns. Healthcare workers exposed to latex on gloves not infrequently develop rhinoconjunctivitis which can progress to asthma and anaphylaxis.

A careful history will usually indicate the cause, confirmed by improvement once the patient is removed from the suspected irritant. However, there may be a reluctance to complain if a worker’s job is jeopardized and prolonged exposure may produce chronic symptoms which do not abate for a week or more after exposure ceases.

The nasal symptoms of blockage and watery discharge may be accompanied by occupational asthma, conjunctivitis, and dermatitis. Clinical findings are usually nonspecific, and confirmation may require direct nasal challenge evaluated with symptom scores and assessment of nasal patency. Carefully graded exposure to increasing doses of the suspected agent in specialized ventilated environmental chambers may be necessary, especially if there are medicolegal consequences of the diagnosis.

Separation of patient and irritant, either by change of job, improved ventilation or use of masks may suffice complemented by conventional pharmacotherapy, for example, topical corticosteroids.

Hormonal Rhinitis

A range of physiological and pathological endocrine conditions can affect the nose. Changes are known to occur in the nose during puberty, the menstrual cycle, and pregnancy24 with some women experiencing blockage, watery discharge, and sometimes severe epistaxis. The symptoms are worst during the last trimester of pregnancy, relating to the blood estrogen level and resolve with delivery. In women with preexisting perennial rhinitis, the nasal symptoms may improve or deteriorate during pregnancy. Hormonal change may also be responsible for the mucosal atrophy which occurs after the menopause. In specific endocrine disorders such as hypothyroidism25 and acromegaly, nasal stuffiness, and discharge may occur.

From a therapeutic perspective, if the symptoms during pregnancy are sufficiently debilitating, medication must be considered but always taking the risk/benefit ratio into consideration. In the first instance saline douche may be of benefit but if ineffective, topical nasal corticosteroids...
have been used for many years without any evidence of a teratogenic effect or other adverse consequences. Certainly, extensive studies in asthmatics using inhaled corticosteroids have failed to show any abnormalities. Oral decongestants theoretically could cause vascular disturbance in the placenta and fetus, but oral pseudoephedrine given within the recommended dosage is approved for use in pregnancy and has been widely prescribed in the United States.

Drug-Induced Rhinitis

A number of medications are known to produce nasal symptoms. These include:

- Aspirin and other nonsteroidal anti-inflammatory drugs. Aspirin intolerance typically increases nasal congestion and secretion and is associated with nasal polyposis and nonallergic asthma (see Chapter 47, "Chronic Rhinosinusitis and Polyposis"). A voidance of aspirin and nonsteroidal anti-inflammatory drugs is clearly important though there is some controversy as to whether avoidance of salicylate-like substances in the diet is beneficial or not. Some have argued that complete avoidance may render individuals more susceptible to inadvertent challenge while others believe a complete salicylate-free diet to be worse than the disease. Other strategies have included salicylate desensitization which must be performed with great care in hospital to manage any severe respiratory reactions. The use of topical lysine aspirin is an alternative approach which has been shown to be of benefit.
- Cardiovascular preparations such as reserpine, guanethidine, phentolamine, methyl dopa, angiotensin converting enzyme inhibitors and alpha-adrenergic antagonist are all known to affect the nose, typically producing nasal stuffiness.
- Topical ophthalmic beta-blockers.
- Chlorpromazine.
- Oral contraceptives, by hormonal modulation.
- Cocaine, more often used recreationally than medically, is a significant irritant producing frequent rhinorrhea and resultant sniffing, hyposmia, and septal perforation. In extreme cases a midline destruction of the nose may result which has proved difficult to distinguish from T cell lymphoma or Wegener granulomatosis.

Rhinitis Medicamentosa. Rhinitis medicamentosa is a well-described condition classically resulting from long-term abuse of topical decongestants. The patient initially suffers a rebound congestion which leads to further use of the decongestant and ultimately develops significant mucosal atrophy. Consequently these preparations are not recommended for longer than 7 to 10 days. Once the condition is established it can prove difficult to wean a patient off the medication. The reason for originally starting the drug should be considered and in mild cases it may be possible to substitute a topical nasal corticosteroid. However, if there are no contraindications, an initial short course of oral prednisolone (30 mg/d for 5 day) may be necessary.

Food-Induced Rhinitis

Food can produce nasal symptoms in a variety of ways. While allergy is a rare cause of isolated rhinitis, food-induced hypersensitivity may result in reaction to the foods themselves or colorants and preservatives. Alcoholic beverages can produce a physiologic vasodilation with associated nasal blockage as well as allergic and nonallergic reactions to their many components. Gustatory rhinorrhea may result from spicy hot foods, probably due to the capsaicin content of red pepper. This substance is known to stimulate sensory nerves inducing release of neuropeptides such as tachykinins.

Emotion

Sexual arousal and stress are known to have an effect on the nose, hence "honeymoon rhinitis," probably due to autonomic stimulation, although therapeutic intervention is rarely sought.

Atrophic Rhinitis

Primary atrophic rhinitis has been attributed to infection, most notably to Klebsiella ozaenae (from the word "ozaena" meaning "stench") but may also relate to environmental factors and general health. The condition is characterized by progressive atrophy of the mucosa with loss of the turbinate bone and resulting in a capacious cavity full of foul-smelling crust. This should be distinguished from secondary atrophy following excessive surgery, trauma, radiotherapy, and chronic granulomatous conditions.

Primary atrophic rhinitis has become less common in countries where social conditions and health have generally improved. It affects both sides of the nose; occurs after puberty and is more common in women. Because of this, an endocrine imbalance has been postulated as a cause while others believe it has an autoimmune basis, possibly initiated by a virus or due to vitamin or iron deficiencies.

The most unpleasant symptom is the foul smell of which the patient is often unaware. The copious crusts often bleed when they detach and may extend into the nasopharynx, producing an unpleasant choking sensation and snoring. The nose paradoxically feels blocked, due to the drying effect in the abnormally patent airway.

Having eliminated other possible underlying conditions by appropriate hematologic studies and imaging, local treatment with saline or alkaline douching, emollients and lubricants such as 25% glucose and glycerine drops and regular decrusting may suffice. Antibiotics directed at Klebsiella are rarely successful in the long term though the fluoroquinolones and metronidazole have been used. A wide range of surgical procedures have been suggested, largely aimed at reduction of the size of the cavity, all with limited success. Closure of the nostrils with small skin flaps as advocated by Young can be helpful, but relapse often occurs on reopening. It was suggested that reduction of airflow inhibited growth of the microorganisms, but this is unproven.

Nonallergic Rhinitis with Eosinophilia/Eosinophilic Rhinitis Syndrome

Nonallergic rhinitis with eosinophilia syndrome was described 20 years ago although its existence as a separate entity is disputed. It should probably be regarded as a subgroup of idiopathic rhinitis characterized by nasal eosinophilia and perennial symptoms of sneezing, itching, rhinorrhea, blockage, and sometimes hyposmia in the absence of demonstrable allergy. It is possible that it represents an early stage of aspirin sensitivity and may be associated with asthma and nasal polyps or may be a form of localized nasal allergy without systemic involvement. Intranasal corticosteroids are the mainstay of medical treatment combined with surgery for the polyps.

Gastroesophageal Reflux

Reflex is increasingly thought to play a role in nonallergic rhinitis, particularly in children.

MECHANICAL NASAL OBSTRUCTION

A common nasal complaint is one of nasal blockage, Congestion, or obstruction. This may arise for a variety of reasons, be it a genuine mechanical obstruction to airflow as a response to autonomic or sensory changes in the nose, inflammation within the ostiomeatal complex, allergic changes or even a perception paradoxically in the presence of a patent or overly patent airway. It is important to investigate carefully this complaint to elucidate the cause since in the past there has been a tendency to offer surgery for the septum and/or turbinates without consideration or treatment of other contributory factors, inevitably compromising a successful symptomatic outcome.

Septal Deviation

Causes of Septal Deviation. Septal deformity can be congenital or acquired, although it should be recognized that a completely straight septum is the exception rather than the rule. This may be due to prenatal or perinatal factors in utero or during delivery. A true dislocation of the septum is rare, more often a horizontal fracture above the maxillary crest occurs which can be relocated immediately. Small microfractures may go unnoticed, presenting in later life or be exacerbated by falls during the "toddler" stage. In adolescence and as young adults, sports injuries, assault, and traffic accidents may all have their effect.

Effects. Any part of the nasal internal and external structure may be damaged, leading to deflections and deformities of the cartilages and bones. These may not be immediately obvious to the individual until infection or allergy intervenes. With age, loss of tensile strength in collagen may lead to collapse of the nasal valve region,
uncovering preexisting nasal asymmetry. The sensation of nasal obstruction may alternate with the nasal cycle or be apparent when lying on that side. Disordered airflow may result in crusting and epistaxis on the deflected area. “As goes the septum, so goes the nose” correctly indicates that septal deviation can be associated with cosmetic deformity of the bridge and columella (see Chapter 53, “Rhinoplasty and Septoplasty”).

Assessment of the external and internal nose, including anterior rhinoscopy and rigid endoscopy is important to assess the septal position and spurs, turbinates and exclude other abnormalities, particularly in the middle meatus and nasopharynx. Instillation of a topical decongestant may help determine the degree of mucosal swelling, particularly of the anterior nasal septum and inferior turbinate. Where available, objective measures of airway can be helpful.

Treatment. Septal manipulation is only of value in neonates when trauma has occurred during delivery. Septoplasty or submucous resection has been described to formally correct septal deviation. The distinction between these two techniques relates primarily to the incision and in practice most surgeons perform a combination of the two. The anterior approach used for septoplasty via a transfixion incision gives excellent access to the whole septum, while the lateral approach used for submucous resection denies access to the caudal septum. Theoretically, there is also a difference in the amount of cartilage resected, but in practice this will vary from individual to individual.

Complications

Septal Hematoma. The septal cartilage relies upon the perichondrium and overlying mucosa for its blood supply. A hematoma may form between the cartilage and perichondrium or between the perichondrium and the septal mucosa (Figure 2). In the former case the blood supply to the cartilage will be damaged and unless the hematoma is drained, cartilage death may ensue. This situation is further exacerbated by secondary infection leading to a septal abscess associated with absorption of the cartilage and saddling of the nose. Consequently the hematoma should be drained, and the nose packed combined with giving broad-spectrum antibiotics.

Fortunately, many septal perforations are asymptomatic, but those of small diameter may make a whistling sound and the larger ones may be associated with crusting, spotting of blood and the sensation of nasal obstruction due to turbulence of airflow. The more anterior the perforation is, the more likely it is to cause symptoms. Although they will never heal spontaneously, only a minority of perforations require active treatment. In the first instance a trial of nasal douching with or without a topical corticosteroid may be given.

Any operations have been described to effect closure of septal perforations, the number being inversely proportional to the overall success of such interventions. These have included rotation and advancement of local tissue flaps, in particular “drop down” techniques, free grafts including fascia, split skin, and composites of, for example, pinna cartilage and skin. Bilateral flap techniques from the gingivalabial sulcus tunneled into the nose have also been used; but, even if successful all these procedures suffer from the essential disadvantages of not providing a ciliated columnar epithelium and from being rather bulky. Alternatively the perforation may be quickly and easily filled with a commercially available button which can be customized to the individual perforation and left in place long term.

Infection/Toxic Shock Syndrome. Infection after nasal surgery is uncommon but is very painful and may cause an elevation of body temperature when it occurs. Cases of toxic shock syndrome have been described as a result of nasal packing. The condition is caused by the toxin produced by a Staphylococcus that when absorbed produces headache, myalgia, nausea, and vomiting secondary to the pyrexia. Tachycardia, hypertension then hypotension, erythema of the skin are followed sometime later by desquamation of the skin of the hands. Toxic shock must be dealt with promptly and definitively. Cultures for S. aureus must be taken, a beta-lactamase-resistant antistaphylococcal antibiotic given systemically, and all packs and stitches removed.

Turbinate Enlargement

Causes. The inferior turbinates, and to a lesser extent, the adjacent septum and middle turbinates, have a complex submucosal structure, composed of vascular sinusoids under autonomic control. Under normal physiologic conditions, the inferior turbinates change in size with the nasal cycle throughout the day. This may be overridden by a number of factors such as exercise, posture, emotion, environmental temperature, and humidity. Generally one is unaware of these changes unless one side of the nose is narrower. A compensatory hypertrophy of the inferior turbinate is often seen on the wider side. A wide range of pathological processes including allergy, inflammation, and infection can produce symptomatic swelling of the turbinates.

Effects. Resistance to airflow primarily occurs in the valve region at the anterior ends of the inferior turbinates. To a lesser extent, the middle turbinate changes, obstructing the middle meatus and abutting the septum.

Treatment. Medical. Although topical decongestant sprays can significantly shrink the mucosa, long-term use will lead to rebound...
congestion and rhinitis medicamentosa. Topical nasal corticosteroids by contrast can be used over long periods of time for most forms of perennial rhinitis or rhinosinusitis.

Surgical. Surgery should only be considered after careful consideration of the cause of the patient’s symptoms and after failure of adequate medication. Most of the techniques can be performed under local or general anesthesia and using headlight, microscope, or endoscopic visualization. As no randomized controlled prospective trial has been performed to determine which of the many techniques is superior in the short or long term, choice devolves to personal preference and all may be accompanied by hemorrhage and crusting.

Lateral Out-Fracture. Single or multiple fractures of the inferior turbinate bone can be done with or without a submucous incision. The turbinate is pushed closer to the medial wall of the maxilla and may even be pressed into the maxilla (antroconchepxy), but the long-term results are debatable as the turbinate may resume its original position and the procedure does not deal with any soft tissue swelling or its cause. A modification, the submucosal out-fracture may be more effective in that it produces multiple small fractures of the turbinate bone through a small mucosal incision.

Submucous Diathermy. This technique has been popular since the early 1900s. A pointed electrode, insulated except for the terminal 3 to 5 mm is introduced into the anterior end of the inferior turbinate and passed along the whole length. The probe is then withdrawn slowly, over 20 seconds with the current on, and the procedure repeated at two or three points. Hemorrhage and adhesions can occur and the patient should be warned that there will be blockage due to reactionary swelling for some weeks after the surgery.

Linear Electrocautery. Linear electrocautery using a red-hot wire electrode to produce a thermal burn or a high-frequency coagulating current using a ball-tip electrode has enjoyed some popularity in the past. The technique has been largely superseded by more precise laser therapy, radiofrequency coablation, and reduction with powered microdebrider instrumentation.

Turbinectomy. Partial or subtotal removal of the turbinate offers a permanent solution to hypertrophy (the attachment of the inferior turbinate concludes genuine total turbinectomy unless a portion of the lateral nasal wall is removed). A part from the occasional mulberry enlargement of the posterior end of the inferior turbinate, it should be remembered that it is the anterior end of the turbinate which offers the greatest resistance to airflow. As with all inferior turbinate surgery, patients must be warned about postoperative hemorrhage which can be profuse. A secondary hemorrhage rate of 8% is quoted, which will be severe in 1%.

Submucous Resection. Dissection of the mucoperiosteum of the turbinate is described though it is difficult to perform in practice due to the irregularities of the bone. It is best achieved by taking off an anterior sliver and then nibbling back the exposed bone so the mucosal edges fall together. A more elegant technique is the use of a powered microdebrider.

Laser Turbinectomy. A variety of cutting and coagulating lasers have been used to “cauterize” and reduce the inferior turbinate, including CO₂, argon, KTP, and neodymium YAG. A cross-hatching of the mucosa is thought to optimize shrinkage while preserving mucosa.

Cryosurgery. Cryosurgery with liquid nitrogen was popular in the past and has been largely superseded by other techniques.

Intraturbinal Corticosteroid Injection. Enthusiasm for the technique of intraturbinal corticosteroid injection diminished after reports of temporary and permanent blindness appeared. These may have occurred due to retrograde flow of particulate matter into the ophthalmic circulation, possibly associated with inadequate vasocostriction.

Foreign Bodies

Types and Effects. A wide range of objects including metal, plastic, organic substances, and live insects find their way into the nose, either accidentally or deliberately with size being the only limiting factor. The result is a unilateral chronic purulent nasal discharge, which in a young child should be attributed to a foreign body until proved otherwise. If the foreign material has been present for some time it may form the nidus for deposition of calcium and magnesium salts, producing a rhinolith which is usually radiopaque (Figure 4).

Management. The history may be misleading and examination difficult, especially if the patient is uncooperative and the nose swollen. Imaging may be helpful but is not exclusive if negative. It is therefore, often necessary to examine the nose and remove the foreign body under a short general anesthetic, which should include a throat pack to avoid aspiration of the object.

GRANULOMATOUS CONDITIONS

A range of systemic conditions, including granulomas, vasculitides, connective tissue disorders such as systemic lupus erythematosus, relapsing polychondritis, eosinophilic angiocentric fibrosis, and skin conditions such as pemphigus, pemphigoid, and scleroderma can all manifest in the nose. Consequently, one should have a low-threshold of suspicion as one may have the first opportunity to make the diagnosis.

Sarcoidosis

Cause and Effects. Sarcoidosis is a systemic condition of unknown etiology characterized by noncaseating epithelioid granulomas. It rarely occurs as systemic lupus erythematosus, relapsing polychondritis, eosinophilic angiocentric fibrosis, and skin conditions such as pemphigus, pemphigoid, and scleroderma can all manifest in the nose. Consequently, one should have a low-threshold of suspicion as one may have the first opportunity to make the diagnosis.

Sarcoidosis

Cause and Effects. Sarcoidosis is a systemic condition of unknown etiology characterized by noncaseating epithelioid granulomas. Consequently, one should have a low-threshold of suspicion as one may have the first opportunity to make the diagnosis.

Sarcoidosis

Cause and Effects. Sarcoidosis is a systemic condition of unknown etiology characterized by noncaseating epithelioid granulomas. It rarely occurs as systemic lupus erythematosus, relapsing polychondritis, eosinophilic angiocentric fibrosis, and skin conditions such as pemphigus, pemphigoid, and scleroderma can all manifest in the nose. Consequently, one should have a low-threshold of suspicion as one may have the first opportunity to make the diagnosis.
similar to that seen in dactylitis and CT may show a superficial nasal mass (Figure 5). Nasal biopsy can be useful when mucosal change is present but is only positive in 7% when the nose appears normal.37 The condition must be distinguished from other granulomatous diseases such as tuberculosis, leprosy, berylliosis, Wegener granulomatosis, and acquired immunodeficiency syndrome.

TREATMENT. Local treatment with saline douche and topical corticosteroids are helpful, and the nose may improve with systemic treatment which usually includes oral corticosteroids, methotrexate, and hydroxychloroquine. Surgery, except for sinus infection, should be avoided as this can exacerbate collapse of the nose.

WEGENER GRANULOMATOSIS

Causes and Effects. Wegener granulomatosis is a systemic condition characterized by granulomas and vasculitis and is also of unknown etiology. An autoimmune basis or infection have been suggested but remain unproven.38 It was originally described affecting the upper and lower respiratory tracts, together with a focal glomerulonephritis which rapidly led to renal failure and death. It is now known to affect any part of the body ab initio and to have a variable natural history, progressing inexorably in some individuals over a few weeks or months to a more insidious limited form in others, which may continue for some years before affecting other organs. Whether all of the latter ultimately progress to the full-blown disease is unknown.

Patients often present with a short history of progressive malaise, pyrexia, weight loss, and a disproportionate feeling of “unwellness” in comparison to what are often fairly nonspecific findings. In the nose the swollen inflamed mucosa produces blockage and blood-stained crusting. There may be destruction of the septum and loss of the inferior turbinates. Sometimes there may be active granulomatous infiltration, burnt-out disease with fibrotic change or secondary infection. and evidence of pulmonary and renal damage. The advent of the c-antineutrophil cytoplasmic antibodies greatly assisted diagnosis being highly specific and sensitive for the condition. However, a negative c-antineutrophil cytoplasmic antibody does not absolutely exclude the condition, particularly in the limited form and/or when oral corticosteroids have been given. CT of the nose and paranasal sinuses may show some midline destruction and often shows opacification of the sinuses40 (Figure 7). This may be due to active granulomatous infiltration, burnt-out disease with fibrotic change or secondary infection. Unfortunately, biopsy is not diagnostic, at best being described as “consistent with” Wegener granulomatosis but is helpful to exclude other pathology such as T-cell lymphoma.

Treatment. Medical therapy for Wegener granulomatosis includes systemic corticosteroids, a range of cytotoxic drugs, for example, cyclophosphamide, azathioprine and mycophenolate mofetil, immunoglobulin infusions, co-trimoxazole, and plasma exchange. Earlier diagnosis and careful monitoring has significantly improved the outcome for these patients, but the condition remains life-threatening in its more severe forms. The nose is again managed with douching and topical corticosteroids. Surgery may be required for secondary infection, but attempts to reconstruct the nose should be resisted until the disease has been quiescent for some years.

AMYLOIDOSIS

Apart from amyloid deposits in the skin of the vestiule in generalized amyloidosis, involvement of the nose and sinus is extremely rare. In contrast to the upper respiratory tract as a whole, only a handful of isolated amyloid deposits have been reported, whereas in generalized plasmacytic malignant lymphoma 20% of the patients may have sinonasal amyloid deposits. The diagnosis may be confirmed histologically by the presence of Congo red reactivity and green birefringence in polarized light. Colchicine has been used in the treatment of the condition.

RHINOPHYMA

In rhinophyma a disfiguring enlargement of the nose develops due to an overgrowth of sebaceous tissue and blood vessels. Tissue overgrowth begins at the tip of the nose and progresses to involve the ala nasae and the columella and is associated with a florid discoloration. The affected tissue may be pared down using a simple knife, electrodissection or laser therapy producing good cosmetic results.

NASAL GLIOMAS AND ENCEPHALOCELE

Nasal encephaloceles are protrusions of brain content through a congenital defect in the skull. If no defect is present then the mass is termed a glioma. These lesions are relatively uncommon and while many are diagnosed at birth some may not become apparent until adulthood when associated with a cerebrospinal fluid leak and meningitis. 60% of gliomas are extranasal, 30% intranasal, and the remainder have both intranasal and extranasal components. The external lesions are found over the dorsum or to one side. There is a general agreement that nasal encephaloceles and gliomas are developmental rather than neoplasms probably due to a failure of the foramen caecum to close thus permitting the brain to
extrude. The intracranial connection may persist as in an encephalocele or be interrupted as in a glioma.

Clinical Features

Nasofrontal encephaloceles are compressible, fluctuant, and pulsatile. Swelling may increase in size on crying or straining. Intranasal encephaloceles protrude through the defect into the upper nasal cavity where they can be mistaken for a nasal polyp. The most common areas are the side, dorsal, and tip of the nose, and the lesion may be a small nodular growth or form a chronic ulcer with a rolled edge. Although many behave in an indolent fashion, unless treated appropriately, they have a tendency to recur which may lead to considerable destruction of the face. The side of the nose adjacent to the medial canthal area can prove particularly problematic.

Basal cell carcinomas are usually very sensitive to radiotherapy but may require surgical excision particularly for recurrence. A variety of local rotation flaps or full thickness skin grafts are available and are discussed in Chapter 54, “Nasal Reconstruction.”

Squamous cell carcinoma though less common may also affect the skin of the nose again in the sixth to eighth decades. The lesion is generally nodular, resembling a keratoacanthoma but can ulcerate. Differentiation from a basal cell carcinoma may be difficult without biopsy (Figure 9). Treatment again relies on radiotherapy and/or surgery. Squamous cell carcinoma has a higher propensity for metastatic spread than basal cell carcinoma, and lesions in the midline particularly on the columella may disseminate bilaterally. In-continuity lymphatic resection is not possible, leading to a potentially poor prognosis.

MALIGNANT NEOPLASMS OF THE SKIN OF THE NOSE

Basal Cell Carcinoma

The skin of the nose is the most common site for basal cell carcinoma in the head and neck. It is considerably more common than squamous cell carcinoma with a peak incidence in the sixth to eighth decades. The most common areas are the side, dorsal, and tip of the nose, and the lesion may be a small nodular growth or form a chronic ulcer with a rolled edge. Although many behave in an indolent fashion, unless treated appropriately, they have a tendency to recur which may lead to considerable destruction of the face. The side of the nose adjacent to the medial canthal area can prove particularly problematic.

Basal cell carcinomas are usually very sensitive to radiotherapy but may require surgical excision particularly for recurrence. A variety of local rotation flaps or full thickness skin grafts are available and are discussed in Chapter 54, “Nasal Reconstruction.”

Squamous cell carcinoma though less common may also affect the skin of the nose again in the sixth to eighth decades. The lesion is generally nodular, resembling a keratoacanthoma but can ulcerate. Acute Rhinosinusitis and Its Complications

Todd A. Loehrl, MD
Timothy Wells, MD
Grant Su, MD

Rhinosinusitis simply defined is an inflammatory and/or infectious condition of 1 or more of the paranasal sinus cavities. A acute rhinosinusitis (ARS) implies that the duration of the condition is less than 1 month. Most cases of ARS are community acquired and are associated with viral upper respiratory tract infections (URI), although other causes may be responsible. It is estimated that 0.5 to 2% of colds result in ARS, and up to 1 in 20 URI lead to acute bacterial rhinosinusitis (ABRS). A acute infectious rhinosinusitis can be broken down into several different categories based on several characteristics including location of occurrence (hospital- or community-acquired), immune status of the patient, and offending microorganism (viral, bacterial, and/or fungal).

The diagnosis of ABRS can be challenging due to inaccessibility of the paranasal sinuses to direct examination. Thus, traditionally clinicians have relied upon relatively insensitive or nonspecific signs and symptoms to arrive at a diagnosis. Furthermore, the fact that paranasal sinus mucosal thickening and fluid is frequently associated with the common cold (acute viral rhinosinusitis) has led to further confusion. Therefore, without culture confirmation, differentiation between acute viral rhinosinusitis and ABRS is difficult. This has led to growing concern regarding the emergence of antimicrobial resistance as a result of the inappropriate prescription of antibiotics for viral URI. In addition, the excessive use of antibiotics for this condition can have a major impact on healthcare costs.

Although the complications of ABRS are less common in recent years, they are still associated with significant short- and long-term morbidity as well as mortality. Thus, although many of these cases are managed in a multidisciplinary manner, it is important that the otolaryngologist-head and neck surgeon have a thorough knowledge of the pathophysiology, evaluation, and medical/surgical treatment of these patients.

EPIDEMIOLOGY

Rhinosinusitis reportedly affects 32 million US adults annually and resulted in 11.7 million office visits as well as 1.2 million hospital outpatient unit visits. This generated direct annual costs in excess of $3.4 billion in that same year. In addition, quality of life and productivity may be adversely affected. Epidemiologic studies suggest that one billion cases of acute viral rhinosinusitis can be anticipated annually. Therefore 20 million cases of ABRS are expected annually, given that approximately 2% of people with acute viral rhinosinusitis go on to develop ABRS. Thus the diagnosis of ABRS accounted for 21% and 9% of all adult and pediatric antibiotic prescriptions, respectively, written in 2002.

The average adult and child in the United States experience 2 to 3 and 6 to 8 episodes of the common cold (viral upper respiratory tract infection) per year, respectively. Viral upper respiratory tract infection rates have a predictable pattern with annual epidemics in the fall, winter, and spring periods, while summer rates are relatively low. As noted previously, 0.5 to 2.0% of the general population with acute viral sinusitis develop ABRS as opposed to the pediatric population where 5 to 13% of these viral infections result in ABRS. As one would expect, the seasonal trends in presumed ABRS have been correlated with those of viral URI.

Many other risk factors must be considered in addition to viral causes including allergy, swimming, sinus ostial obstruction due to anatomic abnormalities, tumors or foreign bodies, and polypoid disease. In addition, in some patients, immune deficiency and disorders of mucociliary clearance may predispose to ABRS.

PATHOGENESIS

Viral

The upper airway provides little in the way of defense to rhinovirus as >90% of nonimmunocompromised subjects inoculated go on to become infected. Approximately 50% of common colds are caused by the human rhinovirus. Other viral offenders include influenza A and B viruses, parainfluenza virus, respiratory syncytial virus, adenovirus, and enterovirus. Influenza and adenovirus are known to injure the nasal epithelium while rhinovirus and coronavirus induce minimal damage. Of the patients who are infected, about 75% go on to develop symptoms of an upper respiratory tract infection. After initial nasal exposure, the virus is transported posteriorly to the nasopharynx and attaches to intracellular adhesion molecule 1, resulting in the activation of several inflammatory pathways. In addition, the autonomic nervous system reaction, characterized by parasympathetic nervous system predominance, results in engorgement of the turbinates vasculature, intercellular leakage of plasma, seromucinous discharge, and stimulation of pain nerves as well as cough reflexes.

Previous investigators have noted reversible computed tomography (CT) or magnetic resonance imaging (MRI) mucosal/fluid abnormalities in 87 and 88% of adults and children, respectively, with early community acquired URI (Figure 1). After 2 weeks, in the adult population, approximately 80% of these findings were found to resolve without antibiotic treatment.

Bacterial

ABRS is most frequently preceded by a viral URI. The causes of secondary bacterial infection are unknown but probably depend upon several factors involving both the host and the offending microorganism. It is known that the passages of the paranasal sinuses and nasopharynx
are colonized by the same bacterial species that cause ABRS. Frequently, as noted above, even in acute URIs air/fluid levels or air bubbles are noted on CT scanning; however, the composition of this material remains unknown. Gwaltney and colleagues demonstrated that nose blowing during an upper respiratory infection might propel mucous secretions into the paranasal sinuses. Specifically, they demonstrated that nose blowing (not sneezing or coughing) results in intra-nasal pressures that might be transiently elevated to 60 to 80 mm Hg. Furthermore, contrast material from the nasopharynx was propelled into the paranasal sinuses by this mechanism. Thus, vigorous nose blowing may provide one explanation for the viscous exudates associated with colds. In addition, the exudates in these patients may be harder to clear both due to increased viscosity and mucociliary dysfunction. Given the mucosal edema and compromised ventilation of the paranasal sinuses, conditions are favorable for bacterial overgrowth. In addition, viruses also have a substantial impact on neutrophil, macrophage, and lymphocyte function resulting in vulnerability to bacterial overgrowth by pathogens known to reside in the nose and nasopharynx as noted above.

**Bacterial Pathogens.** Most commonly, the pathogens in ABRS include Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis (more common in the pediatric population). In addition, other streptococcal species including Streptococcus intermedius, Streptococcus pyogenes, and other α-hemolytic streptococci may be involved as well as Staphylococcus aureus and anaerobic bacteria.

While the bacteria involved in ABRS have not changed over the last half century, their antimicrobial susceptibilities have changed dramatically. Penicillin resistance first appeared in S. aureus followed by β-lactam resistance in H. influenzae and M. catarrhalis. Finally, multiantibiotic resistant S. pneumoniae have emerged in recent years.

**DIAGNOSIS**

**Viral**

Viral URI’s symptoms typically consist of rhinorrhea, sneezing, nasal airway obstruction, facial congestion, hyposmia, sore throat, cough, eustachian tube dysfunction, fever, and myalgias. Purulent nasal drainage is not necessarily consistent with the development of ABRS as this may also occur due to an influx of neutrophils.

**Bacterial**

The clinical signs and symptoms typically associated with ABRS lack sensitivity (69%) and specificity (64%). Radiographically, the diagnosis of ABRS is difficult as well, given that approximately 87% of patients with early community acquired acute URI will have mucosal edema and/or fluid (with or without air bubbles) on CT scan. Further complicating the accurate diagnosis of ABRS is the finding that duration of symptoms does not reliably distinguish prolonged viral infection from ABRS.13 Thus, the clinician must rely on clinical judgment when making the decision regarding the diagnosis of ABRS. In general, ABRS can be considered when a viral URI does not resolve after 10 days or is worsening at 5 to 7 days. Some or all of the following signs and symptoms may be present: nasal drainage, facial pressure/pain, decreased/absent olfaction, fever, cough, fatigue, dental pain, and/or ear pressure.

**TREATMENT RECOMMENDATIONS**

Therapeutic antimicrobial recommendations for ABRS are based upon published evidence of known bacterial pathogens and clinical improvement. Studies have confirmed that appropriately prescribed (spectrum, dose, and duration) antimicrobials are effective in reducing sinus cavity bacterial titers as compared to antimicrobials with an inadequate activity spectrum, dose, or duration. In fact, bacteriologic cure rates of >90% have been reported for appropriately selected antibiotics.19 In the adult population with mild disease and no antibiotics in the prior 6 weeks, the following choices may be considered: amoxicillin/clavulanate (1.75 g/250 mg/d), amoxicillin (1.5 to 4 g/d), cefpodoxime proxetil, cefuroxime axetil, or cefdinir. In patients with β-lactam allergies, trimethoprim-sulfamethoxazole, doxycycline, azithromycin, clarithromycin, erythromycin, or telithromycin may be used, but bacteriologic failure rates range from 20 to 25%. In those patients who have received antimicrobials in the prior 6 weeks, fluoroquinolones (levofloxacin, moxifloxacin) or higher dose amoxicillin-clavulanate (4 g/250 mg/d) may be considered. Failure to respond to treatment within 72 hours requires a switch to another antimicrobial and/or reevaluation of the patient. Further management options might include imaging (CT scan), nasal endoscopy with culture/sensitivity, and/or sinus aspiration.

In the pediatric population, the choices are similar to the adult population with 2 exceptions: (1) dosing is based upon weight, and (2) fluoroquinolones are not an option in the pediatric population. A 10-day treatment course with 1 of the above antimicrobials is recommended. Finally, an inappropriate antibiotic of insufficient duration may prolong infection and potentially morbidity of the disease. Antibiotic options for those patients with severe infections and/or complications of ABRS will be discussed in the following sections.

**ORBITAL COMPLICATIONS**

There are several major ophthalmic complications of ABRS that may occur, including preseptal and orbital cellulitis, subperiosteal abscess (SPA), orbital abscess, cavernous sinus thrombosis, eyelid abscess, and vision loss. The most widely accepted classification of the orbital complications is the modified five-tier system proposed by Chandler and colleagues,20 which depicts the spectrum of orbital involvement as follows: Group I—preseptal edema or preseptal cellulitis; Group II—orbital cellulitis, Group III—SPA; Group IV—orbital abscess; and Group V—cavernous sinus thrombosis. It is important to note that these groups do not necessarily represent a rigid chronology of disease progression since they may be present in combination or evolve from one another. This classification system does however explain the signs and symptoms and helps to organize treatment plans as well as stratify outcomes.

**Group I—Preseptal Cellulitis**

The first group is inflammatory edema or preseptal cellulitis, which is an infection of the soft tissue of the eyelids and periorcular region anterior to the orbital septum. Underlying rhinosinusitis has been implicated in 14.5 to 81% of hospitalized children with preseptal cellulitis.21 On clinical examination, the eyelid is typically edematous, erythematous, as well as warm and tender to touch. Signs of postseptal orbital involvement such as proptosis, visual impairment, and chemosis of the conjunctiva are not observed. Visual acuity, pupillary reaction, extraocular motility, and intraocular pressure are normal. Preseptal cellulitis is usually managed medically with systemic antibiotics and careful clinical observation. However, due to the valveless facial veins, preseptal cellulitis may spread posterior to the septum and produce subsequent intraorbital infections in Groups II to V.

**Group II—Orbital Cellulitis**

Orbital cellulitis is an infection of the orbital soft tissues posterior to the orbital septum without abscess formation. Sinusitis is the major cause of orbital cellulitis, with studies reporting 96 to 100% of hospitalized patients with orbital cellulitis having concurrent sinusitis.22 Orbital cellulitis is also more common in patients younger than 9 years old, with 1 study reporting 68% in a series of 303 patients with orbital cellulitis.22 With the administration of the Hemophilus influenzae type B vaccine, the average age of children with orbital cellulitis has risen with the changing microbiological spectrum. Symptoms of orbital cellulitis may include eyelid edema, erythema, conjunctival chemosis, axial proptosis, limitation of extraocular movement, pain with eye movement, and increased intraocular pressure. In addition to these signs, patients with orbital cellulitis often have more systemic toxicity, such as fever, leukocytosis, and elevated levels of C-reactive protein than patients with preseptal cellulitis. All patients with suspected orbital cellulitis should be imaged and treated with intravenous antibiotic therapy and nasal decongestants. Visual acuity and pupil reflex must be closely monitored. Patients who develop a decrease in visual acuity, an afferent pupillary defect, worsening extraocular muscle...
function, or failure to improve in 48 to 72 hours should undergo surgical sinus drainage with culture.

**Group III—Subperiosteal Abscess**

In SPA, there is an inflammatory fluid that collects in the potential space between the periorbita and the orbital wall. The diagnosis is confirmed by CT scan as a convex mass adjacent to the involved sinus (Figure 2). However, SPA can be suspected based on clinical presentation. In addition to signs of orbital involvement, the eye may exhibit directional proptosis with the globe typically displaced away from the SPA (Figures 3 to 5). The patient may also have limited extraocular motility and pain on globe movement toward the abscess. The most common location of a SPA is along the medial orbital wall secondary to ethmoid rhinosinusitis. The abscess develops when infection breaks through the lamina papyracea or through the fora of the anterior or posterior ethmoidal neurovascular bundles. The periorbita is loosely adherent along the medial orbital wall, which may permit abscess contents to migrate superiorly, inferiorly, or posteriorly within the subperiosteal space. Treatment recommendations for SPA include intravenous antibiotics alone in select cases with careful observation and surgical management in refractory cases. Several studies have reported good response to medical management alone in select cases. In a study by Garcia and Harris, 27 of 29 (93.1%) SPAs resolved with medical therapy in patients that satisfied the following inclusion criteria: (1) age of patients less than 9-years old; (2) absence of frontal sinusitis; (3) medial location of the SPA; (4) small size of the SPA; (5) absence of gas within the abscess; (6) absence of chronic sinusitis; (7) no evidence of optic nerve compromise; and (9) absence of significant ophthalmic symptoms. It was concluded that expansion of a SPA in serial CT scans during the first few days of antibiotic treatment regardless of the ultimate response to treatment. It was concluded that expansion of a SPA in serial CT scans during the first few days of treatment should not be considered antibiotic treatment failure. The time-dependent pharmacokinetics of antibiotic penetration into the SPA influences the resolution of the fluid collection. Given the temporal disparity between the clinical course and CT findings, the clinical course, not the radiographic appearance, should dictate management.

**Group IV—Orbital Abscess**

Orbital abscesses refer to the presence of pus within the orbital fat, which may occur within the muscle cone (intracanal) or outside the muscle cone (extracanal) as a consequence of coalescence of the infectious process. Diagnosis is confirmed by CT scan and corroborated by the signs of eyelid edema, conjunctival chemosis, proptosis, limited ocular motility, afferent pupillary defect, visual impairment, and venous engorgement or papilledema on funduscopic examination. Orbital apex syndrome, consists of unilateral ptosis, proptosis, vision loss, internal and external ophthalmoplegia (ie, palsies of the pupillary and extraocular muscles), and cranial nerve V1 anesthesia, is also indicative of orbital abscess. The clinical presentation may vary depending upon the size and location of the orbital abscess, duration of the infection, virulence of the microorganisms, and host factors. Orbital abscess has a high potential for serious complications. Therefore, any clinical sign or symptom suggestive of orbital abscess warrants immediate imaging and intensive antibiotic therapy. Early surgical intervention is necessary when the presence of an orbital abscess is confirmed.

Abscesses can also occur in other orbital structures such as the lacrimal gland. Patel and colleagues reported a 9-year-old boy with lacrimal gland abscess thought to be caused by spread of infection from the paranasal sinuses. Despite initial surgery to drain the paranasal sinuses, the patient failed to improve, and a repeat CT scan which showed a fluid collection in the left lacrimal gland region causing downward and outward proptosis. Further surgical exploration of the orbit revealed an abscess of the lacrimal gland, which was incised and drained, resulting in complete recovery. In another case, Mirza and colleagues reported a 72-year-old woman with myelodysplasia who initially presented with a preseptal cellulitis secondary to rhinosinusitis. Despite antibiotic therapy and endoscopic drainage of the sinuses, the infection failed to resolve completely, and repeated CT imaging revealed an abscess of the lacrimal gland. Subsequent incision and drainage

**Figure 2** Axial computed tomography scan demonstrating ethmoid rhinosinusitis with adjacent right-sided medial subperiosteal abscess.

**Figure 3** Fifteen-year-old patient with left maxillary, ethmoid, sphenoid, and frontal rhinosinusitis with a resultant left inferior and medial subperiosteal abscesses. The patient underwent left endoscopic sinus surgery and left anterior orbitotomy via inferior transconjunctival and medial transcaruncular approaches to drain the abscesses.

**Figure 4** Coronal computed tomography scan of patient in Figure 3 demonstrating left pansinusitis and adjacent inferior and medial subperiosteal abscesses.

**Figure 5** Axial computed tomography scan of patient in Figure 3 demonstrating left pansinusitis and adjacent inferior and medial subperiosteal abscesses.
of the lacrimal gland abscess led to a complete resolution of the infection. Although abscess formation of the lacrimal gland rarely complicates rhinosinusitis, it should be included in the differential diagnosis when the symptoms fail to resolve after appropriate therapy, especially when there is associated enlargement and tenderness of the lacrimal gland and predominate swelling of the lateral part of the upper eyelid.\(^{28}\)

**Group V: Cavernous Sinus Thrombosis**

Discussed in Chapter 45, “Acute and Chronic Nasal Disorders.”

**Surgical Treatment of Orbital Complications**

The surgical technique for drainage of an abscess should be determined by the location of the abscess. Surgical options include the traditional external drainage of a SPA with or without external ethmoidectomy through a Lynch incision (Figure 5). More cosmetically superior procedures including the transcaruncular external approach and transnasal endoscopic approach have also been described. The advantages of endoscopic ethmoidectomy drainage over external ethmoidectomy include the avoidance of external facial scar, less postoperative edema, and shorter hospital stay.\(^ {29}\) Potential complications of surgical drainage may include seeding of an intracranial abscess or epidural abscesses.

**Loss of Vision.** Visual loss secondary to ARS may occur by several mechanisms including: (1) damage to the ocular surface from exposure keratopathy or neurotrophic keratits; (2) sustained elevated intraocular pressure; (3) thrombophlebitis of the ocular vasculature; (4) optic neuritis caused by extension of infection; (5) mass effect of an abscess causing direct optic nerve compression or obstruction to the vessels supplying the ocular structures; and (6) severe propotion causing a “stretcher” optic neuropathy or ischemic optic neuropathy due to stretching of nutrient vessels.\(^ {30}\) Despite prompt treatment, frequent blindness has been reported in SPA (14 to 33%) and in orbital cellulitis (2.5 to 26%).\(^ {29,30}\) Some authors suggest that patients with acute sphenoethmoiditis are at a relatively higher risk of permanent vision loss due to the close anatomic relationship between the sphenoid and posterior ethmoid sinuses and the optic nerve. In contrast, patients with anterior ethmoid rhinosinusitis may have vision improvement 2 to 6 weeks after treatment.\(^ {33}\)

**Eyelid Abscess.** Abscesses of the eyelid have also been described as a complication of rhinosinusitis. Remulla and colleagues reported 2 patients with lower eyelid abscesses that were believed to have spread from the adjacent infected ethmoidal sinuses.\(^ {34}\) Casady and colleagues described 5 patients presenting with eyelid abscesses whose subsequent workup revealed occult sinusitis.\(^ {29}\) All abscesses were located in the upper eyelid and all patients had ipsilateral rhinosinusitis, including the overlying frontal sinus. In 2 cases, there was radiographic evidence of bony defects between the infected frontal sinuses and the eyelid abscesses. All patients improved after treatment with intravenous antibiotics followed by incision and drainage of the abscess and endoscopic sinus surgery. The authors conclude that the diagnosis of eyelid abscess should be considered when the symptoms are associated with purulent nasal discharge and headache since decreased vision, fever, pain, and orbital signs may not be present.

**Intracranial Complications.** The infections in the paranasal sinuses frequently lead to the development of intracranial bacterial infections due to their anatomic proximity as well as the venous network that traverses the 2 areas. All of these infectious complications are associated with important morbidity and represent true emergencies. However, the incidence, which ranges from 3.7 to 10%, has improved over time.\(^ {36,37}\) This is felt to be a result of the widespread use of oral antibiotics, improved imaging, recognition of the paranasal sinuses as the source of the infection, expedient medical and surgical treatment of the underlying rhinosinusitis, and improvements in intensive care medicine.\(^ {28}\)

Excluding meningitis, the development of intracranial complications of rhinosinusitis occurs more frequently in males and children older than 9 years.\(^ {38}\) The development of the frontal and sphenoid sinuses as well as the increased susceptibility to upper respiratory infections in this population may account for the association.\(^ {39}\) The intracranial complications of rhinosinusitis can be classified as follows: (1) meningitis, (2) epidural abscess, (3) subdural abscess, (4) intracerebral abscess, and (5) venous sinus thrombosis. It should be noted that multiple complications can occur in the same patient concurrently or sequentially. All these entities represent true medical emergencies with high morbidity and mortality warranting thoughtful, urgent medical and frequently surgical therapy.

**Meningitis.** Meningitis remains 1 of the most common intracranial complications of rhinosinusitis. That being said, most cases of meningitis are not associated with rhinosinusitis. When the 2 are related, the most commonly involved paranasal sinus cavities are the sphenoid and ethmoid sinuses. It goes without saying that patients with anterior skull base defects (cerebrospinal fluid leaks, encephaloceles, etc) are at increased risk of developing meningitis. In addition, diving into water with an acute sinus infection has been associated with increased risk of meningitis and is felt to be related to the infectious process being forced intracranially through the olfactory neuroepithelium.\(^ {41}\) Permanent neurologic sequelae are not uncommon and may include seizures, focal deficits, neurologic deterioration, and sensitivity. The decision to proceed with surgical intervention should be made in coordination with all of the consulting services.

**Epidural Abscess.** Epidural abscesses most commonly occur as a complication of frontal sinusitis and may occur in association with osteomyelitis. The relationship to the frontal sinus is felt to result from the interregional venous communications and the loosely adherent dura.\(^ {42}\)

Symptomatically, epidural abscesses tend to be more subtle in their presentation. Presenting symptoms might include frontal headache, drowsiness, and fevers. These symptoms may progress in severity to include focal neurologic deficits, seizures, and/or altered mental status. The diagnosis is dependent on the CT or MRI scan revealing findings consistent with a fluid collection in the epidural space. The treatment of epidural abscess again involves appropriately chosen antibiotics and thoughtful surgical intervention. Again, surgical intervention should be coordinated with the involved consultants, especially neurosurgery. The surgical procedure can be performed simultaneously with any necessary neurosurgical procedures and may include endoscopic ventila­tion/drainage, frontal sinus trephination, osteoplastic flap obliteration of the frontal sinus, or cranialization. A antibiotic therapy should be coordinated with infectious disease specialists and is typically culture directed.
Subdural Abscess. Subdural abscess, also known as subdural empyema, is usually unilateral and involves the space between the dura mater and subarachnoid space. In contrast to other intracranial complications of rhinosinusitis, bacterial sinusitis is the source of infection for the majority, 50 to 70% of cases, while otitis media accounts for a relative minority, 10 to 20%, of cases. Subdural abscesses are associated with relatively high morbidity, mortality, and permanent neurologic sequelae. Aggressive intervention with early craniotomy and direct management of the otorhinolaryngologic origin of the infection has been advocated. These patients most commonly present with fevers, headache, altered mental status, hemiparesis, nausea and vomiting, seizures, and nuchal rigidity. In addition to presenting with relatively severe symptoms, these patients can deteriorate quickly. These symptoms result from thrombosis of meningeal veins, inflammation of the pia mater, and subsequent spread of the infection through the subdural space to other areas.

Diagnosis is generally based upon CT scan and/or MRI (Figure 6). MRI generally reveals areas of enhancement. CT scans may be falsely negative in 20% of cases. Given that most of these infections are associated with rhinogenic or otogenic sources, these areas should be included on imaging as well. Lumbar puncture is recommended only if hydrocephalus is not present, due to the high risk of uncal herniation.

Antibiotic therapy includes broad-spectrum antimicrobials that are capable of crossing the blood-brain barrier. They are further directed by culture and sensitivity results when they become available. Subdural abscesses are usually polymicrobial, most commonly including anaerobes, H. influenzae, an/aerobic streptococci, and staphylococci. Anticonvulsants and corticosteroids are frequently required for the associated seizures and cerebral edema, respectively. Surgical therapy is coordinated with other specialists and usually involves drainage of the abscess and diseased paranasal sinus region at the same setting.

Intracerebral Abscess. Intracerebral abscesses are most frequently located in the frontal and frontoparietal lobes. Most commonly they result as a complication of frontal sinusitis, but ethmoid and sphenoid sinusitis may also be the source. Temporal lobe abscesses may occur secondary to sphenoid sinusitis but an otogenic origin is more common. The abscesses may be multiple in about 13% of cases.

Early symptoms are due to cerebritis and typically consist of fever, lethargy, agitation, and headache. A quiescent period may occur as liquefactive necrosis occurs and the abscess is walled off. Finally as the abscess wall thickens, focal neurologic deficits and seizures may occur as a result of increasing cerebral edema. Subsequent rupture of the abscess or brain herniation can result in death. Diagnosis is with MRI or CT scan. Lumbar puncture is especially dangerous due to potential uncal herniation and thus should be avoided.

Treatment is once again multidisciplinary in nature. Antibiotics can be started immediately, although if the patient is stable, can wait until after culture material is obtained. Surgical therapy is coordinated with other surgical disciplines such as neurosurgery, but consists of drainage either by craniotomy or by stereotactic aspiration. Any involved paranasal sinus cavities can be surgically ventilated as well at the same time.

Frontal Bone Osteomyelitis. Osteomyelitis of the frontal bone is an increasingly rare complication of frontal rhinosinusitis. The term “Pott puffy tumor” is commonly used and is defined as a SPA of the frontal bone associated with osteomyelitis. The subperiosteal collection of pus in the forehead results in a “puffy” fluctuant swelling. In addition, osteomyelitis of the frontal bone may present with a discharging fistula. Both of these extracranial manifestations may occur alone or in combination with the previously discussed intracranial complications. Because of the venous drainage of the frontal sinus, infection of the frontal sinus can extend to the overlying bone by either propagation of septic thrombi or by direct extension.

Diagnosis is based on clinical suspicion in those patients presenting with forehead swelling, that is, puffiness or a fistula. A high degree of suspicion must be maintained for underlying intracranial complications. Appropriate imaging studies usually involving both CT and MRI scanning to assess for intracranial involvement is indicated (Figures 7 and 8).

Treatment again tends to be multidisciplinary in nature, especially in those patients with associated intracranial complications. In patients without associated intracranial complications, frontal trephination is helpful to obtain culture material and to drain the underlying infection. Culture directed intravenous antibiotics are initiated as well. If appropriate clinical improvement does not occur after trephination and intravenous antibiotics, debridement of nonviable bone is indicated. Intravenous antibiotics for 6 weeks duration are generally recommended. If the frontal rhinosinusitis does not resolve with antibiotics, the frontal sinus should be surgically ventilated or obliterated to prevent further complications. In the patient with associated intracranial complications, aggressive bony debridement is carried out in conjunction with any necessary neurosurgical procedures. Long-term culture directed antibiotics are indicated in this situation as well.

Chronic Rhinosinusitis and Polyposis

Rodney J. Schlosser, MD
Bradford A. Woodworth, MD

Chronic rhinosinusitis (CRS) is a clinical disorder that encompasses a heterogeneous group of infectious and inflammatory conditions affecting the paranasal sinuses. Its definition continues to evolve as we increase our understanding of the various pathophysiologies that may result in a common clinical picture.

Epidemiology

CRS is an extremely widespread inflammatory disorder that is one of the most common health complaints in the United States. CRS and CRS with nasal polyps (NPs) comprise a variety of disorders that cause inflammation of the sinonasal mucosa. Estimates of the prevalence of CRS vary due to differences in the definition of rhinosinusitis and methods of diagnosis. In 2001, there were 18.3 million patient office visits for CRS despite many patients not seeking medical attention.1 CRS with NPs is a subset of this disease which is also a prevalent condition affecting between 1 and 4% of the general US population.2 CRS affects men and women equally, but subtypes of CRS appear to have different gender distributions. For example, CRS with NPs associated with aspirin-sensitivity has a female predominance of 2:1.3 Sinus disease is more common in the Midwest and South than in the northeast and western United States and the incidence is lower during the summer months compared to the other seasons. CRS causes significant physical symptoms, decreases quality of life, and impairs daily functioning resulting in millions of days of lost productivity with an important impact on the US economy. The total medical and economic impact of these disorders is unclear due to heterogeneous disease processes, imprecise diagnoses, and overlap with other conditions that produce similar symptoms. Nevertheless, the calculated direct health care expenditures from the primary diagnosis of CRS are approximately $3.39 billion in the United States. In 1996, the total direct and indirect costs were estimated at $5.8 billion annually.4

Diagnosis

Historically, sinusitis was the commonly accepted terminology for inflammation of the paranasal sinuses. This terminology has gradually been phased out in favor of rhinosinusitis because nasal inflammation almost always coincides with inflammatory paranasal sinus involvement.5 Clearly this terminology is more descriptive. This highlights only one of the many changes that have occurred in defining and categorizing CRS over the past several decades. There are still controversies regarding the definitions and diagnoses of all forms of rhinosinusitis. This is likely due to the fact that CRS encompasses a spectrum of diseases that have numerous causes and a range of appropriate treatments. The 1996 multidisciplinary rhinosinusitis task force of the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) proposed definitions of rhinosinusitis based on the duration of clinical signs and symptoms.6 These were divided into acute (up to 4 weeks), subacute (4 to 12 weeks), chronic (>12 weeks), recurrent acute (>4 episodes/yr plus each episode lasting ≥7 to 10 days plus no intervening signs of CRS), and acute exacerbation of chronic (sudden worsening of CRS, return to baseline after treatment). Temporal separations furnish the practitioner with a concrete way to define nasal and sinus inflammation and have since become widely accepted definitions of rhinosinusitis, but they are far from ideal.

For practical purposes, most practitioners refer to two general categories, acute and CRS. Since CRS encompasses a broad range of different disease processes, epidemiologic studies unfortunately lump many different disorders into this common category. While acute rhinosinusitis is discussed thoroughly in Chapter 46, “Acute Rhinosinusitis and Its Complications,” it is important to note that acute rhinosinusitis may develop into CRS in some cases. However, acute rhinosinusitis is usually infectious in nature, whereas chronic disease might result from a wide range of inflammatory processes. CRS is less frequently bacterial in causation and is most broadly subdivided into categories of patients with hyperplastic mucosal changes with polyps and those without polyps.

The clinical diagnosis of CRS has always been somewhat difficult, due to the difficulty defining the disease and the variety of presenting signs and symptoms. The consensus opinion of leading experts in the field of rhinology was pivotal in creating a unifying diagnostic model based on the most common presenting signs and symptoms in patients with all forms of rhinosinusitis.6 These signs and symptoms were divided into major and minor factors (Table 1). A according to this report, a clinical diagnosis of CRS could be made if patients had two or more major factors or one major and two minor factors and these signs and symptoms lasted for >12 weeks. Numerous reports since this consensus opinion have shown a lack of close correlation between subjective measures established by the task force and objective measures commonly applied to CRS. This symptom-based definition of CRS also did not take into consideration the numerous causes of this heterogeneous disease process. In 2003, the Sinus and Allergy Health Partnership (SAHP) convened to help better define and diagnose CRS.7 The SAHP criteria include the prior definition proposed by the 1996 AAO-HNS task force qualifying the duration of disease with continuous symptoms for >12 consecutive weeks or >12 weeks of physical findings. However, objective evidence of inflammation must be present and identified in association with the ongoing symptoms to establish the diagnosis (Table 2). Importantly, the SAHP also incorporates computed tomographic (CT) imaging of the sinuses or Water view plain sinus radiograph as a means of confirming the diagnosis. The SAHP task force also emphasizes the importance of CT scan and endoscopy for confirming the diagnosis for research purposes.

rhinosinusitis may ultimately lead to mucosal tors. Furthermore, multiple episodes of acute infections in terms of exacerbations and recurrences may indicate an underlying chronic inflammatory component. The predisposing causes for CRS paranasal sinuses in the CRS population has been well documented, and most practitioners believe bacteria play a role in the majority of cases. Whether the bacteria play a direct or indirect role in the development of CRS has not been adequately determined.

**Progression of Acute Rhinosinusitis**

The predisposing conditions for CRS parallel those for acute infections in terms of extrinsic, intrinsic, systemic, and local host factors. Furthermore, multiple episodes of acute rhinosinusitis may ultimately lead to mucosal dysfunction and chronic infections. Symptoms are more varied in CRS when compared to acute rhinosinusitis, especially when NPs are part of the disease process. CRS typically has extensive mucosal dysregulation and chronic inflammatory process that can be very difficult to treat. This disease is often recalcitrant to medical and surgical treatments that are currently available. Systemic corticosteroids are used more often in CRS, since this disease has a significant underlying chronic inflammatory component. Furthermore, acute rhinosinusitis is histologically an exudative process characterized by neutrophilic inflammation and necrosis, while CRS is a proliferative process that is most often characterized by thickened mucous membrane and lamina propria. Because acute rhinosinusitis is almost always infectious, it is marked by a normal T helper 1 (Th1)-type of inflammation that is associated with a recruitment of neutrophils as the predominant cell type to fight infection. While this type of infectious inflammation is certainly predominant in CRS secondary to cystic fibrosis, ciliary dyskinesia, and rhinosinusitis of dental origin, most CRS has an atopic (Th2)-type inflammatory response where eosinophils are the predominant inflammatory cells in both atopic and nonatopic individuals with CRS.

**Anatomic Factors**

In some cases, CRS develops from a chronic bacterial infection in a sinus cavity in the presence of an anatomically obstructed ostium. Anatomic abnormalities leading to narrow channels predispose individuals to developing CRS, especially in the presence of some sort of reversible inflammation. Certain anatomic variants may also predispose individuals to CRS, including Haller cells (infundibular), silent sinus syndrome, or a narrow frontal sinus outflow tract from large agger nasi or frontal cells. Once the ostium becomes occluded, a local hypoxia develops in the sinus cavity and sinus secretions accumulate. This creates an environment suitable for rapid bacterial growth. Bacterial toxins and endogenous mediators subsequently damage the highly specialized ciliated respiratory epithelium resulting in a decrease in mucociliary clearance. A vicious cycle erupts with stasis of secretions and further infection.

**Mucociliary Dysfunction**

Mucociliary clearance is especially important in maintaining the homeostasis of the paranasal sinuses and deserves further mention. The ciliary beat of the epithelium removes allergens, bacteria, and pollutants trapped in the mucus or gel layer of the mucociliary blanket through natural drainage pathways. The mucus rests on a periciliary fluid or sol layer that enables the rapid elimination of viscous secretions. Mucociliary clearance can be disrupted by either defective ciliary function due to intrinsic or extrinsic factors or alterations in the viscosity and production of mucus. Intrinsic factors leading to ciliary dysfunction include primary ciliary dyskinesia or Kartagener syndrome. Extrinsic factors that disrupt mucociliary clearance include injury by environmental irritants, endogenous mediators of inflammation, or surgical trauma. Patients with cystic fibrosis have high viscosity mucus secondary to alterations in water and electrolyte transport. The gel and sol layers of the mucus blanket are severely affected, thereby hindering bacterial removal. Airborne irritants, allergens, cold air exposure, or viral upper respiratory infections can increase the production of mucus and exceed the rate of mucociliary clearance. All of these factors may lead to the accumulation of mucus in the sinuses, decrease the removal of bacteria, and create a favorable environment for bacterial growth.

**Bone Inflammation**

Recent work suggests that the bone may play an active role in the disease process and that, at a minimum; the inflammation associated with CRS may spread through the Haversian system within the bone. The rate of bone turnover in CRS is similar to that seen in osteomyelitis. Furthermore, a surgical induced infection with either Staphylococcus aureus or Pseudomonas aeruginosa can induce all of the classic changes of osteomyelitis and induce chronic inflammatory changes in the overlying mucosa at a significant distance from the site of infection. Therefore, the bone inflammation may be an important factor in the spread of chronic inflammatory changes and may explain the recalcitrance to medical therapy. It is still unclear, however, if the bone actually becomes infected with bacteria or if the observed changes are simply reactive.

**Biofilms**

Recent investigations have found that bacteria such as P. aeruginosa form biofilms in the sinuses that may lead to recalcitrant sinus disease. Biofilms are a complex organization of bacteria anchored to a surface. They can evade host defenses and demonstrate decreased susceptibility to systemic and local antibiotic therapy. The persistence of biofilms is largely due to their method of growth. P. aeruginosa grows in microcolonies surrounded by an extracellular matrix of the exopolysaccharide alginate. Biofilms have now been implicated in many infectious processes, including dental caries, periodontitis, otitis media, musculoskeletal infections, nocardiosis, dental infections, staphylococcal osteomyelitis, and cystic fibrosis pneumonia. Furthermore, there is a long list of nosocomial-type infections in which biofilms are involved. These include ICU pneumonia, sputum, A V shunts, contact lenses, urinary catheter cystitis, endotracheal tubes, central venous catheters, and pressure equalization tubes. Bacterial biofilms that have formed on mucosal surfaces have been referred to as mucosal biofilms, as they are bacterial biofilms that have formed in the special environment of the mucosal mcosa, an area expected to have some protection from biofilm formation.
Dentigerous Sinusitis

Dental pathology can occasionally lead to sinusitis of the maxillary sinus with subsequent spread to adjacent sinuses. This pathology can include dental infections, root abscesses, oral-antral fistulae and oral surgery procedures that incite a sinusitis. These patients typically require treatment of both the oral and the sinus pathology to eradicate the infection.

Etiology and Pathophysiology of Chronic Rhinosinusitis with Nasal Polyps

CRS may exist with or without NPs and these entities may represent two points along a spectrum of disease. For the purposes of this chapter, NP is not simply mucosal edema, but rather grape-shaped, soft, smooth, freely mobile mucosal swellings that are often visible on anterior rhinoscopy. Polyps arise from the lateral nasal wall and are best seen with nasal endoscopy when limited to the superior and middle meatus. Inflammatory polyps are most often bilateral but may have a unilateral predominance when existing in association with allergic fungal rhinosinusitis (AFRS). The detection of small polyps but no evidence of sinus disease is relatively common, reported as 32% in an endoscopic autopsy series. Hence, NPs may be present without clinically significant sinus disease and vice-versa. This autopsy series also suggests that NPs are found mainly in the transition spaces between the nose and sinuses and often start in the narrow channels of the ostiomeatal complex. Because small NPs may be missed on anterior rhinoscopy, a diagnosis is more likely after nasal decongestion and nasal endoscopy.

Histologically, NPs are mucosal swellings that contain edema and an extensive fibrous stroma with vessels, glandular elements, and inflammatory cells covered by typical respiratory epithelium that may display benign squamous cell metaplasia. The epithelium has few nerve endings and submucosal glands, and the basement membrane is thickened. NPs are most often associated with a Th2-type cytokine profile and eosinophilic inflammation (85%). NPs that are associated with neutrophilic inflammation and glandular hyperplasia are seen in bacterial infections of dentigerous origin, ciliary dyskinesias, cystic fibrosis, and Young syndrome. Naturally, the disparate inflammatory processes have led to a proposed histologic classification of CRS according to the predominant cellular inflammatory findings.

The cause and effect relationship between NPs and bacterial CRS is a matter of debate. Polyps may form prior to infection from eosinophilic infiltration of the nasal mucosa in response to allergic or nonallergic inflammation. It is also plausible that enlargement of the polyps leads to blocked sinus ostia, stasis of secretions, and bacterial superinfection. However, polyps that arise from bacterial infection in the maxillary sinus of dental origin and those that develop secondary to cystic fibrosis lend support to the development of nasal polyposis secondary to different types of inflammation. The infectious component of chronic disease may ultimately result from the compromise of the normal mucosal barrier mechanisms by long-term inflammation. CRS with NPs should be considered a broad spectrum of disease processes with some individuals having a propensity to develop hyperplastic disease.

Although the etiology of CRS with NPs is largely not understood, there are a number of interesting theories that have been proposed over the last several years. Despite 85% of NPs having eosinophils as their predominating inflammatory cell, there is a dearth of epidemiologic evidence for allergy as the predominant cause. Patients with NPs do not have a higher incidence of allergy when compared to the non-CRS population, nor do patients with NPs have elevated peripheral eosinophil counts. The disease is often unilateral and can cause bony erosion and extension into the orbital or intracranial contents.

Fungal colonization of the nose and paranasal sinuses is a common finding in both normal and diseased sinuses due to the ubiquitous nature of the microorganisms. Taylor and colleagues showed that fungi can be isolated from nearly all sinuses as well as from patients without disease, given sufficiently sensitive culture techniques. Furthermore, an elegant study by Lackner and colleagues showed that fungus could be cultured from the nasal mucus of 94% of neonates after only 4 months of life, proving that fungus colonizes the sinonasal cavities early in life. Under some circumstances, fungal proliferation may lead to the development of fungus balls or saprophytic growth of fungus. In other cases, an intense inflammatory response to ubiquitous fungi

IgE to cultured fungus in a study by Manning and colleagues and other factors such as fungal antigen exposures, with fungal allergy develops AFRS. Therefore, disease or that only a small minority of patients explain the predominantly unilateral nature of the elevated within the control group of patients with specific IgE and this corresponded with the results confirmed AFRS had uniformly elevated fungal-

specimen of eosinophilic inflammation are IL-5 and IL-13. IL-5 is chemotactic for eosinophils and essential for activation and survival, whereas IL-13 induces expression of adhesion molecules necessary for eosinophil migration from the vasculature into the tissue. Eosinophils contain and release a variety of destructive proinflammatory mediators, including major basic protein, eosinophil cationic protein, and eosinophil-derived neutrotoxin. These mediators are toxic to surrounding tissue and epithelium. Disruption of mucociliary clearance and the barrier function of the epithelium allows bacteria and fungi to propagate in the sinus cavities. However, other inflammatory cells besides eosinophils contribute to the pathogenesis of ECRS, including T cells, mast cells, and basophils. These cells also cause excess mucus secretion, vascular leak, and airway epithelial injury through the production of destructive inflammatory mediators. Corticosteroids interfere with the transcription of many proinflammatory mediators and cytokines. This halts the inflammatory process, and the sinus mucosa returns to normal function. Unfortunately, the reversal of inflammation is often temporary and recurs once the corticosteroids are withdrawn. The reasons for this persistent inflammation are poorly understood, but several of the theories are discussed.

**IgE Independent Fungal Inflammation**

Several recent studies point to fungus as a possible inflammatory trigger for CRS independent of a Type I IgE allergic mechanism as seen in AFRS. Ponikau and colleagues showed that 97 of 101 consecutive patients undergoing sinus surgery had eosinophils that were migrating through the epithelium into the mucus of the nasal and sinus lumen. Furthermore, allergy in general or allergy to fungus was only present in half of these individuals. Because the observation was made that the eosinophils cluster around fungi, there is a possibility that eosinophils might target the fungi and trigger the inflammation in patients with CRS. With sensitive enough studies, 100% of patients will have fungus in their sinuses. Hence, eosinophils may be recruited and activated as a response to fungi in patients with CRS, but not in healthy controls. Furthermore, peripheral lymphocytes from patients with CRS will produce large quantities of the cytokines IL-5 and IL-13 when they are exposed to certain fungal antigens. Thus, the fungi in the nasal and sinus mucus may activate and induce Th2 type cytokine production independent from allergy.

**Aspirin-Sensitive Nasal Polyposis**

If patients have NPs in association with asthma and aspirin-sensitivity, this form of ECRS is commonly referred to as Samter triad (Figure 5). A aspirin-sensitivity plays a definitive role in the development of ECRS due to an oversynthesis of leukotrienes. Leukotrienes, also known as the slow reacting substances of anaphylaxis, are a class of inflammatory mediators that increase vascular permeability, inflammatory cell chemotaxis, and smooth muscle constriction. They are produced by a number of cell types including eosinophils, mast cells, macrophages, and basophils and found in the nasal secretions of asthmatics. A chondric acid is cleaved from cellular membranes by phospholipase A2 and subsequently shunted to either the leukotriene pathway by the enzyme 5 lipoxigenase or the prostaglandin pathway by the enzyme cyclooxygenase. Prostaglandin E2, a product of the cyclooxygenase pathway, inhibits 5 lipoxigenase in a feedback loop. Aspirin and other nonsteroidal anti-inflammatory inhibitors inhibit cyclooxygenase and decrease prostaglandin E2, resulting in a net increase in leukotrienes due to uninhibited production. This manifests clinically as bronchospasm, increased mucus production, and inflammatory NPs.

**Bacterial Superantigen**

There is an emerging interest in the potential role of superantigens in the pathogenesis of ECRS. Bacteria possess the ability to produce pathogenic enterotoxins that can activate large subpopulations of the T-lymphocyte pool. These T-cell superantigens bind to human leukocyte antigen class II histocompatibility complexes on antigen-presenting cells and the T-cell receptors of T lymphocytes that are separate from the antigen binding sites. The conventional antigen specificity is bypassed resulting in activation of up to 30% of the T-lymphocyte pool (normal <0.01%). Individuals with major histocompatibility class II molecules, which allow this binding, would be more at risk for this upregulation by a superantigen. The end result is that conventional antigen specificity is bypassed, and there is a subsequent massive cytokine release. An example of this process is seen with the secretion of toxic shock syndrome toxin-1 by S. aureus in toxic shock syndrome. This is the most well-known bacteria that produces superantigens, usually called enterotoxins, and is known to produce more than a dozen different forms. Superantigens are implicated in the pathogenesis...
of other inflammatory diseases, such as atopic dermatitis, Kawasaki disease, psoriasis, and rheumatoid arthritis. In CRS, Bachert and colleagues demonstrated staphylococcal superantigen-specific IgE antibodies to the superantigens S. aureus enterotoxin A (SEA) and S. aureus enterotoxin B (SEB) in NP tissue. In this study 7 of the 20 patients with nasal polyposis were nonallergic on skin prick testing, suggesting that a local allergic response, may be more important than a systemic allergic response and provides evidence of a specific IgE-mediated response to the superantigen itself. Thus, superantigens appear to have the capacity to act as antigens in addition to stimulating nonspecific T-cell activation. Subsequently, Bernstein and colleagues found evidence of SE production in 7 of 13 patients with NPs (55%). The bacterial superantigen hypothesis is a potential unifying theory for the pathogenesis of all types of ECRS. This theory proposes that microbial persistence, superantigen production, and host T-lymphocyte response are fundamental components unifying all common chronic eosinophilic respiratory mucosal disorders. This helps explain how a number of coexisting immune responses, including type I hypersensitivity, cellular antigen-specific immune responses, and superantigen-induced T-lymphocyte activation, could contribute to the heterogeneity of the disease. Nevertheless, it is likely that there are additional mechanisms at work in ECRS.

### Clinical and Laboratory Evaluation

#### History and Physical Examination

Patients with CRS have a number of symptoms that may be similar to other nasal disorders. While nasal obstruction, nasal congestion, and postnasal discharge are the most common symptoms associated with CRS, the banality of these symptoms underscores the fact that these symptoms are also common in patients with allergic rhinitis or other nasal disorders. Thickening of the sinus and nasal mucosa and reactive swelling of the inferior and middle turbinates lead to these symptoms. In allergic rhinitis, a careful history may elicit a description of increasing symptoms with exposure to known allergens and assist with the correct diagnosis. Nasal congestion and rhinorrhea are also common in CRS with NPs, but olfactory dysfunction is far more common in this disorder. Generalized facial pain, pressure, or fullness is often described by patients with CRS and can be localized to an affected side. However, it is imperative the practitioner does not assign the diagnosis of CRS using facial pain or pressure in the absence of other signs and symptoms. Facial pain is not a specific finding, because there are many causes other than CRS. Furthermore, pain is much more common in the acute setting. Headache and dental pain are even less common and subject to the same scrutiny as facial pain/pressure. Other less common symptoms include halitosis, fatigue, cough, and ear pain/pressure. Completing a thorough history of concomitant disorders such as asthma, allergies, and aspirin-sensitivity, will assist with the establishment of an underlying pathophysiology in some cases.

Upon physical examination, CRS patients may have tenderness to palpation or percussion in the periorbital, forehead, or cheek areas. Transillumination of the maxillary and frontal sinuses can suggest the presence of fluid. Maxillary dentition should be inspected for pathology and the oropharynx inspected for postnasal discharge. Mucosal inflammation of the septum and inferior turbinate can be visualized with anterior rhinoscopy, but it should be performed in the decongested state. NPs, especially in children, can alert the physician to the possibility of a systemic disease, such as cystic fibrosis and ciliary dyskinesia.
other important elements of the history and physical examination include eliciting signs and symptoms related to orbital or intracranial extension. Periorbital edema may indicate infection in the presence of a dehiscence of the lamina papyracea or periorbita. Changes in vision, orbital pain, or diplopia can occur with orbital extension of infection which is an emergent situation (see Chapter 46, “Acute Rhinosinusitis and Its Complications”). Gradual unilateral or bilateral orbital proptosis is an absence of orbital pain is often present in massive polyposis, as seen in AFRS. Changes in mental status or meningeal signs may indicate an extension of infection to the intracranial cavity in the form of meningitis or epidural or frontal lobe abscess. Clear rhinorrhea, especially in a previously operated patient, should be evaluated for cerebrospinal fluid leak as described in Chapter 51, “Endoscopic Surgery of the Skull Base, Orbits, and Benign Sinonasal Neoplasms.”

Nasal Endoscopy

As discussed earlier in this chapter, groups of major and minor factors proposed by the rhinosinusitis task force of the AAO-HNS are helpful, but the addition of a definitive sign of mucosal inflammation is the key to establishing a diagnosis. As such, a thorough nasal endoscopic examination is important for helping establish the diagnosis of CRS and CRS with NPs, and indispensable for following the course of the disease. Nasal endoscopes are either rigid or flexible fiberoptic designs and allow a very thorough inspection in the office setting with minimal discomfort to the patient if they are appropriately pretreated with decongestant and topical anesthetic. Nasal endoscopy allows the assessment of mucosal hyperemia, edema, the gross appearance of polyps or origin of NPs, and septal deformities or other anatomic abnormalities impacting sinus drainage. In the postoperative patient, angled endoscopes enable the practitioner to evaluate the status of mucosal edema and inflammation within all the sinuses to assist with medical management decisions. Furthermore, the practitioner can obtain highly accurate sinus cultures under direct endoscopic visualization to help direct specific antibiotic therapy. The characteristics of the sinonasal discharge should be noted as part of the nasal endoscopic examination. Clear, thin secretions are typical of viral or allergic inflammation, mucopurulent discharge indicates the presence of a probable bacterial infection, and thick, tenacious, “peanut butter” mucin is suggestive of AFRS or less commonly ECRS.

Establishing a differential diagnosis of nasal masses is an important part of the clinical evaluation when NPs are present. Sinonasal neoplasms should always be considered as part of the differential diagnosis with tissue sent for pathologic study on patients. “Polyps” may appear locally destructive and indicate the presence of such malignant neoplasms as esthesioneuroblastomas, sinonasal undifferentiated carcinomas, squamous cell carcinomas, and adenocarcinomas. Inverted papillomas are often mistaken for unilateral NPs and often found attached to the lateral nasal wall. Juvenile nasopharyngeal angiofibromas and hemangiopericytomas are extremely vascular tumors that reside in the sinus and nasal cavities. Severe epistaxis will ensue if these tumors are biopsied erroneously prior to an extensive evaluation. Intranasal encephaloceles also may present as a single polyp originating high in the nasal cavity. Further imaging should be performed prior to biopsy of unusual nasal masses. If the mass does not have the characteristic appearance of a polyp, bleeds easily, is unilateral or the site of attachment is not clearly identified, imaging studies are indicated before proceeding. In general, a high resolution CT scan is useful for bone imaging and can reveal dehiscences and erosions from a locally destructive neoplasm or the skull base defect of an encephalocele. Magnetic resonance imaging is complementary to CT scanning because of the ability to identify soft tissue and differentiate tumor from secondary mucosal disease and retained secretions.

Laboratory Studies

Generally, laboratory studies are ordered when the potential results will influence decision-making in the management of the patient. In addition, once a clinical impression is established, further laboratory studies may help confirm or refute that impression. Allergy testing is an example of further laboratory testing that can aid with a diagnosis, help explain the underlying etiology as in AFRS, and change medical decision-making based upon the results. Allergy testing is discussed in Chapter 43, “Allergic Rhinitis.” Serum total and specific IgE and CBC with differential to assess for eosinophilia are useful in patients with CRS with NPs. Elevated IgE is a marker for atopic disease and can help differentiate a patient with AFRS from a patient with ECRS. Serum eosinophilia can be a marker for more extensive sinus disease and may help identify individuals more refractory to surgical therapy. In a retrospective comparative analysis of patients undergoing endoscopic sinus surgery, Zadeh and colleagues compared 34 patients with serum eosinophilia to 34 randomly selected CRS patients. Patients with eosinophilia were more likely to have polyps (77% vs 15%), AFRS (39% vs 3%), asthma (35% vs 24%), multiple recurrent sinus infections (94% vs 32%), recurrent polyps (35% vs 3%),
and require revision surgery (84% vs 24%). An immunologic workup may be indicated with CRS, especially in children. Serum assays for total IgE, specific IgE, IgA, IgG, and IgG subclasses (IgG1, IgG2, IgG3, IgG4) and pneumococcal titers can help determine whether an immunoglobulin deficiency and a weak immune response contribute to refractory disease.

Radiology

Although CRS is primarily a clinical diagnosis, radiologic imaging can confirm the diagnosis in the presence of appropriate signs and symptoms. Plain X-ray films are fairly specific for acute maxillary sinusitis when air-fluid levels are seen, but not routinely useful as a screening study for CRS. The current imaging study of choice is a fine cut coronal CT (or axial with coronal reconstruction) of the sinuses. Imaging should include the entire ostiomeatal complex but also the sphenoid sinuses and the entire length of the anterior skull base. CT provides a road map for endoscopic sinus surgery, spots potential complications from bony dehiscences in the skull base or orbit, and identifies mucosal thickening and trapped secretions within the paranasal sinuses (Figures 6 to 9). Unfortunately, mucosal changes on CT scan are not specific for CRS and may be transient and not indicative of true disease. Approximately 40% of individuals without sinonasal complaints will have paranasal sinus mucosal abnormalities on CT scan.25 This underscores the fact that nasal endoscopy is still the gold standard for identifying inflammatory mucosal disease. CT imaging is undoubtedly a standard next step when clinically diagnosed CRS fails to resolve to medical therapy or patients have persistent sinus symptoms without evidence of disease with nasal endoscopy.

As mentioned earlier, MRI is a complementary study that is helpful in differentiating inflammatory from neoplastic disease (Figure 10). MRI is also sensitive to detecting dural inflammation and the communications of encephaloceles with the intracranial space. However, MRI is limited in usefulness for the evaluation of bony anatomy and for its overly sensitive nature of detecting mucosal inflammation. For further details about MRI and radiologic imaging, please see Chapter 41, "Imaging of the Nasal Cavities, Paranasal Sinuses, Nasopharynx, Orbits, Infratemporal Fossa, Pterygomaxillary Fissure, and Base of Skull."

MEDICAL MANAGEMENT

Antimicrobial Therapy

Antibiotics are by far the most commonly prescribed drugs for CRS. There are few randomized, controlled studies evaluating antimicrobials in CRS. Therefore, antibiotic selection is typically inferred from studies evaluating efficacy in acute rhinosinusitis. Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis are the predominant microorganisms found in acute rhinosinusitis and pediatric CRS. Unfortunately, the causative microorganisms of CRS differ from those found in acute rhinosinusitis. Coagulase-negative staphylococcus is the most common microorganism in the majority of studies, but there is significant debate over the pathogenicity of this microorganism since it is frequently found colonized in asymptomatic individuals.26 Other bacteria frequently cultured from...
patients with CRS include *S. aureus*, anaerobes, Group A Streptococcus, gram-negative rods, and *S. pneumoniae* with a tremendously wide variability among studies. High-dose amoxicillin (2 g/d), amoxicillin/clavulanate, fluoroquinolones, later generation cephalosporins, and the newer ketolides are typical first-line antibiotics for CRS in adults. These drugs have broad coverage and generally demonstrate adequate bactericidal activity against staphylococci and anaerobic species, although gram-negative coverage varies significantly. Many practitioners prefer to preserve fluoroquinolones for culture proven *Pseudomonas* to reduce the potential for overuse and the development of resistance of these valuable antibiotics. In fact, endoscopically directed cultures and sensitivity testing should generally be performed for all individuals with suspected or confirmed CRS if there is mucopurulent discharge present. The duration of antibiotic therapy is not clearly defined, but current recommendations include a 4-week course of first-line antibiotic in addition to a nasal anti-inflammatory medication such as a corticosteroid spray. These recommendations are not based on hard data but extrapolated from several randomized controlled trials that showed inadequate treatment results in 30 to 40% of CRS patients taking antibiotics for 2 weeks or less.

When nasal mucopurulence is present, patients with CRS with NP typically will respond well to a 4-week course of a first-line antibiotic. However, prolonged courses of antibiotics rarely provide relief of nasal obstruction and decrease polyp size. Currently, there are no accepted guidelines for the use of antibiotics as a primary therapy in CRS with NPs, but they are often prescribed in conjunction with corticosteroid therapy in a manner consistent with CRS. On the other hand, the macrolide group of antibiotics may actually have beneficial effects on polyp size and symptoms in the treatment of CRS with NPs, albeit through an immunoregulatory rather than antimicrobial mechanism. Reports suggest a reduction in NP size and symptomatic relief in patients with CRS with NPs who have failed to respond to corticosteroids and surgery. Macrolides are typically used in patients who have failed standard medical and surgical therapy.

Antimicrobial treatment may be used for refractory *AFRS* that has recurred in spite of standard therapy which should include surgical removal of the fungal eosinophilic mucin and polyps and systemic corticosteroids. Oral itraconazole has been shown to be efficacious for treating ABPA, the pulmonary form of the disease, and it has anti-inflammatory properties in addition to its antifungal actions. Given the ubiquitous nature of fungi in our environment and the
colonization of even normal sinuses by multiple fungal species, the role of topical and systemic anti-fungal therapies is still unclear.

Therapy for bacterial superantigen-induced ECRS could theoretically attack the microorganism responsible. In many cases this could be S. aureus, because this colonizes one-third of individuals and was present in 55% of patients in the study by Bernstein and colleagues. Interestingly, all S. aureus produced an enterotoxin in that series. They advocated the use of a topical anti-staphylococcal medication, mupirocin, in these patients. In addition, vigorous saline nasal washes could wash away proinflammatory cytokines as well as bacteria from the nose. Enterotoxin-producing bacteria could also live in biofilms, as well as bacteria from the nose. Enterotoxin-because of the myriad of potential disastrous consequences of superantigen-induced ECRS, corticosteroid therapy should not be taken lightly.

Recurrence of NPs. Administration of oral corticosteroids following the procedure to help reduce the patient has persistent disease, therapy may be continued at a mid-range dose (40 mg per 24 hours) for up to 2 weeks to prevent an Addisonian crisis. The goal of corticosteroid therapy in almost all patients with CRS or CRS with NPs is nasal and sinusal inflammation and mucus. Newer second-generation antihistamines have much less anticholinergic activity, and so they are frequently used as part of an overall treatment plan in patients who are suspected of having inhalant allergies. As mentioned previously, allergy testing should be considered in all patients with CRS with or without NPs, and those who test positive should be treated appropriately with antihistamines, topical corticosteroids, or immunotherapy.

Immunotherapy may play a role in patients with NPs, particularly those with IgE mediated disease, such as AFRS. We typically recommend immunotherapy for all fungi toward which a patient demonstrates atopy rather than basing it upon fungal cultures. A wide range of fungal species have been implicated in AFRS, and fungal cultures appear to change throughout the course of the disease. Bassichis and colleagues reported reoperation rates of 33% in patients with AFRS who were treated with at least 1 month of antileukotriene therapy. Although further placebo controlled trials are indicated, antileukotrienes may provide at the least an alternative therapy in patients with CRS with NPs who are intolerant of chronic doses of corticosteroids. For obvious reasons, this drug class is likely to work best in patients with aspirin-sensitive ECRS.

Other Medical and Ancillary Therapies

Although debate exists over the percentage of patients with CRS who have coexisting seasonal or perennial allergic rhinitis, most agree that underlying allergic rhinitis is an important predisposing factor for CRS. Antihistamines reduce sneezing and rhinorrhea in patients with CRS with NPs, and are suitable in cases in which allergy plays an important role. However, first-generation antihistamines should generally be avoided since their anticholinergic activity can further desiccate already thickened mucus. Newer second-generation antihistamines have much less anticholinergic activity, and so they are frequently used as part of an overall treatment plan in patients who are suspected of having inhalant allergies. As mentioned previously, allergy testing should be considered in all patients with CRS with and without NPs, and those who test positive should be treated appropriately with antihistamines, topical corticosteroids, or immunotherapy.

Antileukotriene Therapy

Currently, there are two classes of antileukotriene drugs approved in the United States for the treatment of asthma: leukotriene receptor blockers (montelukast and zafirlukast) and a 5-lipoxygenase inhibitor which blocks the enzyme that forms leukotrienes (zileuton). Montelukast has also been recently approved for treating inhalant allergies. A n4 antileukotriene therapy is generally well-tolerated, with the most common side effects being headache and dyspepsia. Parnes and colleagues showed in a prospective study that 72% of patients with CRS with NPs had a significant reduction in nasal symptoms, 50% had decreased polyp size, and 60% no longer required oral corticosteroids when they were treated with at least 1 month of antileukotriene therapy. Although further placebo controlled trials are indicated, antileukotrienes may provide at the least an alternative therapy in patients with CRS with NPs who are intolerant of chronic doses of corticosteroids. For obvious reasons, this drug class is likely to work best in patients with aspirin-sensitive ECRS.
This therapy likely helps clear the nasal and sinus cavities of inspissated mucus, bacteria, allergens, and environmental irritants. A diliing antimicrobi- als, such as tobramycin to nasal/sinus irrigation has been a routine part of management of patients with cystic fibrosis due to the heavy coloniza- tion and chronic infections of Pseudomonas. Mupirocin added to irrigations can help eradi- cate methicillin-resistant S. aureus infections. Some advocate this practice for patients with CRS with NPs in the hopes of eradicating any Staphylococcus elicit enterotoxins functioning as superantigens. A mephoterin B irrigations may also eliminate fungal elements that cause a local inflammatory response. Since staphylococ- cal or fungal microorganisms in this situation are not invasive and colonized on top of the nasal mucosa, they may be relatively protected from serum borne antimicrobial agents. For nearly all topical antimicrobial agents, the exact concentra- tion, frequency, and duration of therapy have not been studied in a scientific fashion.

**CONCLUSIONS**

There are many scientific advances in the treat- ment and understanding of the pathophysiology of CRS that have occurred within the last decade. Advances in nasal endoscopy, radiologic imaging, medical treatments, and surgical techniques have allowed for significant improvement in patient management. However, recalcitrant sinus disease is a particular problem and continues to await new therapeutic approaches. Hopefully, further research will lead to novel strategies of medical and surgical therapy that will decrease the need for systemic corticosteroids and their ill effects, while increasing the quality of life for patients stricken with this difficult disease.

**REFERENCES**

The craniofacial region is the most common location in which pain drives patients to seek medical attention. The wide diversity of causes and the extreme overlap of historical features coupled with nonspecific physical findings serve to challenge the physician’s ability to diagnose and ultimately relieve or control patients’ craniofacial pain. However, an understanding of the different types of craniofacial pain provides a powerful tool to meet the challenge.

INNERVATION FOR PAIN

Nociceptors serve as the sense organs in which noxious stimuli create a response that excites afferent nerve fibers that provide the brain with information about location, intensity, quality, and duration of the response. Neurochemicals responsible for this excitation include serotonin and substance P, as well as other neurotransmitters. These afferent fibers are carried to the central nervous system in cranial nerves V, VII, IX, and X and the first 3 cervical nerves.

Pain-sensitive innervation of facial structures is extensive, whereas intracranial pain sensation is limited to specific structures. The extracranial tissues innervated for pain sensation include the muscles of the head and neck, the scalp and facial skin, sinonasal mucosa and perichondrium, temporomandibular joint (TMJ) synovium and capsule, tooth pulp, the external and middle ear, orbital contents, salivary glands, cervical spine, and craniofacial periosteum. Intracranial structures with nociceptive neurons include major arteries, specifically the internal carotids, vertebrals, basilar, middle meningeals, ophthalmics, the circle of Willis, and the major venous sinuses. Nonvascular structures with pain nerve fibers are represented by cranial nerves V, VII, IX, and X and the upper 3 cervical nerves themselves, as well as the pituitary fossa and the base of skull dura mater. The remaining intracranial structures are insensitive to pain, including the brain, most of the dura, the ventricles, and the cranium. The afferents converge on nuclei in the brainstem where multiple synaptic connections occur including transmission to the ipsi- and contralateral thalamus and the somatosensory cerebral cortex. The thalamic nuclei appear to play a role in the affective response to pain, whereas the cortical centers’ role is in localization and intensity recognition of noxious stimuli. The extensive convergence of afferent neurons in brainstem nuclei, however, limits the brain’s ability to distinguish between sources. The result is referral of pain to tissues with a past experience recognized as pain. Specific patterns of pain referral are common, for example from the TMJ and muscles of mastication, radiation is to the ear, cheek, and temple; from the tonsillar fossa and supraglottic larynx to the middle ear; from the maxillary sinus to the maxillary teeth; from the sphenoid sinus to the vertex or occiput, and, of course, angina is sometimes referred to the jaw.

PATHOPHYSIOLOGY

Multiple mechanisms resulting in excitation of nociceptive neurons, that is, generating the perception of pain, are partially understood. One common mechanism is sustained muscle contraction resulting in tension headache. The exact source of excitation is unclear but may be the result of ischemic changes or the production of nitric oxide. Another common scenario is vasodilation of intracranial arteries stimulating trigeminal sensory pathways, which release vasoactive peptides that increase the pain response. The vasodilation seems linked to subtypes of serotonin 5-hydroxytryptamine (5-HT) receptors in vessel walls. Other subtypes of 5-HT receptors, such as 5-HT1B, yield vasoconstriction and inhibit the pain response. It is this basis on which triptan antimigraine agents have their effect by selectively binding to 5-HT1B receptors. An inflammatory mechanism is thought to be responsible when neuropeptides such as substance P are released with mucosal inflammation. These result in neural excitation, resulting in the perception of pain. Neural inflammation following injury or tumor invasion has an excitatory effect. Direct nerve pressure may induce nociceptor activity, as seen in foraminal stenosis. Many agents that result in vasodilation can trigger headache including hypoxia, carbon monoxide, caffeine withdrawal, acute alcohol withdrawal, oral contraceptives, hypoglycemia, and antihypertensives and other vasodilators such as nitroglycerin and monosodium glutamate found in Chinese food. Finally, cerebral mechanisms are also thought to play a role. For example, some migraineurs have been found to have defective release of endogenous opiates, and lowered cortical pain thresholds occur in chronic tension headaches.

CLASSIFICATION

Understanding headache and facial pain is essential to facilitate diagnosis and treatment. To this end, definitions and features of clinical syndromes were first organized by the International Headache Society (IHS) in 1988 and the second edition was released in 2004. This classification, with inclusion of diagnostic criteria for headaches, cranial neuralgias, and facial pain, has facilitated the diagnostic approach and management of craniofacial pain across many medical fields. Table 1 lists the major classification of headaches, cranial neuralgias, and facial pain:

**PATIENT EVALUATION**

History is the essential tool to establish a diagnosis for headache or facial pain. It must be comprehensive to ensure accuracy of diagnosis. Once the features of the cephalalgia are discovered, one can refer to the IHS classification to determine which specific diagnostic criteria are fulfilled (Table 2). In approaching a patient with headache, it is important to rule in or out a comprehensive symptom complex with distinct characteristics of the headache, focal neurological signs, or systemic complaints (see Table 3 for specific serious conditions in which headache is a presenting symptom). Warning features of the headache include sudden onset, highest severity, steady crescendo of intensity, awakening with headache, and exacerbation by coughing or straining. Dangerous associated systemic symptoms include fever, sudden vomiting, declining mental status, syncope, or seizures. Specific physical ailments such as neck rigidity, tender or enlarged temporal artery, unilateral rhinorrhea, skull percussion tenderness, or focal neurologic defects such as visual field loss, diplopia, hemiparesis, and facial nerve palsy may indicate serious underlying pathology. Finally, a history of preexisting malignancy or immunosuppression may herald a serious condition.

The physical examination is guided by history and clinical suspicion. Routine measures should include a check of blood pressure and temperature; assessment of mental status and cranial nerve function; and a visual examination inclusive of pupil size, extraocular movement, visual fields, and fundoscopy. Range of motion testing of the jaw and neck should be performed along with palpation of the TMJ, muscles of mastication, and paraspinal musculature searching for trigger points of neuritic or muscular pain. Ablations may be observed in the external or middle ear, the sinonasal passages, the mouth, and dentition, or herpetic lesions may be seen in dermatomes. Palpation of the temporal arteries should also be performed. Asymmetric skull percussion tenderness may suggest a subdural process. Laboratory testing, including lumbar puncture for cerebrospinal fluid (CSF) analysis, should be limited and guided by clinical impression. Radiologic imaging with computed tomography (CT), magnetic resonance imaging (MRI), or magnetic resonance angiography (MRA) may be indicated when organic pathology is suspected.

### SPECIFIC CLINICAL SYNDROMES

The characteristic features of many craniofacial pain diagnoses are presented along with specific treatment recommendations (see Table 1 for the classification system).

#### Migraine-Type Headaches

Migraines comprise the second most common form of headache, with a prevalence of 18% in women and 6% in men and costing billions of dollars for treatment and lost productivity. Its peak age of onset is in the second or third decade, but children and even infants may also be affected. Migraine headaches usually occur as recurrent episodes of severe, throbbing, unilateral head pain of sudden onset lasting 4 to 72 hours. However, 40% of migraineurs have bilateral pain. The headache often strikes after awakening in the morning. In children, migraine headaches usually end between 2 and 48 hours. Routine activities of daily living may exacerbate the symptoms. Coexisting syndromes with the headache are common including nausea, vomiting, photophobia, and phonophobia. Stress is the usual precipitating factor. A family history of migraine is often present.

Migraine is divided into several types: those without aura (formerly common migraine) and those with aura (formerly classic migraine). They are the 2 most common by far. Migraine without aura is the most common type. It lacks...
any preheadache warning symptoms. Migraine with aura is also common, comprising 20% of migraine sufferers. The typical aura lasts <1 hour and immediately precedes the onset of cephalalgia. It may be precipitated by menses, pregnancy, oral contraceptives, certain foods, or bright lights. Migraine with prolonged aura has symptoms of the aura that last through and beyond the headache up to 7 days. Features of aura include focal neurologic symptoms including visual changes such as scotomata or sensory and motor disturbances such as paresthesia, hemiparesis, or aphasia. Brainstem dysfunction may also occur, resulting in ataxia, lethargy, diplopia, tinnitus, vertigo, or dysarthria.

Prodromes and postdromes are also common features, occurring in approximately 60% of migraine patients. They experience premonition phenomena hours to days before the onset of headache. Specific feelings include mood changes, fatigue, anorexia, or autonomic symptoms such as diarrhea or frequent urination. The postdrome essentially consists of general fatigue, irritability, and food cravings or anorexia. The IHS criteria for migraine without aura is as follows:

1. at least 5 attacks;
2. headache attacks lasting 4 to 72 hours (untreated or unsuccessfully treated);
3. headache has at least 2 of the following characteristics:
   a. unilateral location
   b. pulsatile quality
   c. moderate or severe pain intensity
   d. aggravating by or causing avoidance of routine physical activity
4. during headache at least 1 of the following:
   a. nausea and/or vomiting
   b. photophobia and phonophobia
5. not attributed to any other disorder

For migraine with aura:

1. at least 2 attacks;
2. headaches as described in migraine headache without aura;
3. aura (visual symptoms, sensory symptoms, dysphasic speech disturbance) which is fully reversible;
4. aural symptoms develops gradually over ≥5 minutes; and
5. each aural symptom lasts ≥5 minutes and ≤50 minutes

Nonpharmacologic treatment of migraine disorders includes avoidance of triggers and extremes of lifestyle patterns. Patients should be educated to aim for regularity in exercise, eating, drinking, and sleeping habits rather than a list of prohibitions. Headache diaries are useful to decrease the frequency of attacks and monitor for the escalation in number of headaches and drug use. Medical therapy falls into 2 major categories: preventive and symptomatic treatment. The latter attempts to abort attacks at their onset and controls pain during the headache. Specific behavioral measures that are useful include the application of ice, isolation in a dark quiet room, use of biofeedback or acupuncture, and induction of sleep, as well as the avoidance of known triggers (Table 4).

Symptomatic treatment must be individualized to provide adequate relief with minimal risk and side effects. An approach of using stratified care has proven successful where the strength of the prescription is reflective of the severity of the headache. Relief should not be limited to headache but also should address constitutional

symptoms such as nausea, vomiting, or insomnia. Factors influencing choice of drugs should include the frequency that medications will be required, contraindications, route of administration, prior medication successes and failures, or the need for breakthrough headache therapy. The patient should be instructed to initiate treatment as soon as the headache component of the attack is recognized and at an adequate dose. Often antiemetics or metoclopramide should be given first to avoid worsening or triggering nausea; it facilitates the absorption of antimigraine medication. Non-specific migraine therapy includes analgesics and judicious use of opiates for only severe attacks. Specific therapy uses compounds that are known agonists of the 5-HT1 receptor and include ergot derivatives and synthetic triptan compounds. To avoid chronic ergotamine-induced headache, it should not be taken >2 d/wk. In addition to nausea, angina may be induced by these compounds; thus, their use in patients with risk of coronary artery disease is contraindicated (see Table 5 for agents available for abortive therapy). Triptan therapy can be used early in the course of treatment for patients with substantial disability in keeping with a stratified approach to care.

The recurrence rate for headache in a 24-hour period is reported for some drugs: intranasal dihydroergotamine mesylate has a 14% relapse rate, whereas triptans relapse between 22 and 45% of the time, and intranasal lidocaine relapse 40% of the time. It is important to realize that severe attacks can be so disabling that occasional referral to the emergency department or admission for pain management is necessary. Finally, in difficult to treat cases, referral to a headache center or neurologist is appropriate. For children, A-quin and associates reviewed the use of various agents and found good effectiveness for both acetaminophen and ibuprofen. Oral dihydroergotamine mesylate and sumatriptan in any form were also effective.23 Opiates should be avoided. A gain, abortive therapy should be initiated early in the attack.

Prophylactic therapy is indicated when the frequency of episodes is >5/mo. It can be initiated early in patients unresponsive to acute medication, suffering substantial disability, or showing accelerating frequency of either headache or medication use. Dosages should be titrated within recommended levels, and therapeutic trials of any agent should last at least 3 weeks given that the effects are often delayed. Specific prophylactic agents are listed in Table 6. Preventive medical therapy in children has had some success, although fewer reports exist. Among specific agents used for children, propranolol is most frequently used. Other regimens make use of methotrexate, propranolol, fluvoxamine, cyproheptadine, and pizotifen, a serotonin receptor antagonist.

### Tension-Type Headache

Tension-type headaches (TTHs) include a variety of previously described craniofacial pain conditions such as tension headache, stress headache, muscle contraction headache, fibromyalgia, chronic daily headache, myofascial pain syndrome, and temporomandibular disorder (TMD). This category of headaches is by far the most common, afflicting approximately 80% of the adult population, but these headaches usually do not result in a physician evaluation. The IHS has delineated a spectrum of disorders based on frequency of headache episodes and the presence of palpable pericranial muscle tenderness. Clinically, it is not the intensity but the frequency that leads to the morbidity of the condition and dictates treatment decision making. It is more likely to occur in women, and usually a family history of headaches is present. The headaches are characteristically bilateral, with a tightening or band-like sensation in the frontotemporal region or trapezius muscles. The onset is gradual, whereas the quality is dull, nonthrob- bing, and constant, sometimes lasting for weeks.

These headaches typically do not have associated autonomic symptoms as migraine headaches do, although it is possible when the headaches are severe. The headache by definition lasts from 30 minutes to 7 days and has 2 of the following characteristics: a tightening quality, mild to moderate intensity, bilateral location, and not aggravated by routine physical activity. The cephalalgia is triggered or exacerbated by stress or anxiety in most patients. Some evidence has discounted the idea that persistent muscle contraction is the cause of the pain. Instead, new theories suggest an abnormality in central pain control. The subdivisions of infrequent episodic, frequent episodic and chronic differ by the following criteria:

1. Infrequent episodic: at least 10 episodes occurring on <1 d/mo on average (<12 d/yr)
2. Frequent episodic: at least 10 episodes occurring on ≥1 but <15 d/mo for at least 3 months (≥12 and <180 d/yr)
3. Chronic: headache occurring on ≥15 d/mo on average for >3 months (≥180 d/yr)

The other category of TTHs is chronic and was previously labeled chronic daily headache. Some debate still exists as to whether all chronic daily headaches are tension type. The IHS also recognizes that migraine headaches can transform into a chronic daily headache with features more similar to TTHs. This may represent an evolution of the headache process which is often related to

overuse of treating drugs. According to Silberstein and Lipton, chronic daily headache must be divided into both tension type and migraine-like type, as well as other entities. They note that the chronic tension type constitutes about 25% of all daily headache patients.

Treatment of TTHs uses nonpharmacologic and pharmacologic therapy. First, chronic medication overuse must be eliminated, a step that will improve many cephalalgia sufferers. Any psychiatric comorbid conditions should be identified and evaluated appropriately as a risk factor for treatment failure. Nonpharmacologic remedies include reassurance, muscle relaxation, simple muscle exercises, stress management, biofeedback, and physical therapy with thermal modulation, ultrasonography, or electrical stimulation. Pharmacologic therapy can be organized into abortive therapy in episodic and chronic TTHs and preventive therapy for chronic TTHs. Established abortive agents include: acetaminophen, acetosalicylic acid, caffeine, and nonsteroidal anti-inflammatory drugs (NSAIDs). As a rule, immediate relief medication of any sort should not be taken ≥2/ wk. A gents capable of fostering dependence are best avoided. These include caffeine, opioids, and benzodiazepines.

The use of medication in the management of chronic TTHs is more diverse. Injection of local anesthetics into trigger points may provide sustained relief. Prophylactic therapy is indicated in patients with frequent headaches which is traditionally defined as ≥2/wk or detrimet to quality of life. TTHs characteristically are not severe, and the usual indication for prophylactic or preventative therapy is for frequency of headaches. Amitriptyline has been used most often, with proven success. Sodium valproate, topiramate, propranolol, venlafaxine XR, tizanidine, L-5-hydroxytryptophan, and the nitric oxide synthase inhibitor L-N^6^-methyl arginine hydrochloride (L-NMMA) have also been used with reported success. Injection of botulinum toxin into pericranial muscles has recently been shown to be safe and effective although the mechanism of relieving pain is poorly understood.

Cluster Headaches

Cluster headaches, previously known as Horton cephalalgia, are less common than tension-type or migraine-like type headaches; however, the severity of the headaches is much greater. They affect men more often than women. They are unilateral, excruciating, and located around the eyes or in the maxilla and usually occur in middle age. The attacks typically last minutes to 3 hours. No aura or nausea occurs, but the cephalalgia is associated with unilateral lacrimation, rhinorrhea, and injection of conjunctiva. Posis and miosis may also occur. The headaches often wake a patient at the same time each night. Typically, the patient “searches for relief” by pacing or rocking back and forth. A cluster period is the segment of time during which attacks tend to occur several times per day for several weeks. The cluster period ends with remission of attacks and start of a headache-free period, hence the attacks occur in “clusters.” Triggers of attacks in a given cluster period include alcohol, histamine, nitroglycerine, rapid eye movement sleep and low oxygen saturation of obstructive sleep apnea (OSA). Rapid eye movement as a trigger causes sleep deprivation which in conjunction with the headache may lead to depression. Patients with strictly nocturnal attacks require an evaluation for OSA and an overnight polysomnography where indicated. Successful treatment of OSA using continuous positive airway pressure support may eliminate nocturnal cluster attacks.

The IHS classification of cluster headaches requires meeting the diagnostic criteria listed in Table 7.

A typical features suggest a structural lesion influencing the cavernous sinus such as pituitary adenoma, impacted molar teeth, parosellar meningioma, and nasopharyngeal carcinoma. These features include absence of periodicity, low-grade background headache that does not subside, and neurological signs other than miosis and ptosis. Important disorders that require differentiation include giant cell (temporal) arteritis, acute closed angle glaucoma, cerebrovascular disorders, tumors, and trigeminal neuralgias (TGNs).

The etiology of cluster headaches is unclear, but several mechanisms are suspected. Circadian hormonal fluctuation suggests a hypothalamic dysfunction, whereas excitation of a nerve plexus in the carotid sheath and adventitia may increase trigeminal discharge rates resulting in facial pain.

A subset of patients demonstrate an autosomal dominant transmission in their families. Variants of cluster headache also occur. Chronic paroxysmal hemianicria (Sjaastad syndrome) is a variant with shorter, more frequent attacks, occurs more often in women, and is absolutely responsive to indomethacin. SU NCT syndrome (an acronym for short-lasting unilateral neuralgiform headache attacks with conjunctival injection, tearing, sweating, and rhinorrhea) is a cluster-like headache, mostly in men, in which attacks last 10 to 60 seconds. It may be precipitated by touch to the nose or periorbital area, chewing, or ingestion of citrus fruits.

Treatment of cluster headaches consists of abortive measures and prophylactic therapy. Along with providing reassurance for the patient, episodes can be ended with inhalation of 100% oxygen for 10 minutes. However, there are logistical challenges with this therapy. Sumatriptan is the most effective self-administered medication for the symptomatic relief of the cluster attack. Sumatriptan, 6 mg, administered subcutaneously will achieve relief in 15 minutes. Zolmitriptan is an effective oral medication that is effective in 30 minutes. Dihydroergotamine IM or IV may provide relief in 30 minutes or 10 minutes, respectively. These agents all work by inducing a central vasocostriction. Intranasal 4% lidocaine may also be effective. At least 3 episodes of cephalalgia should be treated with any 1 agent before declaring it a failure and moving to another agent. Analgesics are too slow to be effective, and corticosteroids have not been proven to be beneficial in the acute setting.

Prophylactic medications are the mainstay of treatment. Short-term or transitional prophylaxis can be used during a cluster period to suppress attacks, while maintenance prophylaxis is used before and throughout the duration of the cluster period. In general, they should be used early in the cluster period until the patient has been headache free for at least 2 weeks and then followed by a tapering period. Transitional prophylaxis includes short courses of prednisone, dexamethasone, and ergotamine tartrate or a greater occipital nerve blockade. Maintenance prophylaxis may be required when transitional prophylaxis and suppression therapy have been discontinued or in anticipation of seasons or months when attacks occur. Effective prophylaxis has been achieved with a variety of agents and is most often achieved using calcium channel blockers such as nifedipine or verapamil, low-dose ergotamine in sustained-release form, lithium carbonate, and methysergide for no greater than 4 months to avoid the rare complication of retroperitoneal fibrosis. Multidrug therapy may be necessary. Newer approaches have used valproate, topiramate, pizotifen, and phototherapy with bright light. Histamine desensitization may offer relief to patients with chronic cluster headaches refractory to treatment. Invasive approaches for refractory cases include trigeminal nerve blockade and blockade of the sphenopalatine ganglion. The most effective procedure for typical cluster headache is radiofrequency ablation of the trigeminal ganglion.

HEADACHE ATTRIBUTED TO HEAD AND/OR NECK TRAUMA AND POSTTRAUMATIC HEADACHE

Intracranial hematomas (intracerebral, subdural, or epidural) often have headache as a presenting symptom. It is moderate to severe and on the side of the hematoma. Ipsilateral skull tenderness...
Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) accounts for 1 to 4% of all headaches evaluated in the emergency department. It typically presents as the worst headache of the patient’s life. Besides the severe intensity, the cephalgia is sudden and may gradually worsen; it is bilateral and associated with neck stiffness, fever, transient loss of consciousness, diplopia, or seizures. A sentinel or warning headache that is severe occurs in as many as 50% of patients several days or weeks before the major hemorrhage. These headaches which abate within minutes to hours are called thundereclap headaches and may be difficult to distinguish from a benign headache. However, they do warrant evaluation. Physical examination may reveal altered mental status, restlessness, nuchal rigidity, retinal hemorrhages, papilledema, and focal or general neurologic signs such as cranial nerve III or VI palsy, aphasia, hemiparesis, or ataxia. If aneurysmal bleeding is the source, onset is in minutes; with arteriovenous malformation leaking, the onset is often more insidious, occurring in less than 12 hours. Rupture of a moyamoya lesion may also produce SAH. The neurologic sequelae include devastating brain injury or death, but sometimes only minimal change occurs.

The diagnosis of SAH can be challenging, especially in a patient who loses consciousness and falls. Blood seen on CT may be incorrectly attributed to trauma rather than a ruptured aneurysm. Hypertension may occur with the hemorrhage and can be confused with hypertensive crisis. Even electrocardiogram findings are common after SAH and may incorrectly suggest cardiac disorders. Lastly, physicians must keep in mind that between one-third to half of patients will present atypically with symptoms that are mild, respond to analgesics or lack meningismus which results in a diagnosis of a benign headache. The evaluation for SAH should include a noncontrast head CT with 3 mm cuts to find collections of blood. A lumbar puncture and evaluation of CSF should be performed next if the CT is negative for blood or mass effect. A normal findings include elevated CSF pressure and the presence of red blood cells that does not diminish from tubes 1 to 4. Red blood cells found only in the first tube are usually indicative of a traumatic tap. Xanthochromia is a much more specific finding for SAH but may require more than 12 hours to develop. If any test indicates that a SAH has occurred, further diagnostic testing should be directed toward determining the cause using CT angiography, MRA, or angiography by direct intra-arterial catheterization, which is currently considered the gold standard. Radiographically detected unruptured aneurysms and vascular malformations should receive neurosurgical evaluation to prevent catastrophic hemorrhage. Patients with SAH should be stabilized and transferred to centers with neurovascular expertise with a dedicated neurosurgical critical care unit. The goals of therapy are twofold: prevention of rebleeding by either endovascular coiling or surgical clipping and prevention and management of vasospasm and other complications.

Giant Cell Arteritis

Giant cell arteritis, often called temporal arteritis, is associated with polymyalgia rheumatica. Essentially, they are different manifestations of the same condition. The cause is unknown, but speculation relates immune responses, infectious triggers, and genetic susceptibility. The condition mostly affects women over 50 years of age. It presents as a new-onset, daily, intermittent or continuous, temporal localized headache that is moderate to severe, burning sharp or throbbing, unilateral or bilateral and lasts months to years.

Patients with giant cell arteritis complain of aching of the jaw during chewing, weight loss, generalized fatigue, and low-grade fever and often have extremity pain attributable to coexistent polymyalgia rheumatica. Visual symptoms include blurring, scotoma, and even sudden blindness. Physical findings consist of palpably thickened or tender scalp arteries that may have a diminished or absent pulse. Palpation of muscle does not reveal trigger points, and muscle strength is typically normal. An erythrocyte sedimentation rate (ESR) is almost always elevated over 50 mm/h in patients with giant cell arteritis. If the diagnosis is suspected, a temporal artery biopsy is essential to confirm the diagnosis. Inflammation in the artery is often segmental; therefore, a 5 cm long segment of artery should be excised; even then, false negatives may occur. Histologic examination of involved vessels reveals necrosis in the vessel’s media with infiltration of macrophages and giant cell formation. Color duplex ultrasonography is being investigated as a diagnostic tool potentially to replace biopsy. Treatment should begin immediately to avoid sudden blindness, a complication found in up to 30% of untreated patients. This is secondary to involvement of the ophthalmic artery. Prednisone is the drug of choice and should be administered at high daily doses of 60 mg. Pain reduces dramatically within days. Once headache has gone into remission and the ESR corrects, prednisone can be tapered over a period of weeks to a daily maintenance dose of 5 to 10 mg while continuing to check for a rise in the ESR. Often treatment must be continued for several years to avoid the complication of blindness. Sometimes the segmental excision of the temporal artery relieves the patient of localized tenderness. However, this does not preclude the need for treatment with corticosteroids.

Carotid Artery Pain

Carotid artery pain may occur secondary to dissection or idiopathic carotidynia or after endarterectomy. Carotid artery dissection is characterized by head and neck pain on the side of the condition following trivial trauma in a young or middle-aged patient. It may cause referred
dissection can be demonstrated by ultrasonography, MRI with MRA, intra-arterial angiography, or surgical findings. For treatment, early anticoagulation is essential to avoid the 15% risk of mortality. This is followed by warfarin for 6 months. If ischemic signs persist after acute hepaminization, surgical intervention may be warranted. Carotidynia is a self-limited inflammation of the carotid fascia or adventitia. It may be induced by viral infection. Physical findings include carotid tenderness, swelling, or intense pulsations. Structural evaluation of the artery is normal. Treatment with NSAIDs may alleviate the pain until spontaneous resolution occurs.

HEADCHE ASSOCIATED WITH NONVASCULAR INTRACRANIAL DISORDERS

The IHS classifies nonvascular intracranial causes of headache into 8 groups. The symptoms, signs, and diagnostic investigations of 3 important syndromes are presented below.

1. progressive headache with at least 1 of the following characteristics: daily occurrence, diffuse and/or constant (nonpulsating) pain, aggravated by coughing or straining;
2. intracranial hypertension fulfilling the following criteria:
   a. alert patient with otherwise normal neurologic examination or has any of the following abnormalities: papilledema, enlarged blind spot, visual field defect, sixth nerve palsy, and increased CSF pressure (>200 mm H₂O in the nonobese, >250 mm H₂O in the obese) measured with lumbar puncture in the recumbent position or by epidural or intraventricular pressure monitoring;
   b. normal CSF chemistry and cellularity (low CSF protein is acceptable);
   c. intracranial disease (including venous sinus thrombosis) ruled out by appropriate investigations; and
   d. no metabolic, toxic, or hormonal cause of intracranial hypertension.

Associated symptoms include unilateral or bilateral pulsatile tinnitus, visual dimming occurring for a minute or 2 at a time, eventual constriction of visual fields, and possible blindness. It may be triggered by otitis media or mastoiditis, irregular menses, recent rapid weight gain, corticosteroid withdrawal, or ingestion of vitamin A, tetracycline, or naldixic acid. MRI and magnetic resonance venography have successfully identified patients with sinus venous pathology who would have otherwise received a diagnosis of IHH. Magnetic resonance venography has become part of the routine work up as recognition of sinus thrombosis has a crucial therapeutic implication. Treatment consists of weight reduction, a low-sodium diet, and diuretics, specifically acetazolamide or furosemide. In severe headache, lumbar puncture can be used to reduce CSF pressure acutely; however, repeated puncture is no longer advocated. CSF diversion by a ventriculoperitoneal shunt may be necessary for refractory cases or when visual fields fail to improve. Transnasal, transthyroidal optic nerve decompression with release of the optic nerve sheath and annulus of Zinn may also be necessary to correct chronic visual field disturbances. High-pressure hydrocephalus differs from benign intracranial hypertension by the identification of enlarged ventricles on head CT or MRI.

Low CSF pressure also commonly precipitates a headache. This may be in response to a lumbar puncture or CSF fistula. The headache appears or worsens when the head is upright and resolves after lying down. The pain is constant when the head is upright and is located in the occipital region or vertex. Nausea is common, and vomiting relieves the headache. Oculomotor or abducens palsies have been reported. Resolution is rapid (usually within several days) following lumbar puncture unless a persistent fistula occurs at the tap site. If this is suspected, a blood patch of the epidural space at the site of puncture is curative. This condition may occur without lumbar puncture and should raise suspicions of post-traumatic, iatrogenic, or spontaneous CSF fistula. If this occurs, site identification by intrathecal metrizamide/contrast CT or myelography should be performed and a surgical repair initiated.

Primary or metastatic intracranial neoplasms present with headache 40 to 50% of the time. The headache is usually bifrontal, but worse ipsilaterally and progressively worsens over time. It is exacerbated by Valsalva maneuver, rises in intrathoracic pressure, and bending over. However, the classic early morning brain tumor headache is uncommon. Sudden vomiting, cranial nerve palsies have been reported. Resolution of pain may be initially achieved with nonnarcotic analgesics, but eventually, narcotics or neuromuscular dihydroergotamine. As medication is withdrawn, patient, resulting in the use of increased dosages. Finally, headache-free intervals cease to exist. Both ergotamine and dihydroergotamine, nonnarcotic analgesics and narcotic analgesics have been implicated. Common examples include aspirin, acetaminophen, NSAIDs, barbiturates, codeine, hydrocodone, oxycodone, and propoxyphene. The IHS noted that use of ergot derivatives for more than 50 g of aspirin or more than 100 tablets of an analgesic per month. Resolution within a month after discontinuing the substance is typical. Although the IHS classification has separate criteria for chronic daily headache and MOH, both may be occurring in the same patient. Initially, therapy should be directed toward withdrawal of overuse medication and then toward the management of the underlying headache. The goals of therapy are to decrease the frequency, severity, and duration of headache by using both pharmacologic and nonpharmacologic measures. Nonpharmacologic measures include patient education, addressing psychosocial issues, and equipping the patient with behavior therapy skills like relaxation. Pharmacologic therapy involves the following: discontinuation of overused medication, initiation of bridge therapy, preventive therapy, and acute therapy in the post-overuse setting. Overuse medications such as barbiturates, opiates, and benzodiazepines should be tapered, whereas other medication such as NSAIDs can be withdrawn abruptly. With abrupt withdrawal, bridge therapy can include NSAIDs, for example, naproxen, prednisone 60 mg/d tapered over 2 weeks or subcutaneous dihydroergotamine. As medication is withdrawn, patients may revert back to their primary headache condition which should be evaluated for the appropriate acute therapy in the post-overuse setting. Medication should be used specifically for the primary headache. Relapse rates approach 45% so close follow-up is required. Headache from withdrawal of a chronically used substance may also occur. In general, the diagnostic criteria for withdrawal headache of a given drug is illustrated below:

1. bilateral and/or pulsating headache;
2. daily intake of a substance for 3 months, which is interrupted;
3. headache develops in close temporal relation to withdrawal of the substance; and
4. headache resolves within 3 months after withdrawal.

For caffeine, opiates, and estrogen, there are specific time intervals for criteria B, C, and D. The headache is diffuse, dull, and mild to moderate in severity. It may be associated with nausea, restlessness, and vomiting. Persistent abstinence is the mainstay of treatment but may require hospitalization to prevent the patient from consuming more of the offending medication.

HEADACHE ATTRIBUTED TO INFECTION

Intracranial infections include meningitis, encephalitis, brain abscess, or subdural empyema, which may present with a generalized, bilateral, severe, constant headache often with nuchal rigidity, positive Kernig and Brudzinski signs, and fever. The onset is rapid, usually over several hours. Patients with meningitis will present with at least 2 of 4 symptoms: headache, fever, nuchal rigidity, and decreased level of consciousness. A ambiguous presentations may occur in immunosuppressed patients, atypical infections such as tuberculosis, fungal meningitis, neurophilis, or epidural abscess. When evaluating a patient with suspected meningitis, CT scan before lumbar puncture is indicated in the following cases: immunocompromised state, history of central nervous system disease, new onset seizure (within 1 week), papilledema, abnormal level of consciousness, and focal neurological deficit. If lumbar puncture is delayed for neuroimaging, the patient should be given medical therapy including empirical antibiotics and dexamethasone. Culture and antigenic studies from CSF from lumbar puncture are diagnostic. Treatment requires appropriate intravenous antibiotic therapy and surgical drainage of abscesses.

HEADACHES ATTRIBUTED TO DISORDER OF HOMEOSTASIS

Hypoxia, as seen in high-altitude headache, is a known source of cephalalgia. Descent and oxygen therapy are the treatment. A more common cause of chronic hypoxia is found in sleep apnea syndrome, in which morning headache is common. It is diffuse, dull, and mild and may be associated with short-term memory loss and inability to concentrate. The diagnosis is suggested by more significant symptoms of the syndrome, specifically fatigue, daytime somnolence, and apneas witnessed by a bed partner. Resolution of the headache occurs quickly following correction of the hypoxia by continuous positive airway pressure or surgical intervention.

Headache is more likely to result from acute than chronic arterial hypertension. The acute rise in blood pressure can be secondary to administration of pressors, pheochromocytoma, malignant hypertension (including hypertensive encephalopathy), preeclampsia, and eclampsia. Typically, headache begins with diastolic pressures greater than 115 mm Hg. It is throbbing, associated with nausea, and does not respond to analgesics.

Treatment involves controlling and correcting the source of the hypertension. Once this is achieved, the headache resolves within days to months.

HEADACHE OR FACIAL PAIN ASSOCIATED WITH CRANIOFACIAL OR CERVICAL DISORDERS

This is a heterogeneous group of cephalalgias which encompasses a group of headaches attributed to a disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structure. If disease involves any extracranial organ of the head or the skull itself, pain may ensue. Facial or head pain is localized to the affected structure but may radiate or be referred and develops in close temporal relationship with the pathological lesion. If the lesion is corrected, headache resolves in <1 month. Examples affecting the cranial bones include osteomyelitis, multiple myeloma, and Paget's disease of bone.

Cervicogenic headache is a relatively common condition created by a disorder afflicting the cervical spine. Women are more frequently affected than men. It is characterized by headache that is unilateral, unchanging, dull, and nonpulsatile. It tends to start at the occiput and radiate to the frontal region where the pain is most intense. It is bilateral, one side is usually of worse intensity. Pain may also radiate into the shoulder or arm. A attacks are precipitated by awkward positions, neck movement, or palpation of trigger points such as the greater occipital nerve or over the C2 vertebral body. Associated symptoms of nausea and photophobia or phonophobia are present in 50% of patients. Neck examination reveals a reduced range of motion of the spine and possibly muscle tenderness, spasm, hypertrophy, or atrophy. Criteria for its diagnosis have been proposed by both the IHS and the Cervicogenic Headache International Study Group. In the IHS criteria, currently established causes of cervicogenic headache include tumor, fracture, and rheumatoid arthritis but not cervical spondylosis and osteoarthritis. One distinctive feature of cervicogenic headache is a positive response after an appropriate diagnostic nerve block, which is directed towards the structure suspected to be mediating or causing the headache. The objective of the diagnostic criteria is to assist the clinician to detect a lesion, which has been established as a cause of cervicogenic headache, then demonstrate the lesion to cause the headache, and finally abolish the headache consistently with a diagnostic blockade of the specific cervical structure or nerve supply. The IHS criteria are described as follows:

1. pain, referred from a source in the neck and perceived in one or more regions of the head and/or face;
2. clinical, laboratory and/or imaging evidence of a disorder or lesion within the cervical spine or soft tissues of the neck, known to be or generally accepted as a valid cause of headache;
3. evidence that the pain can be attributed to the neck disorder or lesion based on at least 1 of the following:
   a. demonstration of clinical signs that implicate a source of pain in the neck
   b. abolition of headache following diagnostic blockade of a cervical structure or its nerve supply using placebo or other adequate controls
4. pain resolves within 3 months after successful treatment of the causative disorder of the lesion.

Cervical radiographic data reveal either abnormalities on flexion and extension films, abnormal posture, or evidence of bone or joint pathology. Treatment centers around physical therapy and stretching exercises, use of NSAIDs, and chronic nerve blockade for refractory cases.

Sinonasal disorders are a frequent source of headaches but are probably over credited by the population as a whole. Frontal headache and facial pain are 2 of the 3 major symptoms suggesting the presence of sinusalitis, the other being purulent nasal drainage. A cute sinusitis is a leading cause of facial pain, second only to dental disorders. The IHS classification for headache from rhinosinusitis is given below:

1. frontal headache accompanied by pain in one or more regions of the face, ears, or teeth;
2. clinical, nasal endoscopic, CT and/or MRI imaging and/or laboratory evidence of acute or acute-on-chronic rhinosinusitis;
3. headache and facial pain develop simultaneously with onset or acute exacerbation of rhinosinusitis; and
4. headache and/or facial pain resolve within 7 days after remission or successful treatment of acute or acute-on-chronic rhinosinusitis.

However, chronic sinusitis is not validated as a cause of headache or facial pain. The cephalalgia feels like a dull pressure of moderate intensity and can be either unilateral, bilateral, or periorbital. It is worse in the morning and when bending or performing the Valsalva maneuver. Associated symptoms include purulent nasal drainage, nasal obstruction, altered sense of smell, asthma exacerbation, cough, malaise, and diziness. Nausea and visual change are infrequent associated symptoms.

Pain with the inflammatory process lasts days or weeks with fluctuating severity. The location and extent of the sinusalits do not correlate well with the severity or site of pain. However, a few tendencies are common. The area overlying an infected sinus is often tender. Pain for sinusitis
referred to upper maxillary teeth typically originates in the maxillary sinus. Occipital or vertex pain from sinusitis most likely represents sphenoid sinus disease. An infected sinus can refer pain to the frontal, retro-orbital, and temporal regions. Physical examination finds tenderness to percussion over involved sinuses. Transillumination is not useful to delineate the presence of sinusitis. Other physical findings center around inflammatory changes in the nose. Radiographic imaging is helpful to confirm an uncertain diagnosis of sinusitis or to evaluate response to treatment. As plain films have poor sensitivity, a screening coronal sinus CT has become the imaging study of choice. Treatment requires medical therapy to reverse the inflammatory cause of the headache and includes antibiotics, decongestants, and possibly corticosteroids, with analgesics used in the interim for symptomatic relief until the sinusitis is resolved.

Rhinologic headaches other than those caused by sinusitis also occur, albeit much more rarely. Nasal anatomic abnormalities occasionally associated with facial pain include impacted septal deviation or spurs, hypertrophic turbinates, and even an occasional large maxillary retention cyst. However, most sinonasal neoplasms do not cause pain. The cause of rhinogenic pain may be related to direct sensory stimulation from 2 mucosal surfaces contacting each other. The pain is usually dull and aching and unilateral. An anatomic abnormality can be seen on examination after decongesting the nose. If the cause is mucosal contact, topical lidocaine can be used as a diagnostic test as the pain should diminish or disappear after application. Medication may effectively control turbinate hypertrophy, but surgical approaches are effective in managing the anatomic defects.

Elongated styloid process, better known as Eagle syndrome consists of recurrent throat and neck pain exacerbated by swallowing. Otolgia, dysphagia, and foreign body sensation are often present and are secondary to an elongated styloid process impinging on the carotidplexus or branches of cranial nerve IX. It may develop subsequent to tonsillectomy because of inflammatory changes. Palpation of the styloid process in the tonsillar fossa exacerbates the dull pain, whereas injection of a local anesthetic provides relief and is diagnostic. A lateral plain film of the head reveals a styloid process greater than 2.5 cm long. Reassurance and medical therapy with NSAIDs or corticosteroid injection around the stylohyoid ligament may be successful. Otherwise, treatment involves surgical shortening of the calcified stylohyoid ligament (elongated styloid process) through the tonsillar fossa.

TMJ disorders are frequent causes of facial pain and headache. These disorders are divided into 2 major groups: those with demonstrable organic disease, which is uncommon, and those of myofascial origin from masticatory muscles, which is common. The IHS has established the following diagnostic criteria for TMJ disease:

1. Recurrent pain in 1 or more regions of the head and/or face;
2. X-ray, MRI, and/or bone scintigraphy demonstrate TMJ disorder;
3. Evidence that pain can be attributed to the TMJ disorder, based on at least 1 of the following:
   a. Pain is precipitated by jaw movements and/or chewing of hard or tough food;
   b. Reduced range of jaw opening or irregular jaw opening;
   c. Noise from one or both TMs during jaw movements; and
   d. Tenderness of the joint capsule(s) of one or both TMs.
4. Headache resolves with 3 months and does not recur, after successful treatment of the TMJ disorder.

Women are far more likely to suffer from TMJ pain. The pain is located preauricularly and in the temporal region of the head; it is intermittent, lasting hours to days; is mild to moderate in intensity; can be unilateral or bilateral; and is exacerbated by jaw movement. Associated features include otalgia, bruxism, trismus, TMJ crepitus, and jaw locking. Usually, there are neither muscular trigger points nor symptoms of nausea or visual change. Etiology of the discomfort includes diseased joints that can occur on the basis of arthritis (the most common cause), traumatic causes such as fractures or dislocations, internal derangements of the intra-articular disk, or developmental defects.

Physical findings include audible joint clicking on one side or both and decreased range of motion. Normal vertical opening between central incisors ranges from 42 to 55 mm. Palpation should cover the head and neck musculature and TMs involving intraoral pterygoid palpation, noting any asymmetry, tenderness, spasm, hyper trophy, atrophy, triggering of referred pain, or crepitus when opening or closing. If pathology is suspected, a TMJ radiographic series may reveal a joint abnormality. The usual indications for imaging include suspected fractures, degenerative joint disease, ankylosis, or tumors.

Management of TMJ disease includes reassurance, education, NSAIDs, restriction of jaw opening, a soft diet, and physical therapy. Occasionally, biofeedback or corticosteroid injection may be helpful. If pain is chronic, tricyclic antidepressants may be beneficial. Because of the potential for dependency in chronic conditions, narcotics are best avoided. A cute disk or condylar displacements may require manual reduction to relieve pain and restore range of motion or relieve a joint locked open or closed. Often sedation or general anesthesia is necessary to relax the muscles to facilitate the manual reduction. The use of a bite appliance may alleviate chronic headache or muscle pain secondary to bruxism or joint pain secondary to anterior disk displacement. A throccentric, sclerotic therapy, and arthroscopic surgery are reserved for chronic dislocations, disk derangements, or condylar anomalies.

Oromandibular dysfunction involves pain in the TMJ without organic disease. Other terms describing this condition include myofascial pain dysfunction syndrome and TMJ pain dysfunction syndrome. The etiology of pain seems to have its origin in myofascial tissues or central processes disinhibiting sensory pain pathways. The IHS system classified this as a TTH that does not purely meet the criteria of episodic or chronic TTHs. A diagnosis requires at least 3 of the following: the creation of noise with jaw movement, limited range of motion, pain during jaw use, locking of the jaw, or a history of clenching or grinding of the teeth. The pain is typically continuous, dull, aching, poorly localized, usually unilateral, discomfort of mild to moderate degree involving the ear, angle of the jaw, and temple. The pain rarely wakes the patient, and the location of pain may shift. The patterns of referred pain often do not make neurologic sense. It may be associated with swelling, numbness, stiffness, or erythema. The hallmark of this myalgia are the presence of trigger points that, when palpated, reproduce the referred pain. Examination will reproduce the pain when masticatory and neck muscles are palpated. Full range of jaw motion may be lost with this disorder. A trigger point injection of an anesthetic (such as 1% procaine) can confirm that point’s significance by relieving the pain.

Therapy consists of reassurance, modification to a soft diet, physical therapy, trigger point local anesthetic injection, and medications. A mitriptyline for at least 2 months is an effective choice, whereas NSAIDs may or may not be. Occlusion splints relieving bruxism may help, as might attention to abnormal occlusal factors that can precipitate the disorder. Because of the self-limited nature of the condition, invasive approaches should be avoided.

CRANIAL NEURALGIAS

Cranial neuralgias are conditions affecting nerves with sensory functions in the head and neck, resulting in severe stabbing or throbbing pain in the distribution of the involved nerve. They can involve any cranial nerve with sensory fibers or cervical roots 1, 2, or 3. The conditions are subdivided into persistent painful disorders and paroxysms of pain (tic-like) disorders.

Therapeutic injury to a nerve or inflammatory changes can result in chronic neuralgia. Trauma or surgery to the cranium or face may result in entrapment neuritis or formation of a neuroma, typically 2 to 6 months later. The occurrence is greatest in the third branch of the trigeminal nerve because of the frequency of injury related to mandibular fracture or tooth extraction. Symptoms include hypersensitivity and pain to light touch, pain in an area of skin that has lost its sensory innervation, and aggravation of pain by cold or emotional duress. The pain is sharp and lancinating. A central cause of a neuralgic pain can occur as anesthesia dolorosa following surgical ablation of the trigeminal
ganglion. The condition is characterized by sharp pain and numbness in the distribution of any or all branches of the trigeminal nerve after trigeminal rhizotomy or trauma. Treatment uses anti-convulsant medications, in particular, carbamazepine, or sometimes baclofen or clonazepam. A mitroproline has also been employed with success.6 Injection of local anesthetics into trigger points or surgical resection or repair of neuromas is necessary for refractory cases.

Inflammatory conditions are also well known to cause neuralgia. A prime example is acute herpes zoster of a branch of the trigeminal nerve, the seventh cranial nerve, or cervical roots. The ophthalmic branch of cranial nerve V is the most commonly involved nerve. A cute herpes zoster is characterized by an intense burning or stabbing pain in the distribution of the involved nerve which is followed within 1 week by a herpetic eruption in the skin distribution of the same nerve. Motor divisions of involved nerves may be paretic. The pain subsides within 3 months of the onset, but the motor palsies have a poor prognosis for complete recovery. The goals of therapy during the acute phase is to minimize the duration of the attack, decrease the severity of pain, and prevent the development of postherpetic neuralgia. Treatment of the acute phase consists of a 7- to 10-day course of an antiviral agent. Prednisone or oral corticosteroid therapy has been demonstrated to accelerate healing of crusts and cessation of pain, but it has no effect on the prevention of postherpetic neuralgia. There is also a risk of disseminated herpes zoster, therefore it should be used only in patients with severe symptoms at initial presentation. Prednisone 40 mg can be started and tapered so that the last dose is given with the end of antiviral therapy.67 Noncorticosteroidal anti-inflammatory drugs or opiates may be necessary to control pain. A cute herpes zoster is common in lymphoma patients, so a new outbreak should raise suspicions about that possible comorbidity.

Chronic postherpetic neuralgia exists when herpes zoster pain persists for >3 months. It is characterized by the distribution of the originally afflicted nerve. It is more likely to occur in patients who are over 60 years old when the acute infection starts, and in this group it is less likely to resolve spontaneously.13,22,71 Noncorticosteroidal anti-inflammatory drugs and opiates fail to relieve the neuralgia. Instead, topical anesthetics as gabapentin are more effective and may be used only in patients with severe symptoms at initial presentation. Gabapentin, phenytoin, baclofen, sodium valproate, and carbamazepine may be employed for at least 2 weeks, and medications may be used in combination. Tricyclic antidepressants and NSAIDs may also be beneficial. Surgical radiofrequency ablation, specifically trigeminal rhizotomy, is recommended for patients refractory to medical therapy, whereas temporary blockade may be indicated for patients experiencing intense activation of the disease.

Glossopharyngeal neuralgia is a disorder similar to TGN but affecting cranial nerve IX. Men in their forties or fifties are more likely to have this disorder. The pain characteristics include repetitive, brief attacks of lancinating pain located in the soft palate, base of the tongue, pharynx, and ear. The trigger point is located in the tonsillar fossa and can be provoked by swallowing or yawning. Associated symptoms may include hiccupping, nausea, vertigo, tinnitus, aural fullness, hearing loss, dysgeusia, bradycardia, and syncope. Evaluation and management are identical to those for TGN.50

Superior laryngeal neuralgia is characterized by unilateral lancinating attacks of pain at the side of the larynx over the thyrohyoid membrane. Pain radiates to the ear and submandibular region and is precipitated by swallowing, straining the voice, playing a musical instrument, or turning the head. The pain paroxysms last minutes to hours for days or weeks at a time. Dysphonia may be present secondary to involvement of the external branch of the superior laryngeal nerve affecting the cricothyroid muscle. Injection of local anesthetic as a nerve blockade confirms the diagnosis when pain is relieved.59 The condition is managed with anti-convulsants as in TGN or with surgical sectioning of the superior laryngeal nerve.

Occipital neuralgia is a paroxysmal stabbing aching pain over the occiput in the distribution of the greater or lesser occipital nerve combined with reduced sensation in the same area. Associated symptoms include visual disturbances, dizziness, nausea, tinnitus, and scalp paresthesias. The physical findings include a positive Tinel sign or palpable tenderness of the involved occipital nerve.69 Confirmation of the diagnosis is made by obtaining relief from pain after an injection of local anesthetic is performed to block the nerve. Management consists of heat, physical therapy, rest, transcutaneous electrical nerve stimulation units, NSAIDs, baclofen, or carbamazepine. Cervical collars are of questionable benefit. Invasive measures for refractory cases include local blockade with bupivacaine in combination with an injectable corticosteroid, alcohol blockade, or even nerve section.69

Sluder sphenopalatine neuralgia is currently classified as a cluster headache, though it is also considered a cranial neuralgia. When first described it was found to occur in episodes that recurred weekly to monthly. The pain is localized to the maxillary area with autonomic symptoms. On the affected side, there can also be diminished sensibility of the soft palate, a high arched palate, and diminished taste sensation. Treatment includes application of cocaine to the mucosa overlying the palatal mucosa, removal of the precipitating septal spur, or ablation of the sphenopalatine ganglion.51,70

"Ophthalmoplegic migraine" is a syndrome with recurrent attacks of migraine-like headache accompanied by or followed by paresis of the third, fourth, or sixth cranial nerves which may be due to a recurrent dymyelination or ischemic neuropathy. It is a rare cause of monocular blindness.13,22,71

UNCLASSIFIABLE FACIAL PAIN (ATYPICAL FACIAL PAIN)

A typical facial pain fails to fit the profile of any specific craniofacial condition. The prosopalgia (facial pain) is unilateral or bilateral, is located in the face and upper neck, and is a constant ache or burning with exacerbations. It does not localize to anatomic regions or have relation to specific structures as TMJ arthralgia or myofacial pain does. It lasts for years, is exacerbated by stress, and is associated with paresthe-

Primary Paranasal Sinus Surgery

James A. Stankiewicz, MD
Joseph M. Scianna, MD

The undertaking of primary paranasal sinus surgery requires a detailed familiarity of the relevant anatomy, a fundamental appreciation for the normal nasal physiology, a comprehensive understanding of the surgical indications, and a respect for the potential complications that may arise. The anatomy and physiology of the nose and paranasal sinuses are discussed in Chapter 37, “Embryology, Anatomy, and Physiology of the Nose and Paranasal Sinuses.” Indications for primary paranasal sinus surgery can be divided into absolute and relative indications. Absolute indications include: orbital abscess secondary to acute infection, frontal lobe abscess/meningitis secondary to acute infection, mucocele, or fungal mycetoma. Relative indications include chronic rhinosinusitis failing medical therapy, headaches, facial pain, recurrent acute sinusitis, obstructive nasal polyposis, and asthma exacerbations in patients with Samter triad.

While the absolute indications for primary sinus surgery represent a relatively straightforward presentation and thought process, the relative indications for primary sinus surgery are hinged upon symptomatic rhinosinusitis with or without polyposis. The term rhinosinusitis to some degree has become an ambiguous term encompassing a plethora of disease processes that develop from both environmental and host factors. Rhinosinusitis can be acute, subacute (<3 months duration), chronic, or an acute exacerbation of chronic rhinosinusitis. Rhinosinusitis may be accompanied by atopy and associated with polypos, asthma, and aspirin sensitivity (Samter triad). Many theories exist regarding the formation of nasal polypos, although the exact mechanism is not yet understood. Nasal polypos are present in 5% of nonatopic individuals and only 1.5% of people with allergic rhinitis. No racial or sexual predilection is reported. The prevalence is increased in patients with cystic fibrosis and those with Samter triad.

Controlling rhinosinusitis with medical therapy can be difficult. Currently, prolonged antibiotics, oral or topical antifungal agents, oral and nasal corticosteroids, nasal steroids, mucolytics, leukotriene inhibitors allergy evaluation, and immunotherapy—all represent medical measures aimed at controlling chronic rhinosinusitis. Clear documentation of medical intervention and failure is essential prior to advancing to surgery. Intervention requires a detailed preoperative evaluation including a radiographic evaluation, concise surgical planning targeted at the specific disease areas, and most importantly a continued postoperative treatment period.

**PREOPERATIVE EVALUATION**

Preoperative evaluation of the patient with rhinosinusitis begins with a complete otolaryngologic history and physical examination. For patients with absolute indications for surgery, the historical presentation is generally straightforward. Mental status alterations including obtundation, and visual changes can accompany meningitis or epidural or frontal lobe abscess. A subjective progression of diplopia, visual loss, or ocular pain may accompany orbital cellulitis with abscess formation (Figure 1). Severe pressure and/or transcutaneous drainage may be presenting clues that a mucocele has developed. Lastly, fungal mycetoma may present innocuously, causing specific pain or symptoms related to the single sinus involved.

The typical presenting complaint of a patient with rhinosinusitis will be nasal obstruction and anosmia. Repeated sinus infections, headache, and a medical history of asthma and aspirin sensitivity are commonplace. History of hay fever or allergic symptoms may also be present. A sinonasal questionnaire may aid in the evaluation of rhinosinusitis and nasal polyposis and can quantify the severity of subjective complaints. Although many different questionnaires exist in the literature, an effective questionnaire will focus on qualifying the baseline symptoms of the disease as well as the level of exacerbation of the disease process.

Establishing the history of previous and current therapeutic measures and the relative effectiveness of these interventions provides an indication to the severity of the disease process. In many instances, medical therapy including an oral corticosteroid and 4 to 8 weeks of antibiotics provided intermittent relief of symptoms, but rapid return to baseline upon cessation of therapy. Besides the approved or recommended medical interventions that patients will disclose, questioning the patient with regards to nontraditional therapy especially over-the-counter remedies will provide additional insight. Over-the-counter topical decongestants, in particular, when used for prolonged periods can be exacerbating factors to rhinosinusitis. Herbal medications may increase the likelihood of intraoperative bleeding or postoperative difficulties.

Nasal or midface trauma or cosmetic intervention, including rhinoplasty and septoplasty, represents important historical information. Dehiscence of the lamina papyracea or intranasal anatomic alterations may occur in such injuries. In addition, nasal trauma with severe septal deviation may necessitate septoplasty for visualization. While most cosmetic interventions do not address the sinuses, occasionally intranasal scarring and synechiae may be associated with this type of surgery.

Assessing for risk of anesthesia, a propensity for bleeding or familial difficulties with...
coagulation or anesthesia will increase the safety of operative intervention. A social history with emphasis on tobacco use, chemical exposure, and environmental exposures that may contribute to nasal irritation is important to establish. A complete review of systems with attention to endocrine disorders such as diabetes, immune disorders such as HIV infection and gamma globulin deficiencies as well as systemic disorders such as Wegener granulomatosis provides important diagnostic information.

A complete head and neck examination is routine in preoperative evaluation. Obviously attention to the external and intranasal structures is important; however, documentation of extraocular muscle mobility, pupillary size and responsiveness, preexisting facial sensory deficits, and any facial deformity secondary to nasal obstruction is paramount. Extensive nasal polyps may be visible on anterior rhinoscopy (Figure 2). Classification and documentation of the percentage of airway blockage provides pre- and posttherapy comparison. Evaluation of the turbinates, nasal septum, and the nasal valve helps determine potential causes for airway obstruction. Response of the nasal mucosa of the inferior turbinates to a vasoconstrictive agent such as neosynephrine may also aid in evaluating nasal obstruction. This is important since it can be problematic to perform excellent sinus surgery but have the patient continue to complain of nasal obstruction due to large turbinates or sepal deviation.

Flexible nasal endoscopy is highly important in the preoperative evaluation. Determination of extent of disease and visibility of normal anatomical structures such as the uncinate process and middle turbinate will indicate the complexity of the surgical intervention. The presence of pus, indicative of active infection, or allergic or fungal mucin (a thick mucus with a peanut-butter like appearance and consistency) may be visible (Figure 3). One must also be cognizant of the numerous intranasal tumors, such as esthesioneuroblastoma, sinonasal carcinoma, nasopharyngeal carcinoma, T-cell lymphoma (formerly known as midline destructive granuloma), and inverted papilloma, which may be causing sino-nasal symptoms. If either a benign or malignant neoplasm is suspected, proper radiographic and pathologic evaluation should be pursued.

Laboratory evaluation for the typical rhinosinusitis patient mandates an allergy screening. The choice of allergy screening is based upon institutional and physician preference with the radioallergosorbent test and skin prick tests being the 2 most common forms of testing. Understanding the role that atopy plays in a patient's disease process will help to ensure a successful postoperative treatment strategy. Obtaining a total IgE level is not essential, but this may be useful when allergic fungal sinus disease is suspected. Expensive laboratory screenings that are more appropriate for the recalcitrant patient include evaluation for gamma globulin deficiencies. The sweat chloride test is a necessary adjunct to the evaluation of the pediatric patient but is generally not necessary in the adult population.

Computed tomography (CT) is a reliable and informative part of the preoperative evaluation. A screening coronal sinus CT (5 mm images) delineates the extent of disease as well as the relevant anatomy. Identification of the level and integrity of the skull base, dehiscences of the lamina papyracea or the carotid canal, the frontal sinus drainage pattern, and anatomic variants, such as agger nasi, Haller, or Onodi cells, will aid in preventing operative complications. The level of the skull base and its slant or slope can be measured by a variety of means. The medial rectus and superior aspect of the orbit can act as landmarks in the identification of a low-lying skull base (Figure 4). Other important information that can be obtained includes any deformity of the nasal septum, as well as the presence of a concha bullosa of the middle turbinate that may contribute to nasal or ostial obstruction. A heterogeneously opacificed sinus may be indicative of fungal debris or inspissated secretions, and bowing of bony structures may suggest a chronic expansile process, such as mucocele formation. Magnetic resonance imaging can differentiate a polyoid mass from inspissated secretions but is not an essential component of preoperative planning.

While the screening sinus CT provides a cost-efficient evaluation of important bony anatomy, a 3-dimensional high-resolution CT such as those used for computerized guidance during surgery may provide additional information in significant detail. The use of computer-assisted surgical navigation can be an effective adjunct to surgical intervention; but it is not standard of care for primary paranasal sinus surgery nor should it be used in lieu of an understanding of the sinonasal anatomy as viewed through an endoscope (Table 1). The American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) has endorsed the following statement regarding computer-aided surgery:

---

**Figure 2** Endoscopic view of nasal polyp as seen during anterior rhinoscopy.

**Figure 3** Fungal mucin. (A) Fungal debris on endoscopic examination with typical peanut butter consistency. (B) Axial computed tomography scan with calcification in left maxillary sinus typical of fungal debris.

**Figure 4** Normal coronal image from computed tomography scan. Level of normal skull base (white line) can be seen in relation to the medial rectus muscles (red ovals) and the superior most aspect of the orbit (black line).

**Table 1** Guidelines and Indications for Computer-Guided Sinus Surgery

| Revision sinus surgery |
| Distorted sinus anatomy of developmental, postoperative or traumatic origin |
| Extensive sinonasal polyposis |
| Pathology involving the frontal, posterior ethmoid, and sphenoid sinuses |
| Disease abutting the skull base, orbit, optic nerve, or carotid artery |
| Cerebrospinal fluid rhinorrhea or condition in which there is a skull-base defect |
| Benign and malignant sinonasal neoplasms |

Adapted from reference 35.
The AAO-HNS endorses the intraoperative use of computer-aided surgery in appropriately select cases to assist the surgeon in clarifying complex anatomy during sinus and skull base surgery. There is sufficient expert consensus opinion and literature evidence base to support this position. This technology is used at the discretion of the operating surgeon and is not experimental or investigational. Furthermore, the AAO-HNS is of the opinion that it is impossible to corroborate this with level 1 evidence. These appropriate, specialty specific, and surgically indicated procedural services should be reimbursed whether used by neurosurgeons or other qualified physicians regardless of the specialty. (AAO-HNS guidelines: http://www.entlink.net/practice/rules/image-guiding.cfm.)

PERIOPERATIVE CONSIDERATIONS

An important step in any sinonasal operative procedure is to obtain a detailed and comprehensive informed consent. Explanation of risks of sinus surgery should include, at minimum: (1) entrance into the orbit resulting in hematoma, diplopia, or blindness, (2) violation of the skull base resulting in cerebrospinal fluid leak, meningitis, brain damage, or death, and (3) recurrent disease requiring repeat or revision surgery. These should be clearly understood by the patient. An understanding that surgical resection of nasal polyps and maintenance of the sinonasal cavity will require continued postoperative medical therapy will alert the patient to the importance of follow-up and compliance.

After establishment of informed consent and prior to preparation in the operating room, an intranasal vasoconstrictive agent such as oxymetazoline begins the operative preparation. The choice of anesthetic depends on the preference of the surgeon, the degree of expertise of the anesthesiologist, and the patient. General anesthesia is favorable for the comfort of the patient, although local and sedative anesthesia can be used.

After induction of anesthesia with the patient in a supine position, the operating table is placed in slight reverse Trendelenburg position and cantilevered to the patient’s right. The patient’s head is also turned slightly to the right and placed in a foam headrest to maintain this position. This provides comfortable positioning for the right-handed surgeon decreasing the potentially awkward endoscopic angle of working in the left nasal cavity. A ministration of intravenous corticosteroids and antibiotics can ensure at this time.

Nasal preparation continues with injection of 1% lidocaine with 1:100,000 units of epinephrine along the lateral nasal wall in the region of the sphenopalatine foramen, the root of the middle turbinate (anterior and superior to the uncinate process), and into any visible polyps. After injection of nasal cavities, insertion of 4% cocaine pledgets proceeds. Placement of a cocaine soaked pledget lateral to the middle turbinate in the middle meatus aids in vasoconstriction of this area. This is not always possible depending on the extent and nature of the disease and other underlying patient factors. Several institutions employ pledgets soaked in topical epinephrine at strengths varying from 1:1,000 to 1:100,000 to aid hemostasis further.

After injection, an intraoral, obstructing throat pack may be placed to prevent ingestion of blood during the surgery and aspiration of resected sinonasal contents. During the positioning and preparation of the patient, care is taken to ensure that both eyes are clearly visible during the surgery. Taping of the lateral canthus will provide eye closure and protection from external abrasion, while providing the surgeon with the opportunity to visualize and palpate the eye during surgery.

Positioning of the bed, the patient, the anesthesia staff, the nursing staff, and the operative instrumentation should accentuate the surgeon’s comfort while maintaining patient safety. While monitors are not essential for endoscopic sinus surgery, they allow the surgeon to operate in the upright position and avoid undue strain on the back and neck. A sitting or standing position is up to the surgeon’s preference. If computer-guided imagery is being employed, proper registration and anatomical verification should proceed. Foot pedals for operating powered instrumentation should be positioned appropriately.

APPROACH TO PRIMARY PARANASAL SINUS OPERATIONS

Prior to beginning the operation, reverification of the site of disease and confirmation of the involved sinuses should take place both endoscopically and via review of available imaging. Identification of normal anatomic structures such as the uncinate process, the middle turbinate, the inferior turbinate, and the nasopharynx initiates the surgical procedure. If nasal polypoid disease is obliterating these structures, careful, conservative dissection of the polypoid tissues will allow visualization of important landmarks, anterior ethmoid sinuses, and maxillary antrostomy.

If a concha bullosa is identified on preoperative imaging or endoscopically, it may contribute to the obstruction of the natural ostium of the maxillary sinus and hinder surgical progress. The concha bullosa should be resected with maintenance of the structural integrity of the middle turbinate. After injection of 1% lidocaine with epinephrine the anterior surface of the concha bullosa is incised with a sickle knife. A high-angle punch forceps can be used to remove the anterior wall of the concha bullosa while simultaneously preserving the mucosa of the medial wall of the middle turbinate (Figure 5). Loose fragments of bone can be trimmed with a punch forceps or carefully removed with a grasping forceps. Care should be taken to avoid tearing or shearing of normal sinus mucosa, particularly when using grasping forceps. In general, posterior- and inferior-directed movements after grasping bone fragments that may still have a mucosal attachment will help prevent tearing of the mucosa.

Mucosal Attenuation

Once anatomic localization of structures occurs and clear visualization is available, manipulation of the maxillary sinus and its natural ostium represents a primary step in disease eradication. Anatomically, the uncinate process protects the natural ostium of the sinus and must be addressed to proceed. The uncinate process may

Figure 5 Computed tomography (CT) image and intraoperative images of a concha bullosa. (A) CT scan with right concha bullosa (white arrow). (B) Concha bullosa surgically opened. (C) Concha bullosa after resection of the lateral half.
be displaced anteriorly and medially secondary to polyposis or it may be lateralized and adherent to the lamina papyracea in conditions such as a hypoplastic maxillary sinus. A probe inserted in the hiatus semilunaris can be used to palpate the space between the uncinate process and the lamina papyracea (the ethmoid infundibulum), and this information will help prevent accidental puncture of the medial orbital wall. With the uncinate process identified, 1 technique for resection is to remove a portion of the inferior third in a retrograde fashion using a back-biting forceps. Opening this forceps to an acute angle will prevent inadvertent trauma to the lamina papyracea and violation of orbital contents. Retrograde uncinate resection should proceed to the hard lacrimal bone with avoidance of damage to the lacrimal duct. A probe can then be used to displace the superior and inferior uncinate remnants anteriorly for resection with the microdebrider. As with any maneuver in paranasal sinus surgery, care should be taken to avoid damage to the normal mucosa.

An angled telescope (30°, 45°, or 70°) can then be used to identify the natural ostium of the maxillary sinus. This may be obstructed by polyps, in which case visible polyps should be removed from the area. Positioning the microdebrider window vertically and not toward the lamina papyracea (medial orbital wall) will avoid inadvertent damage to orbital fat and its contents in situations in which either an iatrogenic or inherent dehiscence of the lamina is present. If the natural ostium is open in nonpolyoid disease, no formal antrostomy is necessary. With careful identification of the diseased natural ostium of the maxillary sinus, a probe can be introduced and the ostium can be dilated posterior and inferi orly creating a wide maxillary antrostomy. The size of the maxillary antrostomy in nonpolyoid disease is not nearly as important as ensuring that any antrostomy communicates with the natural ostium of the maxillary sinus. Inadvertent creation of a posterior fontanelle antrostomy may result in a recirculation phenomenon or persistent disease that will require revision surgery. In polyoid sinusitis, a large antrostomy is necessary. With the establishment of the maxillary antrostomy, the superior limit of the orbital floor and the lateral limit of the medial orbital wall can now be delineated. Disease adjacent to or within the maxillary sinus can then be safely removed with either a straight or a curved microdebrider. Avoidance of circumferential trauma around the antrostomy will help avoid postoperative cicatricial scarring.

**Ethmoid Sinuses**

If ethmoid disease is present, one should attempt to distinguish between anterior and posterior ethmoid disease. The anterior and posterior ethmoids are divided anatomically by the vertical portion of the basal lamella of the middle turbinate. However, the ethmoid bulla represents the most posterior of the anterior ethmoid cells and should be removed to access the posterior ethmoid cells appropriately. Entrance into the bulla with resection of bone and polyloid disease should proceed with preservation of the mucosa overlying the lamina papyracea laterally. Clear identification of the maxillary ostium aids in clarifying the lateral extent of dissection. As the ethmoid bulla is removed, the vertical and horizontal portions of the basal lamella should be evident. Identifying the horizontal basal lamella and maintaining its integrity will avoid unnecessary damage to the sphenopalatine artery and maintain the stability of the middle turbinate. The suprabullar cells are removed to complete the anterior ethmoidectomy.

To enter the posterior ethmoid, the inferior and medial aspect of the vertical basal lamella will be removed. Preoperative identification on a CT scan of a posterior ethmoid cell lateral and superior to the sphenoid sinus (the Onodi cell) will ensure a complete posterior ethmoidectomy (Figure 6). Lack of recognition of an Onodi cell can result in inadvertent entrance through the skull base, potential optic nerve injury, and undressed sphenoid disease secondary to confusion of the Onodi cell with the sphenoid sinus.

**Sphenoid Sinus**

Once the inferior cells of the posterior ethmoids are adequately removed the natural ostium of the sphenoid sinus can be identified. Use of a calibrated probe can identify the anterior wall of the sphenoid at approximately 7 cm from the nasal sill at a 30° angle (Figure 7). Resection of the lower one-third of the superior turbinate may also be helpful to provide adequate visualization for the sphenoidotomy. In most cases, the natural ostium of the sphenoid lies just medial to or directly posterior to the lower one-third of the superior turbinate. In the absence of an Onodi cell, visualization of the sphenoid os represents the termination of the posterior ethmoidectomy. The sphenoid sinus can be approached via a posterior ethmoidectomy or transnasally medial to the middle and superior turbinates as previously described. Sphenoidotomy should proceed in an inferior and medial direction with care taken not to disrupt the inner mucosa of the sphenoid sinus. The choice of instrument used for widening the sphenoid ostium is dependent upon surgeon preference. An optimal size of the sphenoidotomy should allow for adequate ventilation of the sinus and take into account the natural healing process, which will ultimately reduce the diameter of the surgically widened ostium (Figure 8). Circumferential damage to the os will potentiate cicatricial scarring.

**Ethmoidectomy**

Establishment of the posterior level of the skull base is dependent upon proper identification and visualization of the sphenoid sinus. A total ethmoidectomy may safely proceed beginning inferiorly and posteriorly and continuing in an anterior, superior direction after correct identification of the sphenoid sinus. Careful yet firm disruption of the ethmoid cell septations occurs tangentially along the skull base. While proceeding tangentially along the skull base, care must be taken to avoid cephalad movements that increase the likelihood of cranial base penetration. In addition, using instrumentation laterally in the...
ethmoids will prevent injury of the lateral lamella (which lies medially) and decrease the likelihood of cerebrospinal fluid leak.

**Anterior Ethmoid Sinus and Frontal Recess**

Whether or not a posterior ethmoidectomy was completed, removal of the anterior ethmoid cells can provide eradication of disease sufficient to allow for drainage of the frontal sinus. Manipulation of the anterior ethmoid cells should be accomplished similarly to the posterior ethmoid cells. A blunt probe or curved dissecting curette angled laterally, away from the vertical lamella of the cribiform plate, will optimize safety while operating along the anterior skull base. Opening of the frontal recess at the termination of a total ethmoidectomy will avoid hemorrhage that tends to obstruct optimal visualization with the endoscope. Careful preoperative identification of an agger nasi cell and entrance into the cell in its most inferior medial extent or from a posterior to anterior direction is optimal. The frontal recess represents a difficult area to manipulate and sits posterior to the agger nasi cell and over the bulla ethmoidalis. Variable drainage of the frontal sinus into the middle meatus, the infundibulum or via a suprabullar tract provides distinct challenges. In general, a complete and thorough anterior ethmoidectomy will afford drainage of the frontal recess.

Patients with purely polypoid disease rarely complain of frontal sinus symptoms and often frontal sinusotomy is not necessary; however, persistent bacterial or fungal infection, complicated, refractory sinuses, and frontal sinus pain that is uncontrolled with medical therapy represent indications for proceeding with frontal sinus surgery. Remember, the first place polyps return is generally in the area of the frontal recess. When the frontal recess requires manipulation, realize that the attachment and proximity of the anterior root of the middle turbinate increases the likelihood for obstructive scarring. Careful identification with a curved probe or curette begins the process. A ngled endoscopic viewing greatly assists the surgeon with manipulation in this area. Once identified, polypoid disease is removed with an up-biting forceps or a curved microdebrider. Again, careful avoidance of disruption of normal sinus mucosa will prevent scarring. A void circumferential tissue removal and concentrate on removing disease and bone anteriorly. Whether a single sinus or multiple sinuses are addressed, careful cleaning of bony debris and residual mucosal disease at the termination of the procedure promotes controlled nasal healing and minimizes the debridement required at the first postoperative visit. Proper hemostasis can be achieved with minimal use of a suction electrocautery device. Many hemostatic topical agents are available; however, many result in the formation of granulation tissue, disrupting the optimal postoperative result. Careful attention to the integrity of the middle turbinate will determine if there is a need for a medialization procedure. To obtain a controlled adhesion of the middle turbinate to the septum, a minor abrasion of the mucosa of the medial wall of the middle turbinate is created. A corresponding mucosal abrasion is created on the adjacent part of the nasal septum. To maintain the medialized position, a small pack is placed between the anterior aspect of the middle turbinate and the medial wall of the maxillary sinus for at least 1 week. In general, additional packing is not required. Packing can be placed along the lateral aspect of the middle turbinate to control minor oozing. In addition, lower packs along the floor of the nasal cavity can help control some immediate postoperative bleeding (common if a septoplasty was performed) but generally can be removed prior to discharge from the recovery area. To aid the anesthesiologists and ensure an uneventful termi-
nation of anesthesia, removal of the previously placed throat pack and suctioning of the oral cavity pharynx and stomach should be carried out. Evaluation and documentation of mental status and vision should occur when the patient is awake and appropriate. A ny abnormality should be taken seriously and appropriately investigated.

**POSTOPERATIVE CARE**

The postoperative care represents a key period in treatment of the patient with primary paranasal sinus surgery. Optimizing and controlling the healing process helps ensure that unwanted adhesions, scarring, and postoperative infections are minimized. In patients with severe polypoid disease, the use of a tapering dose of oral corticosteroids should be considered. In patients that demonstrated acute infections, a broad-spectrum antibiotic can be employed and altered appropriately based upon intraoperative cultures. Fungal disease may mandate corticosteroid tapers over a more prolonged, 3 to 4 weeks period. All patients with nasal packing require antibiotic coverage to prevent the development of toxic shock. Removal of nasal packing usually occurs within 3 to 5 days of the operation. Gentle endoscopic suctioning and debridement should occur at that time as well. Try to make sure all ostia are open but limit tissue trauma. A variety of nasal irrigation systems and solutions exist. Regardless of the type of nasal irrigation, flushing of the postoperative sinus cavity helps a clear and clean the nasal cavity. For most patients, continued use of a nasal inhaled corticosteroid is required for prevention of recurrent disease. We feel that a topical corticosteroid drop (and not a spray), used postoperatively twice per day for patients with severe disease or once per day in limited disease for about 3 weeks, aids in the healing process.

**COMPlications**

While a variety of complications related to endoscopic sinus surgery can occur and include meningitis, blindness, and death. The use of applied anatomy and unobscured visualization will help minimize them. Minor complications, such as persistent bleeding, postoperative infection, and unwanted adhesions, can be dealt with careful attention during the postoperative period. Intraoperative identification of violation of the lamina papyracea or damage of the skull base is achieved with minimal use of a suction electrocautery device. M inor complications still can occur in essential first step in prevention of major complications. Failure to recognize a complication will only result in magnification of the problem and potentiate recurrence of the complication in additional patients. Intraoperative management involves careful planning and open communication with anesthesia and nursing staff. A proper intraoperative consultations should be obtained. All parties involved should be aware of the necessity of adjunctive treatments, procedures, and hospitalizations. Documentation and communication with the patient, the patient’s family, and the associated staff remain paramount.

**SUMMARY**

The first opportunity to eradicate disease surgically represents the best chance at therapeutic success. Understanding the proper indications for surgical intervention, and documentation of medical therapeutic failure are paramount. Sinonasal disease resulting in nasal obstruction, hoypnusia, recurrent sinus infection, calcific sinus infections, headache, and exacerbation of asthma represent the common symptoms of the patient with sinus disease. Allergy may play a prominent role and should be properly investigated and controlled. Surgical intervention requires careful planning and attentive surgical technique. A voiding iatrogenic damage to nondiseased mucosa and sinuses, identification and preservation of normal anatomic structures, and early recognition of intraoperative complications are essential. A n 85 to 90% success rate can be obtained with a single operation and adequate, attentive postoperative medical therapy.

**REFERENCES**

Endoscopic sinus surgery has been utilized for the treatment of refractory chronic rhinosinusitis (CRS) for over 20 years. The goal of endoscopic sinus surgery is restoring normal sinus function with resultant subjective patient improvement. However, there are some patients who fail to achieve lasting relief from sinus surgery. The management of these patients is challenging and medical management is the cornerstone of treatment. However, at times, additional surgery may be considered. Revision sinus surgery, which often necessitates primary or revision frontal recess surgery, is a technically challenging endeavor. Altered/complex anatomy, polyps, infection, bleeding, and high patient anxiety all play a role.

ETIOLOGY OF PERSISTENT POSTOPERATIVE DISEASE

A primary consideration in the assessment of endoscopic sinus surgery failure is the presumed nature of the underlying disease process. CRS has been broadly defined into disease with and without polyps for the purposes of research. In the majority of patients who do not have polypoid disease, the goal of an endoscopic sinus procedure is restoration of the normal sinus physiology that had been altered by chronic inflammation. These patients are, therefore, expected to achieve long-lasting relief from an endoscopic sinus procedure.

However, in patients with CRS with polyps it is recognized that there may be an underlying physiologic abnormality refractory to surgical cure. The surgical goal in these patients, therefore, is subjective quality of life improvement, decreased mechanical obstruction exacerbating inflammation, and improved access to the sinus cavities. In these patients, the source of the problem has been variably attributed to factors such as defective host immunity, IgE-mediated reaction to fungus, biofilms, osteitis, and superantigens, among others. Whatever the cause, it is the mucosal inflammatory process that is the underlying pathology, with altered sinus drainage being a contributing or resultant factor. Taking this into consideration, there are carefully selected patients who have persistent polypoid disease after surgery that may receive benefit from revision procedures.

The reasons for surgical failure can be broadly classified into persistent mechanical obstruction, mucosal disease, or a combination of both. Mechanical obstruction can occur postoperatively from a failure to address successfully the initial disease or via the creation of iatrogenic obstruction. Mucosal preservation technique, appropriate instrumentation, computer navigation, and adequate postoperative debridement theoretically minimize these issues but cannot fully prevent them, even in the most skilled hands.

An early return of polyps and signs of persistent inflammation may, therefore, represent sequestered disease with persistent obstruction or evidence of refractory disease from mucous membrane abnormality. Additionally, clearly defined disease processes such as cystic fibrosis, Samter triad, and all of the granulomatous diseases can play a role.

EVALUATION OF THE PATIENT AFTER SINUS SURGERY

There are numerous reasons that sinus surgery may fail. Some of these are correctable, and most are treatable. Postoperative disease can manifest as an early return of symptoms, which must be carefully examined to determine any correctable reasons for failure.

Patients may complain of a recurrence of their symptoms or new symptoms. A careful history must be taken that compares the patient’s symptoms before and after surgery. Questions must be focused on determining the benefit of the initial surgical or recent medical interventions. Are the symptoms the same as before surgery? Have the current symptoms replaced the old ones? Are the symptoms consistent with a recurrent acute or chronic process? Is the patient...
currently symptomatic? How often have they been treated with medical therapy, including prolonged courses of antibiotics and systemic corticosteroids? When was the most recent course of medical therapy?

The goal of the history is framing the current symptoms in light of a complex and prolonged sinus history. Knowledge of the current medical therapies is critical to an accurate assessment. Recurrent acute processes that improve with medical therapy are suspicious for disease that was not addressed at the initial surgery. If they are new compared to the preoperative condition, this is concerning for an iatrogenic process.

The routine use of nasal endoscopy in this setting is critical. Nasal endoscopy assists in the accurate diagnosis of infection, early detection of polypoid disease and evaluation of the patency, and location of surgically created ostia. Furthermore, nasal endoscopy in the postoperative patient allows for an accurate culture of purulent debris and the determination of appropriate culture directed antibiotics.

Any signs of inflammation, infection, or polyposis in the postoperative patient should prompt the practitioner to look for reasons for these changes. The postoperative cavity should be examined for signs of inflammation or infection, position, or resection of the middle turbinate or its remnant and visualization of the ostia. Typically a 30° or 45° endoscope is adequate. Examination with a 70° endoscope is often helpful. Attention to the position of the maxillary ostia with angled endoscopy and the visibility of the frontal recess and sinus are critical. Inflammation in the frontal recess may manifest as polyps or purulent drainage and may be the sign of an incomplete dissection or iatrogenic disease. This in turn may lead to downstream maxillary sinus disease. Again, a culture should be taken of any purulent secretions consistent with infection.

With persistent symptoms, particularly with persistent disease on endoscopy, repeat computed tomography (CT) should be considered. Persistent symptoms with a normal endoscopic examination may also warrant a CT to look for radiographic areas of sequestration not visible on endoscopy or to rule out sinus disease as causing the patient’s symptoms. The goal of CT, therefore, is to look for persistent bony partitions that may be contributing to areas of inflammation or to establish that the symptoms do not correlate with active sinus inflammation.

CT examination will reveal any evidence of a retained uncinate, persistent infraorbital cell or a posterior fontanel antrostomy. Residual ethmoid partitions and mucosal thickening in this area may be evident. Persistent or new disease in the frontal recess resulting from a residual uncinate, agger nasi cell, retained bullar lamella, and frontal sinus cells will also be evident. Image guidance scan with sagittal reconstructions is particularly useful in examining the frontal recess. Furthermore, magnetic resonance imaging may be necessary to evaluate patients in whom a bony dehiscence has been found on CT.

In the evaluation of the patient who has had sinus surgery, it is important to attempt to correlate symptoms with objective findings to prevent unnecessary surgical and medical interventions. For example, a patient who complains primarily of headache, but whose endoscopic examination and CT scan are normal, is unlikely to benefit from additional surgical procedures, and a careful headache evaluation is warranted. Alternatively, a patient who complains of recurrent infections but is currently asymptomatic with a normal endoscopic examination, is also uncertain to benefit from revision surgery and should be reevaluated during disease exacerbation. At the time of illness, it will then become apparent what contribution, if any, residual anatomic imperfections are playing in the disease complex. Only by attempting to tease out the nuances of the endoscopic appearance of the cavity, the radiographic appearance of the unseen portions of the cavity, and how the patient’s symptoms correlate with changes in these objective measures will make an

appropriate determination for the need for future surgery.

GENERAL CONSIDERATION IN REVISION SINUS SURGERY

There is significant literature on the most common radiographic and anatomic findings necessitating revision surgery. In one report, partial amputation of the middle turbinate with resultant lateralization was the most common finding. In another, lateralization of the turbinate was followed by incomplete anterior ethmoidectomy and middle meatal antrostomy stenosis. In a study on revision frontal sinus surgery, residual agger nasi cell, ethmoid bulla remnants, superior uncinate remnant, middle turbinate remnant, polyps, and unopened frontal recess cells were most commonly reported. Regardless of the literature, however, each patient must be taken as an individual with careful evaluation of the unique anatomy that is factoring into his or her disease process. The goals of a revision procedure must be carefully delineated. The endoscopic examination and fine cut CT scan must be meticulously examined for the specific anatomic issues to be corrected. Focusing on what led to the initial failure, the revision surgery must attempt to accomplish its goals with different methods, that is, preoperative preparation with oral corticosteroids may alter the visualization, computer guidance may better delineate the anatomy, septoplasty may allow for increased access to the middle meatus, and more frequent postoperative debridements may prevent scarring. Simply performing the same procedure is less likely to result in long-term success than the initial procedure and is more likely to lead to negative long-term consequences, that is, intractable frontal recess scarring.

These clearly defined goals must be framed for a patient so that they have appropriate expectations. In the setting of a previous failure, it is unreasonable for a surgeon to assure a patient of cure with a revision sinus surgery. Expectations that include symptomatic improvement and increased ability to manage a difficult disease are more reasonable.

Operative Techniques

As previously stated, there are numerous challenges inherent to revision sinus surgery that make it orders of magnitude more challenging than primary surgery. Landmarks are often absent, polypoid change may obscure relevant anatomy and anatomic boundaries may have been removed, that is, dehiscent lamina papryacea, resected basal lamella, making the procedure more difficult and potentially more prone to complication.

However, the basic principles of endoscopic sinus surgery still hold. Critical review of the CT scan at the time of the procedure is essential with emphasis on potential pitfalls and goals of the procedure. Shape, slope, and symmetry of the skull base, location of the anterior ethmoid artery in relation to the skull base, dehiscence of the lamina papryacea or skull base, middle turbinate resection, and the presence or absence of Onodi cells are critical pieces of information to prevent potential complication. Furthermore, both authors utilize image guidance for all but the most simple revision cases and all cases of frontal recess dissection.

Osteitic bone, persistent inflammation, and polyps make revision sinus surgery bloodier with resultant decreased visualization. Adequate decongestion with injection of local anesthetic with epinephrine (1% lidocaine with 1:100,000 epinephrine) and topical oxymetazoline (or 4% cocaine) on pledgets can make the difference between success and failure. An intraoral descending palatine block, an intranasal sphenopalatine block, injection of the residual uncinate, and insertion of the middle turbinate—all decrease intraoperative bleeding. These injections can be done safely with a preinjection aspiration and slow infusion of small volumes. If polyps are present, injection of the polyps themselves can also minimize bleeding. Cotton pledgets soaked with decongestant should be placed
Maxillary antrostomy is one of the most commonly performed endoscopic sinus procedures. When it fails to improve maxillary sinus inflammation, one should be prompted to look for the reason. Identification of the potential cause of the persistent disease is often more complicated than correcting it. The most common reasons for failed maxillary antrostomy are as follows:

1. retained uncinate and persistent inflammation in the area of the natural ostium;
2. persistent infra-orbital cell (Haller cell) with persistent obstruction (Figure 1);
3. posterior fontanel antrostomy with (Figure 2)
   a. persistent inflammation in the natural ostium and
   b. recirculation from the natural ostium into the posterior fontanel antrostomy;
4. trapped secretions including
   a. dehydrated debris in maxillary sinus (Figure 3),
   b. debris under scar at the base of the maxillary sinus after Caldwell-Luc or extensive mucosal stripping of the sinus (Figure 4); and
5. rarely, recirculation from a large middle meatal antrostomy over an inferior turbinate remnant into an inferior meatal antrostomy (Figure 5).

Identification of these factors requires a careful review of a CT scan and nasal endoscopy. Not infrequently, these processes manifest as recurrent acute infections with no objective measures in between. Therefore, serial examinations and CT may be necessary to observe the source of the inflammation. Once identified, correction of persistent maxillary sinus disease requires comfort with angled

carefully, with endoscopic visualization to prevent mucosal trauma that exacerbates bleeding. It is beneficial to prevent trauma to the septum or turbinates from the start versus attempting to control it later.

Revision Maxillary Sinus Surgery. Maxillary antrostomy is one of the most commonly performed endoscopic sinus procedures. When it fails to improve maxillary sinus inflammation, one should be prompted to look for the reason. Identification of the potential cause of the persistent disease is often more complicated than correcting it. The most common reasons for failed maxillary antrostomy are as follows:

1. retained uncinate and persistent inflammation in the area of the natural ostium;
2. persistent infra-orbital cell (Haller cell) with persistent obstruction (Figure 1);
3. posterior fontanel antrostomy with (Figure 2)
   a. persistent inflammation in the natural ostium and
   b. recirculation from the natural ostium into the posterior fontanel antrostomy;
4. trapped secretions including
   a. dehydrated debris in maxillary sinus (Figure 3),
   b. debris under scar at the base of the maxillary sinus after Caldwell-Luc or extensive mucosal stripping of the sinus (Figure 4); and
5. rarely, recirculation from a large middle meatal antrostomy over an inferior turbinate remnant into an inferior meatal antrostomy (Figure 5).

Identification of these factors requires a careful review of a CT scan and nasal endoscopy. Not infrequently, these processes manifest as recurrent acute infections with no objective measures in between. Therefore, serial examinations and CT may be necessary to observe the source of the inflammation. Once identified, correction of persistent maxillary sinus disease requires comfort with angled

Figure 9 Example of a technique to avoid a destabilized middle turbinate. This can occur when the turbinate is medialized for middle meatal access. The destabilized turbinate may make intraoperative middle meatus access difficult, and it can scar laterally making postoperative access a challenge. Left middle turbinate is medialized with a transeptal stitch.

Figure 10 Coronal (A) and sagittal (B) computed tomographic scans with contrast of an opacified sphenoid sinus with a dehiscent right internal carotid artery.

Revision Maxillary Sinus Surgery. Maxillary antrostomy is one of the most commonly performed endoscopic sinus procedures. When it fails to improve maxillary sinus inflammation, one should be prompted to look for the reason. Identification of the potential cause of the persistent disease is often more complicated than correcting it. The most common reasons for failed maxillary antrostomy are as follows:

1. retained uncinate and persistent inflammation in the area of the natural ostium;
2. persistent infra-orbital cell (Haller cell) with persistent obstruction (Figure 1);
3. posterior fontanel antrostomy with (Figure 2)
   a. persistent inflammation in the natural ostium and
   b. recirculation from the natural ostium into the posterior fontanel antrostomy;
4. trapped secretions including
   a. dehydrated debris in maxillary sinus (Figure 3),
   b. debris under scar at the base of the maxillary sinus after Caldwell-Luc or extensive mucosal stripping of the sinus (Figure 4); and
5. rarely, recirculation from a large middle meatal antrostomy over an inferior turbinate remnant into an inferior meatal antrostomy (Figure 5).

Identification of these factors requires a careful review of a CT scan and nasal endoscopy. Not infrequently, these processes manifest as recurrent acute infections with no objective measures in between. Therefore, serial examinations and CT may be necessary to observe the source of the inflammation. Once identified, correction of persistent maxillary sinus disease requires comfort with angled
which did not improve with medical therapy.

Figure 13  Endoscopic view of a right frontal sinus before (A) and 5 weeks after (B) completion of frontal recess dissection. The agger nasi cell (ANC) was carefully removed using a combination of frontal sinus seekers and punches. The anterior ethmoid artery (AEA) is clearly visible in both images. This patient had an opacified frontal sinus above this, which did not improve with medical therapy.

Figure 14  Frontal sinus instruments by Karl Storz. (A) Frontal sinus seekers, (B) Kuhn frontal sinus punches.

Revision Ethmoid Sinus Surgery. The revision ethmoid cavity is often difficult to navigate due to altered landmarks, and image guidance is essential. Frequently, the loss of the middle and superior turbinates obscures the anatomy, and osteltic partitions complicate dissection (Figure 8). This osteitic bone is difficult to maneuver and leads to increased bleeding. Additionally, these osteitic partitions are often thicker than the adjacent lamina papyracea and skull base, making manipulation potentially disastrous. Furthermore, large segments of osteitic bone will recur, and it will not be possible to achieve mucosal normalcy.

Therefore, one of the primary goals of revision ethmoid surgery, as in primary surgery, is to prevent the development of osteitis. Meticulous mucosal preservation with removal of partitions with cutting instruments will minimize this problem. The goal is a single ethmoid cavity lined with normal mucosa so all partitions should be removed flush to the lamina papyracea and skull base if possible. It is common to find small loculations of mucopus trapped behind these partitions. Preservation of the residual middle turbinate is critical to maintain landmarks and prevent laterization and iatrogenic frontal recess disease.

To maximize middle-meatal visualization and minimize ethmoid inflammation, any residual concha bullosa must be addressed. On CT, the concha may be completely opacified and may be difficult to identify, appearing like a thickened middle turbinate. Pneumatization may not involve the head of the turbinate and may involve only the vertical lamella. Therefore any middle turbinate that is thicker than several millimeters must be carefully analyzed. The lateral lamella should be carefully removed with cutting instrumentation. Image guidance is also helpful as a concha bullosa that was missed on the initial procedure can be challenging to locate.

One potential consequence of revision ethmoid surgery is a destabilized middle turbinate. This can occur when the turbinate is medialized for middle meatal access. The destabilized turbinate may make intraoperative middle meatus access difficult and it can scar laterally making postoperative access a challenge. Controlled synchiae of the turbinate to the septum, suture to the septum, or prolonged middle meatal packing should be considered in these patients to decrease the likelihood of this occurring20 (Figure 9).

In revision ethmoid surgery, the skull base must be identified early, and the lateral cavity should be examined for undissected cells. These lateral cells are often the result of a retained uncinate that pushed initial dissection medially. If visualization and instrumentation in the lateral posterior ethmoid cavity is limited with
a 0º endoscope, there is likely to be residual uncinate.

The importance of delicate, mucosal-preservation technique with cutting instruments cannot be overemphasized. The microdebrider has revolutionized sinus surgery in this regard but must be used with caution as it can also strip mucosa and can violate both the lamina papyracea and the skull base.

As in primary sinus surgery, dissection should proceed from a posterior to anterior direction after identification of the skull base. Partitions should be removed to the skull base with cutting instruments. Care must be taken to not twist partitions as they may be more robust than the skull base. In the revision case, the middle turbinate may be absent, and medial skull base dissection must proceed carefully to prevent inadvertent injury to the lateral lamella of the cribiform. When the limits of the 0º endoscope and/or the limits of 45º cutting instruments have been exhausted, an angled endoscope should then be used. Anterior ethmoid dissection should then proceed and will be discussed in the section on frontal sinus surgery.

Revision Sphenoid Sinus Surgery. The reasons for sphenoidotomy failure can broadly be categorized into 2 groups. In the first, the sphenoid was not entered (intentionally or unintentionally); whereas in the second, it was entered, but it was closed by secondary scarring.

The revision sphenoidotomy, as is all revision sinus surgery, is often complicated by altered anatomy. The natural ostium of the sphenoid sinus always lies medial to the superior turbinate and is reliably identified in this position in primary sphenoidotomy. However, after primary surgery, the superior turbinate may be missing, may be fused to the middle turbinate forming a “uniturbinate,” or may be altered in appearance by resection of its basal lamella making reliable identification difficult. Additionally, the natural ostium may be scarred and osteitic and may not be easily penetrable. In fact, the face of the sphenoid may be thicker than the back wall of the sphenoid, making vigorous penetration of the sphenoid face potentially disastrous.

An opacified sphenoid sinus on CT poses a challenge when the lateral wall or roof is dehiscent and the contents of the sinus are unknown (Figure 10). Magnetic resonance imaging in these cases will help identify the contents of the sphenoid and will determine the location of the carotid artery, pituitary, optic nerve, and dura.

The 2 principal endoscopic approaches to the sphenoid are transnasal (medial to the middle turbinate) and transethmoid. The vast majority of revision sphenoidotomies utilize the transethmoid approach as there is often ethmoid surgery that should be revised. Additionally, in the setting of a failed transnasal sphenoidotomy, the transethmoid approach should be attempted.

In the transnasal approach, the middle turbinate is gently lateralized and the superior turbinate is identified. The natural ostium of the sphenoid sinus is identified medial to the superior turbinate and is enlarged with a J-curette, sphenoid mushroom punch, and/or Kerrison rongeur. The inferior aspect of the superior turbinate is often trimmed to allow for additional lateral enlargement. In this approach, lateral dissection is limited by the middle turbinate which may result in a smaller than adequate sphenoidotomy. Additionally, if work should be performed on the ethmoid or maxillary sinuses, the middle turbinate is at risk for becoming flail as work is done both medial and lateral to the turbinate. As stated previously, the flail turbinate can scar laterally, prevent postoperative access to the middle meatus and create iatrogenic frontal recess disease. Furthermore, the postoperative care of the transnasal sphenoidotomy is difficult due to discomfort from instrumentation medial to the middle turbinate, adjacent to the nasal septum. Postoperative scarring may occur if the sphenoidotomy cannot be adequately debrided. The transnasal sphenoidotomy may fail for all these reasons.
One of the biggest reasons for failure of primary transethmoid sphenoid surgery is difficulty identifying the sphenoid or misidentifying an Onodi cell as the sphenoid sinus. This is even more challenging in revision cases, when the anterior edge of the superior turbinate may be difficult to identify. In these instances, critical review of the radiographic relationships among the superior turbinate remnant, Onodi cell, if present, and the location of the actual sphenoid sinus is paramount. Image guidance may be essential to performing a safe sphenoidotomy.

Assuming the superior turbinate is still present, it can be preserved or the inferior aspect of it can be resected. When the superior turbinate is preserved, the sphenoidotomy is performed just lateral to the most inferior aspect of the vertical portion of the superior turbinate just above the superior turbinate horizontal lamella (Figure 11). This can be done with a straight probe or a J-curette and can be enlarged with a circular punch or Kerrison-type forceps.

Alternatively, the sphenoidotomy can be performed after identifying the natural ostium of the sphenoid sinus, which is always medial to the superior turbinate. Some argue against this technique as it requires resecting the inferior portion of the superior turbinate and potential olfactory neuroepithelium loss. After identification of the natural ostium, it is enlarged as described above. One advantage of this approach is the large potential size of the ostium; from the septum medially to the orbital apex laterally.

In all sphenoidotomies, care must be taken inferiorly to avoid injury to the posterior septal branch of the sphenopalatine artery, which runs along the inferior face of the sphenoid. Injury can occur without intraoperative bleeding due to vasoconstriction from local anesthetic injection and may manifest as significant postoperative epistaxis. When injury occurs, cautery may be necessary to achieve hemostasis.

When approaching the revision sphenoidotomy, as in all revision surgery, considerations for the reason for initial failure must be made. One of the most common is misidentification of an Onodi cell for the sphenoid sinus. This is common when there is a large Onodi cell and a small sphenoid. In rare instances, the entire sphenoid may lie medial to the superior turbinate. Resection of the inferior aspect of the superior turbinate is necessary in these cases as the point of normal entry just lateral to the superior turbinate is the intracranial cavity.

When a large Onodi cell is present in a revision case, it is helpful to remove the common wall between the medially located sphenoid and the lateral Onodi cell. It is critical to remember that in these cases the optic nerve and carotid artery lie in the Onodi wall and may be dehiscent. In the setting of a revision procedure with a small sphenoid, it is beneficial to create a large sphenoidotomy in continuity with the natural ostium.

In cases of a scarred ostium, the most likely initial insult is circumferential mucosal injury to the sphenoidotomy. In a large sphenoid, the creation of a large sphenoidotomy to the anatomic boundaries of the skull base, orbital apex, and septum may be adequate. In cases of a small sphenoid and a failed revision, creation of an inferior mucosal flap that is rolled over the edge of the raw bone may be helpful (Figure 12). Resection of the floor of the sphenoid has also been described. The sphenoid may also be connected to the contralateral sphenoid via a posterior septectomy with removal of the intersphenoid septum.

Frontal Sinus Surgery. Frontal sinus surgery is one of the most complex aspects of rhinology. It is included in a chapter on revision surgery for this reason and for the fact that the frontal sinus surgery is one of the most common causes of refractory or iatrogenic sinus disease requiring surgical revision.

One useful way to consider frontal sinus surgery is the “integrated approach” as described by Kuhn. In this approach, frontal sinus disease is evaluated in a systematic, step-wise
approach starting from the least invasive surgical procedure. Key to understanding this thought process is the knowledge that the cause of frontal sinus disease is obstruction of the drainage pathway (frontal recess) of the frontal sinus, rather than a problem with the frontal sinus itself. It must be emphasized that the term "frontal duct" has been abandoned because no such structure exists. The frontal recess is in fact an "inverted funnel" shaped space that connects the frontal sinus to the anterior ethmoid region.26 Furthermore, the natural mucociliary clearance of the frontal sinus is down the lateral wall of the frontal recess, whereas the mucociliary clearance of the medial aspect of the recess and interfrontal sinus septum is in the superior direction.26

The "integrated approach" to the frontal sinus consists of the following procedures:25

1. endoscopic frontal sinusotomy (Figure 13);
2. extended endoscopic procedures:
   a. frontal sinus rescue (FSR) procedure,
   b. endoscopic frontal sinusotomy combined with trephination, and
3. open procedures:
   a. osteoplastic flap (without obliteration) combined with endoscopic frontal sinusotomy,
   b. osteoplastic flap with frontal sinus obliteration,
   c. frontal sinus unobliteration and
d. frontal sinus cranialization.

**Endoscopic Frontal Sinusotomy.** Advances in frontal sinus instrumentation, angled endoscopy, fine cut CT scanning techniques, and image guidance have significantly improved visualization of and access to the frontal recess and sinus (Figure 14). However, the tenets of frontal sinus surgery remain unchanged from initial techniques described nearly one-quarter century ago. A fundamental understanding of frontal recess anatomy, which is highly variable from patient to patient, is the key to successfully performing and maintaining frontal sinusotomy patency (Table 1). The relationships between the uncinate insertion, middle turbinate, agger nasi cell, bullar lamella, supraorbital cells, and various Kuhn-type frontal cells must be completely understood preoperatively if frontal sinus surgery is to be attempted.27 Often, harm is done by blunt instrumentation (ie, curved suction, curette) of the frontal recess without adequate resection of the partitions between these cells. Bluntly dissecting with large suctions or image guidance seekers in the frontal recess will increase the likelihood of postoperative scarring and iatrogenic frontal recess disease. Therefore, the frontal recess should be left alone and the superior aspect of the uncinate should be preserved if a surgeon is not comfortable using angled endoscopy and instrumentation. Furthermore, image guidance should be available for frontal sinus surgery.19

![Figure 19](A) Fluoroscopy images of balloon dilation of a left frontal sinus. The guidewire is advanced into the frontal sinus (A) and a balloon is advanced over the guidewire (B). The balloon is then gradually inflated (C) and (D) and then deflated and withdrawn. The efficacy of this technique within the spectrum of frontal sinus disease remains to be demonstrated.

Adapted from reference 27.
The anterior ethmoidectomy and endoscopic frontal sinusotomy are performed after completion of the posterior ethmoidectomy. Angled endoscopes are used (initially 30º or 45º) when visualization with the 0º endoscope is limited. It is impossible to perform an appropriate, safe, functional frontal sinusotomy with a straight endoscope without unnecessary resection of structures, that is, middle turbinate, middle turbinate insertion, so this should not be attempted. The advantage of a 30º endoscope is that it allows continued visualization of the posterior skull base and sphenoidotomy. However, complete frontal dissection is not possible with this endoscope. The 45º endoscope may provide better illumination and will allow for dissection of the frontal recess if extensive high recess dissection is not necessary.

After switching to an angled endoscope, partitions are removed with a combination of frontal sinus punches and seekers (see Figure 14). Historically, the curette was used, and the fragments were removed with angled giraffe forceps. This technique is still valid; however, removal of the fragments with the giraffes may result in mucosal stripping if not done carefully. Judicious use of a microdebrider with an angled blade will separate these fragments from the bone and allow for safer removal. The position of the anterior ethmoid artery must be determined on the preoperative scan and can be noted by its indentation in the lamina. In a significant percentage of individuals, the artery will be in a portion below the skull base and is located in a position that makes it susceptible to injury during frontal recess instrumentation.

Dissection proceeds from a posterior to anterior direction. Care must be taken medially and posteriorly as the bone may be exceptionally thin in the areas of the lateral lamella of the cribiform and posterior frontal recess, respectively. Once the anterior ethmoid partitions have been removed, a 70º endoscope (or continued use of the 45º endoscope) can be utilized to visualize the frontal recess. Removal of the free walls of the agger nasi and frontal sinus cells can then proceed. The posterior and medial walls of the agger nasi cell are free, while the anterior wall is the frontal bone and the lateral wall is the lamina papyracea. The posterior and medial walls of the frontal sinus cells are also free-floating (except the frontal bullar cell, to be discussed separately) (see Table 1). Dissection of the frontal recess and agger nasi cells must then proceed from a posterior to anterior and medial to lateral direction. The location and position of the uncinate insertion must also be determined. Lateral insertion onto the lamina papyracea will create a recessis terminalis, which may be mistaken for the agger nasi cell or perhaps the frontal recess. This can be determined by careful examination of the coronal CT scan and must be addressed from medial to lateral. These cells and the partitions between them are removed using a combination of frontal sinus punches, seekers, and judicious use of an angled microdebrider. (Figures 15 and 16).

A frontal cell that pneumatizes high into the recess warrants special note as it poses a particular challenge in frontal sinus surgery. These cells may have a free edge laterally, medially, and anteriorly. The cap of the cell may also be violated. They may be Type III frontal cells with a free posterior edge or a frontal bullar cell without posterior access. Frontal bullar cells cannot be approached from posterior to anterior as the posterior wall of the cell is the skull base. These cells are particularly difficult to manage when they pneumatize high into the frontal sinus, and the cap of the cell is difficult to reach from below. These well-pneumatized cells often have

Figure 20 Left frontal sinus rescue (FSR). (A) Stenotic frontal ostium with a partially resected middle turbinate. (C) Mucosa was removed from the middle turbinate remnant medial to the frontal ostium. (D) Bone of the middle turbinate remnant is then removed using a combination of cutting instruments.

Figure 21 Frontal ostium after a frontal sinus rescue (FSR) as shown in Figure 20.

Figure 22 Extended frontal sinus rescue 5 weeks after surgery. Note the channel cut into the middle turbinate that had previously been lateralized. Mucosal flap (blue arrows) was reflected over the bare bone to facilitate healing and break up the circumferential scar.
lateral and medial walls that are opposed to the interfrontal sinus septum and lateral frontal sinus floor, which makes access to the frontal sinus difficult without stripping mucosa. The technique for removing these cells involves careful manipulation of a frontal sinus seeker between the mucosa of the frontal sinus and the mucosa of the wall of the cell, fracture of the wall of the cell, and careful removal of the wall fragment with a giraffe. Often, all of the cell cannot be removed (Figure 17). If stenting of the frontal recess is considered, soft, flexible material should be used (Figure 18).

The safety of a balloon system for dilating sinus ostia was introduced at the annual meeting of the American Academy of Otolaryngology in September of 2005. Preliminary data on intermediate length results were then presented in September of 2006. This instrument system allows for the dilatation of the natural ostium of the frontal sinus with complete preservation of the mucosal lining of the frontal outflow tract. Bone is not removed and instrumentation of the narrow confines of the recess is limited. At the time of the writing of the chapter, this was performed utilizing fluoroscopy although the guides are able to be tracked with image guidance. The exact role that these instruments play in frontal sinus surgery is unclear. However, particularly in the case of an isolated frontal sinus process, they may be considered (Figure 19).

Extended Endoscopic Frontal Sinus Procedures. Extended endoscopic frontal sinus procedures are considered in the setting of a failed primary endoscopic procedure and not as the primary mode of treating frontal sinus disease. They should be considered in order of presentation, as they result in progressively more destruction of normal anatomy. The least invasive procedure should be considered first, followed successively by more invasive procedures.

The FSR is a delicate procedure that potentially creates a large frontal sinusotomy. The FSR addresses the lateralized middle turbinate or middle turbinate remnant. The goal of this procedure is to create a frontal sinusotomy that occupies the entire distance between the lamina papyracea and the nasal septum while breaking up the circumferential scar of the ostium with a mucosal flap (Draf IIb procedure). The mucosa of the roof of the nose is removed medial to the existing frontal sinusotomy. If the middle turbinate remnant is adherent to the nasal sidewall, it is separated from it with a sharp knife. The bone of the middle turbinate remnant is removed carefully up to the roof of the nose, with care taken not to dissect too far posteriorly with resultant injury to the cribriform plate. Image guidance is essential. The remaining mucosal flap from the lateral aspect of the middle turbinate remnant is reflected to the roof of the nose, thereby breaking up the circumferential opening (Figures 20 and 21). If the entire middle turbinate is present, and the recess is narrow, this procedure can still be performed (extended frontal sinus rescue) by creating a "neo-middle turbinate remnant." A large straight-through cutting instrument can be used to cut a channel through from the insertion of the middle turbinate at the nasal sidewall to the skull base. The FSR can then be performed on the remnant of the middle turbinate anterior to the cut. Seventy-degree endoscopy is critical for both of these procedures (Figure 22).

Figure 23 (A) Complicated frontal recess with a interfrontal sinus septal cell (IFSS) and stenotic frontal recess (FS). (B) The scar was violated (blue arrow); and, due to previous failure, the decision to perform a trephine was made (C) and (D). When the trephination was visualized endoscopically (E), there was noted to be a pocket of pus lateral in the sinus, which was suctioned out of the sinus with direct visualization. A stent (blue arrow (E)) was then placed from below and visualized from above. (F) Final view of the stent visualized via the nose with a 70º endoscope.

instrumented from below, and vice versa. This through the trephination. The recess can then be visualized from above after inserting the endoscope anterior table. The frontal recess can then be visualized with a frontal sinus ante-

rior table. The frontal sinus and frontal recess. A tumor that extends laterally into the frontal sinus can be addressed with direct visualization with preservation of the functional sinus.

Open Procedures. Historically, the osteoplastic flap with frontal sinus obliteration has been championed as the “gold standard” for treatment of frontal sinus disease. However, this approach is prone to late failure and is plagued by the inability to image the frontal sinus after obliteration. It is for this reason, that obliteration of the frontal sinus should be considered the absolute last resort when all other attempts to manage the sinus have failed.

However, the osteoplastic flap unequivocally provides the best visualization of the frontal sinus and frontal recess and should be considered without obliteration when endoscopic approaches have failed. It is the ideal approach for managing benign tumors of the frontal sinus, that is, inverted papilloma or bony tumors. A tumor that extends laterally into the frontal sinus can be addressed with direct visualization with preservation of the functional sinus. The osteoplastic flap can also be used in the management of the previously obliterated frontal sinus.

The approach is via a standard coronal incision. Care is taken laterally over the temporalis muscle to remain deep to the superficial layer of the deep temporal fascia, remaining in the temporal fat pad to prevent injury to the frontal branch of the facial nerve. Subgaleal, that is, supraperiosteal, dissec-
tion then proceeds to the glabella. The periosteum is incised lateral and superior to the frontal sinus. A 6 ft Caldwell radiograph or image guidance may be used to determine roughly the size of the sinus. The outline of the sinus should then be made using the 6 ft Caldwell or image guidance, staying as close to the periphery as possible. Transillumination should be avoided as a technique for frontal sinus size determination as it overestimates the size of the sinus. A sagittal saw is used to make the bony cuts, and the anterior table is fractured forward, while remaining pedicled at the glabella region by the intact periosteum. The pathology of the sinus can then be directly addressed. The tumor can be removed, and any drilling is done under direct visualization. This is combined with an endoscopic frontal sinusotomy as described above.

In the case of tumor removal, frontal sinus function can be maintained by fashioning silastic sheeting to lay in the sinus with a portion that extends into the frontal recess (see Figure 18). This can be removed 6 months later, after the completion of wound healing. This has been shown to maintain frontal sinus aeration even in the setting of significant frontal sinus pathology.

Patients who have had frontal sinus obliteration warrant specific consideration. It is common for these patients to have significant pain, pain for which the obliteration may have been the

If the frontal sinus cannot be successfully instrumented with endoscopy alone, the addition of a frontal sinus trephine should be considered. An incision is made in the eyebrow and deep dissec-
tion is made superiorly and medially to the area over the frontal sinus. The proper location of the trephine is through the anterior table of the frontal sinus and frontal recess.

After incising the periostium and confirming the location with the CT scan, a 4 mm bur is used to drill a hole through the frontal sinus ante-

rior table. The frontal recess can then be visualized from above after inserting the endoscope through the trephination. The recess can then be instrumented from below, and vice versa. This technique is particularly helpful when there is pneumatization of a cell into the frontal sinus that cannot be reached via standard instrumentation from below (Figure 23).

The Draf III is a procedure that creates a common outflow track for both frontal sinuses across a superior septectomy (Figure 24). It is commonly performed with a drill (modified intranasal endoscopic Lothrop), which detractors have claimed creates a large circumferential area of denuded bone. McLaughlin and colleagues modified this technique by describing a transseptal approach, which protects the lateral frontal recess mucosa. Additionally, it can also be performed with frontal sinus punches, which theoretically limit mucosal damage. However, this technique is limited by the anterior to poste-

rior dimensions of the frontal recess and frontal ostium. Furthermore, due to the ease of drilling in the frontal recess, it is frequently performed prematurely before endoscopic maneuvers that directly address the anatomy causing frontal recess obstruction are attempted.

Figure 26 Coronal (A) and (B), sagittal (B) and axial (C) computed tomography scan of a patient with extensive supra-orbital pneumatization with a failed frontal sinus obliteration. SOE = supraorbital ethmoid.

If the frontal sinus is incised lateral and superior to the frontal sinus.

A 6 ft Caldwell radiograph or image guidance may be used to determine roughly the size of the sinus. The outline of the sinus should then be made using the 6 ft Caldwell or image guidance, staying as close to the periphery as possible. Transillumination should be avoided as a technique for frontal sinus size determination as it overestimates the size of the sinus. A sagittal saw is used to make the bony cuts, and the anterior table is fractured forward, while remaining pedicled at the glabella region by the intact periosteum. The pathology of the sinus can then be directly addressed. The tumor can be removed, and any drilling is done under direct visualization. This is combined with an endoscopic frontal sinusotomy as described above.

In the case of tumor removal, frontal sinus function can be maintained by fashioning silastic sheeting to lay in the sinus with a portion that extends into the frontal recess (see Figure 18). This can be removed 6 months later, after the completion of wound healing. This has been shown to maintain frontal sinus aeration even in the setting of significant frontal sinus pathology.

Figure 27 (A) CT scan of a patient with a previous frontal obliteration and significant forehead pain. (B) Osteoplastic flap was performed which revealed extensive areas of mucosa and mucopurulent debris in the frontal recesses and low in the frontal sinus as well as pockets of mucus in the periphery of the sinus. (C) Silastic was cut to the shape of the frontal sinus and rolled into each frontal recess to be removed endoscopically.

Figure 28 Computed tomographic scan of a patient 1 year after conservative management of iatrogenic trauma to the left frontal sinus from a craniotomy. The mucosa of the sinus was carefully preserved, and the communication to the intracranial cavity was plugged with fascia and reinforced with a titanium plate. A computed tomography scan was obtained 3 months after injury and 1 year after injury, which showed stable scarring of the lateral part of the frontal sinus with no evidence of an expansile process.

initial indication. In these patients it is difficult to determine if there are trapped areas of mucus or pus that are symptomatic but not expansile. This is a particular worry when there is extensive supraorbital pneumatization that would have been difficult or impossible to obliterate successfully at the initial procedure. Unfortunately, interpretation of imaging in these patients is difficult, and referral to a rhinologist should be considered. However, if there is clear radiographic evidence of an expansile process, a frontal mucopyocele will need to be addressed endoscopically or via an osteoplastic flap (Figure 26).

When these sinuses are addressed via an osteoplastic flap, it is common to find a large collection of mucopus in a mucosal lined portion of the frontal sinus, multiple pockets of mucopus throughout the sinus, mucopus in an obstructed supraorbital cell, and/or mucopurulent debris above scar in the frontal recess but below the frontal sinus. These mucosal lined spaces should be connected to the nose utilizing silastic sheeting and stenting as the conduit (Figure 27). Reobliteration can also be considered but is realistically no more likely to result in a cure at a second attempt.

As stated, above, the frontal sinus obliteration has been championed for decades as the gold standard for the management of frontal sinus disease. At present, it should be used sparingly, and if considered a referral to a rhinologist should also be considered. Additionally, there are many situations in which frontal sinus obliteration should be avoided. The principle behind these contraindications is that an obliterated frontal sinus is impossible to image postobliteration and it is difficult, if not impossible, to remove all the mucosa of the frontal sinus.25 Relative contraindications to frontal obliteration include: frontal sinus tumors, polypoid eosinophilic inflammatory disease of the frontal sinus, extensive supraorbital pneumatization, frontal sinus posterior table dehiscence and orbital roof dehiscence.25 In the setting of tumors, obliterating the site of the tumor is oncologically unsound as visualization and observation is not possible. Obliteration for inflammatory polypoid disease does not address the actual pathology. In cases of dehiscent frontal sinus walls, it is impossible to remove the mucosa that is adherent to the dura or periorbita. In these patients, it is better to maximize drainage into the nose and create a large frontal sinusostomy that allows for endoscopic visualization and radiographic imaging. There are limited circumstances, however, when obliteration of a small frontal sinus without extensive supraorbital pneumatization may be an option of last resort.

Lastly, frontal sinus cranialization is a procedure that has a limited role in the setting of frontal sinus management in certain craniofacial approaches to the skull base. It is used for comminuted frontal sinus fractures as well. There are some, however, who argue that the risk of intracranial mucopyoceles exceeds the risk of a frontal mucocele and that these frontal sinuses can be successfully managed conservatively after repair of the dura.25 The frontal sinus can be drained into the nose at the initial setting or subsequently. However, the standard of care of the management of these complex frontal sinus issues has yet to be determined in the era of endoscopic management of sinus disease. At present, a conservative approach to anterior table fractures has been advocated by Smith, and colleagues41 (Figure 28).

POSTOPERATIVE CARE

Postoperative care is crucial to the success of revision and frontal sinus surgery. In the revision cavity, areas of previous scarring are prone to scar again and must be attended carefully. Early suctioning of clot, removal of bone fragments and lyses of adhesions are critical. Furthermore, if frontal sinus surgery is going to be successful, comfort with frontal debridement and having the appropriate equipment for debridement are essential.

CONCLUSIONS

The field of rhinology is in its adolescence and continues to evolve. Technology is continuously advancing, as is the knowledge regarding the complexity of disease management. However, certain tenets of surgery remain unchanged: (1) operate from known to unknown; (2) maintain visualization and appropriate instrumentation at all times; and, above all else, (3) do no harm. These basics must be applied to all sinus surgery, particularly revision and frontal sinus surgery, within each individual practitioner’s limitations.

Endoscopic Surgery of the Skull Base, Orbits and Benign Sinonasal Neoplasms

Brent A. Senior, MD
John Alldredge, MD

As the experience and success of endoscopic sinus surgery for benign, inflammatory conditions have increased over the past two decades, so too have its applications. The indications for endoscopic sinus surgery have broadened to include the treatment of a variety of orbital conditions, repair of cerebrospinal fluid (CSF) leaks, and resection of sinonasal and skull base tumors. Endoscopic surgical techniques provide improved visualization and magnification over traditional open procedures and when combined with modern computed tomography (CT) scanning, magnetic resonance imaging (MRI), and image guidance, result in less morbidity and bleeding, no need for external incisions, and shorter hospital stays than external surgical approaches.1–4

ENDOSCOPIC CEREBROSPINAL FLUID LEAK REPAIR

Central to extended application of endoscopic surgery for skull base and orbital lesions is management of CSF leaks. The repair of CSF leaks has evolved tremendously over the past several decades. In 1926, Dandy first described intracranial repair of an anterior skull base CSF fistula via a frontal craniotomy. Advantages of the intracranial approach include the direct visualization of a dural tear and ability to treat an adjacent injury and to use a vascularized pericranial flap in repair of the defect. Among the disadvantages, however, are the need for a large external incision, high risk of anosmia, need for frontal lobe retraction, and the risk of intracranial hemorrhage.1,4 This type of intracranial approach, with a quoted success rate of between 60 to 80% became the standard for many decades and is still frequently utilized today.5,4

In 1948, Dohlman performed the first extracranial repair of a CSF fistula via a fronto-orbital incision. This extracranial approach was taken a step further in 1952, when Hirsch performed the first transnasal approach. In 1981, Wигand reported the first endoscopic repair of a CSF leak.7 Since that time, minimally invasive surgical approaches have been refined, and diagnostic tests and equipment improved. High success rates greater than 90% and low morbidity have led to the minimally invasive endoscopic approach becoming the standard of care for repair of CSF leaks.8–10

To ensure successful endoscopic repair and management of CSF leaks, one must have an understanding of normal CSF physiology. Most of CSF (70%) is formed from the choroid plexus in the lateral, third, and fourth ventricles, with the remaining 30% produced from a combination of capillary ultrafiltration and water metabolism.11,12 CSF is produced at a rate of 20 mL/h or 350 to 500 mL/d; the total volume of CSF in a person at any one time is about 90 to 150 mL, as the volume is turned over approximately three to five times each day. Normally, the CSF flows from the lateral ventricles, to the third and fourth ventricles, and finally into the subarachnoid space surrounding the brain and spinal cord. CSF absorption occurs via the arachnoid villi which act as one-way valves for CSF flow into the connecting dural sinuses. A pressure gradient of 1.5 to 7 cm H2O is required for antegrade flow; anything less causes closure of the valves, preventing retrograde flow. Normal CSF pressures measured in the lumbar cistern with the patient lying in the decubitus position vary with respiration but range from 5 to 15 cm H2O. Reasons for variation include age, time of day, and activity level. Neurologic symptoms may develop with pressures exceeding 15 to 20 cm H2O.11,12

The cause of a suspected CSF leak must also be taken into account before making any decisions regarding definitive treatment or management. CSF leaks occur in approximately 1 to 3% of all closed head injuries, usually presenting between 2 days and 3 months after the initial insult.13,14 As an estimated 70% of these CSF leaks may close without surgical treatment, initial conservative management includes elevation of the head of bed, strict bed rest, stool softeners, and possibly a lumbar drain. Surprisingly, despite the high closure rate of posttraumatic CSF leaks with conservative therapy, long-term follow-up has shown a 30 to 40% incidence of ascending meningitis in these patients. This may be secondary to closure with only a thin layer of fibrous tissue or mucosa, as dura lacks the capacity to regenerate.10,14

The most common causes of iatrogenic CSF leaks are functional endoscopic sinus surgery and neurological surgery. In sinus surgery, iatrogenic injuries may result from bone resection with or without powered instrumentation, resulting in a variety of leaks ranging from pinpoint disruption of dural sheaths surrounding olfactory fila to large leaks greater than 2 cm in size; however, injuries that might have been minor or inconsequential with more traditional instruments, may prove to be major when created as a result of a misuse of powered instrumentation. The recent increased use of powered instrumentation has also led to devastating injuries of the orbit, optic nerve, and carotid artery.15 These iatrogenic leaks created as a result of endoscopic sinus surgery usually occur at the lateral lamella of the cribriform or the posterior ethmoid roof. The lateral lamella of the cribiform plate is thin, and injuries usually occur when dissecting in the frontal recess or resecting the middle turbinate too close to the skull base. It is particularly susceptible to injury in the setting of a deep olfactory fossa resulting from a tall lateral lamella, a feature that should be sought out on preoperative computed tomographic scanning. It is similarly susceptible when asymmetry of the ethmoid roof is present with one side much higher than the other, potentially leading an operator to dissect too high.

Injury to the posterior ethmoid roof may occur in the presence of a low roof or a highly pneumatized maxillary sinus that extends superomedially, resulting in a relative decrease in the height of the posterior ethmoid roof. Injury to the sella diaphragm during transphenoidal pituitary surgery is the most common cause of iatrogenic CSF leak encountered during neurological surgery.16

Both intracranial and sinonasal tumors may lead to CSF leak directly or indirectly. Invasion of tumors across the skull base with resultant destruction can lead to large defects. Treatment of such tumors with surgery, radiation, and chemotherapy may also lead to devascularization of the adjacent tissue, resulting in a difficult to repair skull-base defect. Tumors may also obstruct CSF outflow causing an increased intracranial pressure (ICP), hydrocephalus, and a resultant CSF leak. Treatment of these leaks must first be directed toward the primary tumor to correct obstruction. Repairing a leak without first treating an obstructing lesion may elevate an already increased ICP by closing off the relief valve created by the CSF...
fistula.10 In some situations, long-term shunting may be needed.

Congenital CSF leaks are somewhat rare. They usually result from defects at the foramen of Monro, cribriform plate, or lateral recess of the sphenoid sinus. They may be present at birth or acquired later in life. CSF leaks are often asymptomatic but can present with symptoms such as headache, rhinorrhea, or meningitis. A diagnosis can be made using various imaging modalities, including computed tomography (CT) and magnetic resonance imaging (MRI).

One imaging modality, CT cisternography, is particularly useful for slow or intermittent leaks as the location of the leak can be determined by the location of the contrast. A diagnosis can be made and a rough location of the leak can be determined by the location of the contrast. A diagnosis can be made and a rough location of the leak can be determined by the location of the contrast. A diagnosis can be made and a rough location of the leak can be determined by the location of the contrast.

Another imaging modality, CT cisternography, is particularly useful for slow or intermittent leaks as the location of the leak can be determined by the location of the contrast. A diagnosis can be made and a rough location of the leak can be determined by the location of the contrast. A diagnosis can be made and a rough location of the leak can be determined by the location of the contrast. A diagnosis can be made and a rough location of the leak can be determined by the location of the contrast.

Once a CSF leak is suspected, diagnosis and localization of the leak can be challenging. Several studies and tests can aid in these tasks. If a patient presents with a history of multiple episodes of meningitis, headache after blowing their nose, or unilateral salty tasting clear rhinorrhea, the nasal secretions can be collected and sent for beta-2 transferrin analysis; this protein is only found in CSF, perilymph, and aqueous humor. Although this test will not reveal the location of the leak, only 0.17 mL is required, and false positives are rare.10,20 Beta-trace protein, which is the second most abundant protein in CSF, may be an alternative to beta-2 transferrin, as it is a less costly and quicker test. Used mainly in Europe, its use in the United States has been mostly limited to research.21,22

High resolution thin-cut axial and coronal computed tomography scans are invaluable for locating suspected skull base defects. Although these scans cannot definitively diagnose a leak, they may reveal subtle skull base dehiscences suggestive of leak origin. Radioactive cisternograms may also be helpful in both diagnosis and localization of a CSF leak. In this study, pledges are placed intranasally for several hours after intrathecal injection of a radioactive tracer. A diagnosis can be made and a rough location of the leak can be determined by the location of the pledges positive for the radioactive tracer. Although not used often, this test may be particularly useful for slow or intermittent leaks as the pledges stay in for several hours.

A another imaging modality, CT cisternography, requires a lumbar puncture for the instillation of intrathecal contrast, may also be helpful in diagnosing and identifying CSF leaks. This modality may be particularly beneficial in identification of leaks in the frontal recess and sphenoid sinus where contrast pooling may occur over time. MR and MRI cisternograms are non-invasive studies that do not require intrathecal contrast; they may be a helpful complement to high resolution thin-cut axial and coronal computed tomography in identifying CSF leaks, especially if an intracranial lesion or neoplasm is suspected.10,12,23

Preoperative injection of intrathecal fluorescein can be useful in the diagnosis and localization of a CSF leak prior to repair (Figure 1). This can, of course, be placed in conjunction with insertion of a lumbar catheter in selected cases for use in the perioperative period. Intrathecal fluorescein may be a sensitive study if adequate exposure of the skull base is obtained to ensure optimal visualization; the use of a blue light filter on the endoscopic light source may also increase accuracy in difficult cases. When utilizing this technique, it is important to use a minimal concentration of fluorescein so as to avoid seizures and other unwanted neurologic side effects. A solution of 0.1 mL of 10% fluorescein diluted in 10 mL of autologous CSF or injectable saline has been used safely and efficaciously around the world; however, it is not approved by the US Food and Drug Administration for this purpose.10,12

In some cases of CSF leak repair, particularly spontaneous and high pressure leaks, a lumbar drain may be utilized. Initial placement of the lumbar drain may prove somewhat difficult for patients with significant leaks. Placement in this situation can be assisted by either placing the drain before intubation with the patient in the upright sitting position or after intubation with the head of the bed elevated. Before graft placement, 10 to 15 mL of CSF drained from the lumbar catheter may facilitate graft positioning. Once the graft is placed, and the repair is complete, the drain should be kept open, draining 5 to 10 mL/h. Lumbar drains are usually left in for 48 to 72 hours postoperatively, with the first 24 hours being the most important. They can be clamped for approximately 24 hours to ensure that no leak is present with mobilization of the patient before removal. If a leak is present, they may be left in place for 2 to 4 days or the patient can be taken back to the operating room for exploration of the persistent leak.10 Surgeons must be aware of the complications associated with the use of lumbar drains including meningitis and air-siphoning with resultant pneumocephalus. Pneumocephalus is a greater risk in the setting of large skull base defects, seen frequently in the setting of trauma.

One must also avoid positive pressure ventilation when repairing CSF fistulas. Positive pressure ventilation carries the risk of pneumocephalus, which can be fatal.10 A "deep-extubation" or extubation under deep anesthesia is also preferred so as to avoid any coughing and/or straining that might occur during extubation; this may cause a sudden increase in ICP and displace grafting materials.24 The use of antibiotics is somewhat controversial; the author chooses to use perioperative antibiotics, such as ceftriaxone or vancomycin, which have suitable penetration across the blood-brain barrier. Antibiotics are generally continued as long as nasal packing remains in place.

The specific approach to a CSF leak is determined by its proper identification and exact location. Transnasal endoscopic surgery for CSF leaks of the cribriform plate and ethmoid roof begins with adequate decongestion with topical oxymetazoline (0.05%) and injection of 1% lidocaine with epinephrine (1:100,000). Next, a standard endoscopic total ethmoidectomy and maxillary antrostomy are performed to maximize exposure. In addition, a sphenoidotomy, frontal sinustomy, or middle turbinate resection may be performed for exposure purposes but more importantly to prevent postobstructive mucoceles.10,12

For sphenoid sinus lesions, location is of utmost importance (Figure 2). Centrally located leaks can usually be repaired with an endoscopic transthyroid or transsphenoidal approach. A more wide sphenoidotomy is performed, resection of the posterior nasal septum and intersinus septum may further improve visualization. Lesions located in the lateral recess of the sphenoid can be more challenging. Although most can be reached with a combination of a transethmoid approach and various angled endoscopes and instruments, some may require a transpterygoid approach. In this approach, the posterior wall of the maxillary sinus is removed after endoscopic sphenoethmoidectomy and maxillary antrostomy are performed. Next, the pterygopalatine fossa is entered, and the main branches of the internal maxillary artery are identified, clipped or cauterized. Great care is taken to preserve the vidian nerve, infraorbital nerve, and sphenopalatine ganglia. The periosseum of the commonly pneumatized pterygoid plates is then elevated. Finally, the bone of the anterior face of the sphenoid is drilled or curetted away to gain access to the lateral recess of the sphenoid sinus.12,25
Frontal sinus leaks can be divided into those adjacent to the frontal recess, involving the frontal recess, or involving the frontal sinus proper. Leaks located just posterior to the frontal recess in the anterior ethmoid roof can usually be repaired endoscopically; a complete frontal sinus dissection should be performed in these cases to avoid a postobstructive mucocele. CSF leaks that involve the frontal recess itself can often be repaired with a combined endoscopic and open technique or “above-and-below” approach. Although endoscopic techniques and equipment are constantly evolving, CSF leaks that involve the frontal sinus proper, especially the lateral and superior walls, usually require an osteoplastic flap for adequate exposure. Endoscopic Draf 3 procedures or modified Lothrop procedures, which resect the floor of the frontal sinus combined with frontal trephination, are useful adjunctive procedures for lesions that extend into the frontal recess from the frontal sinus.

Although repairs of CSF leaks and encephaloceles have an approximately 90% success rate when repaired endoscopically, open extracranial approaches involving a traditional craniotomy may be necessary in patients with multiple, large skull base defects or large tumors with extensive intracranial extension.

In all cases of repair, after the leak has been identified and maximal exposure obtained, the surgical site is carefully prepared by removing several millimeters of mucosa surrounding the defect until the entire surrounding bone edges are exposed. At this point, if an encephalocele is present, it is reduced and fulgurated to the level of the skull base with a flexible bipolar suction cautery (Figures 3 and 4). Great care is taken to achieve optimal hemostasis so as to avoid retraction and intracranial hemorrhage. After this is done, 10 to 15 mL of CSF may be drained from the lumbar drain before graft placement. The drain is then set to a continuous drainage of 5 to 10 mL/h.10

The decision of how to repair the actual defect depends on the size of the defect, the cause of the leak, and the ICP.11 Smaller defects (1 to 3 mm) can usually be repaired with a soft tissue overlay graft, whereas larger defects (>3 to 4 mm) may require multiple layers of repair. Large defects, and smaller defects with an accompanying elevated ICP (Figure 5) should be repaired with a more rigid underlay graft, followed by a soft tissue overlay graft.10

When using an underlay graft, adjacent dura is optimally elevated from the skull base. This, of course, is performed intracranially, and smaller otoologic instruments are often useful. Once adequate elevation of the dura has been achieved, a rigid or soft tissue graft can be gently placed within the epidural space; this may be followed by an external overlay soft tissue graft. Once the tissue grafts are in place, a thin layer of fibrin glue or microfibrillar collagen may be applied to maximize graft adherence (Figure 6). Only a small amount of material is used; however, as too much may prevent remucosalization and actually impair healing of the repair. Multiple layers of absorbable packing follow graft placement.4,10

Ultimately, a nonabsorbable packing, such as a Merocel sponge, is placed for added support of the repair site and allowed to remain for several days. These multi-layered types of closures are used to maximize grafting success, ensure a more watertight closure to prevent meningitis, and add rigid structural support to the repair site, thus preventing future herniation of intracranial contents. Studies have shown that free mucosal grafts act as a sort of scaffolding and adhere to overlying bone at 1 week; they are replaced by fibrous tissue by 3 weeks.10,26

Various free grafting materials can be used in the repair of skull base defects, as none has shown to be consistently superior to others. Common rigid grafts include septal bone, septal cartilage, turbinate bone, and mastoid cortex. Soft tissue grafting materials include septal mucosa, temporalis fascia, turbinate mucosa, abdominal fat, fascia lata, pericardium, alloplastic collagen, and cadaveric dermis. Composite grafts consisting of turbinate bone and mucosa have also been used successfully. One must remember that if a mucosal graft is used, the mucosal side of the graft must be directed extracranially, so as to avoid serious intracranial complications such as mucocele formation and meningitis.4,10,23,27,28

For this reason, a surgical marking pen is used to make a blue dot on the mucosal surface of the graft so as to avoid any confusion when placing the graft into tight spaces. As mentioned previously, “spontaneous” CSF leaks represent a difficult, distinct clinical entity and deserve additional discussion. In fact, while endoscopic repair of “nonspontaneous” CSF leaks may enjoy only a 10% recurrence rate, that is, 90% success rate, the rate of recurrence for “spontaneous” leaks can be anywhere from 25 to 87%.16,29–31 So, although most patients who have undergone CSF leak repair do not require long-term CSF diversion, it should be considered in patients with “spontaneous leaks.”4,32–34 These “spontaneous” CSF leaks may be classified as being “high-pressure” leaks. Clinically, they may represent a form of benign intracranial hypertension, as patients are often middle-age obese females who present with pressure-type headaches, pulsatile tinnitus, balance problems, and visual disturbances.11 Radiographically, these patients with increased ICP may have an empty sella syndrome, where the elevated ICP may lead to dural herniation through the sella diaphragm into the sella turcica, giving the appearance of an absent pituitary.35 Dilated temporal horns and ventricles may also be noted on CT scans of the head in these patients.4 This elevated ICP may...
be transmitted by pulsatile hydrostatic forces to the weaker areas of the skull base such as the ethmoid roof, cribiform plate, and especially the lateral recess of the sphenoid sinus which is often extensively pneumatized.12,37

Schlosser and colleagues have recommended routinely placing lumbar drains in the setting of spontaneous CSF leaks at the time of surgery.33 This approach facilitates removal of CSF immediately before repair, confirmation of a watertight seal after repair, CSF diversion in the immediate postoperative period, and making decisions regarding long-term management. By measuring CSF pressures on postoperative day 2 through the already indwelling lumbar drain, they confirmed that most patients with “spontaneous” leaks had an elevated ICP with the mean pressure being over twice the upper limit of normal; in addition, they recognized that patients with “traumatic” leaks had lower ICPs. Patients with “spontaneous” leaks noted to have elevated ICPs, can be given a challenge of intravenous acetazolamide. The lumbar drain can be reopened to monitor the effect of the diuretic on ICP. If the pressure is appropriately lowered (<10 cm H₂O), the lumbar drain can be removed, and the patient started on oral diuretic therapy. If the ICP is not lowered appropriately or remains elevated (>35 cm H₂O), neurosurgical consultation can be obtained for long-term diversion via placement of a ventriculoperitoneal shunt. In this way, lumbar drains and measurement of ICPs can aid in the long-term management of patients with “spontaneous” CSF leaks.33

Postoperatively, patients are kept on strict bed rest, especially when a lumbar drain is in place. The patient is placed on stool softeners with the head of the bed elevated approximately 30° to decrease CSF pressure at the repair site. After the lumbar drain is removed, they are instructed to continue to sneeze with an open mouth and avoid nose-blowing, Valsalva maneuvers, heavy lifting, and strenuous activity for up to 4 weeks. After this, they are restricted to only light activity for the next 4 weeks. Patients are seen 1 week postoperatively when any nonabsorbable packs are removed and minimal debridement is performed. Thereafter, they are then seen every 1 to 2 weeks for debridement, suctioning, and routine postoperative management so as to avoid infection, mucus stasis, and crusts. Of course, great care is taken to avoid any manipulation of the repair site.

ENDOSCOPIC SURGERY OF THE ORBIT

Orbital Decompression

In 1990, Kennedy and colleagues described transnasal endoscopic orbital decompression for Graves orbitopathy, also known as dysthyroid orbitopathy.36 Graves disease is an autoimmune disorder that can affect the thyroid gland, as well as the orbit. In Graves disease, autoantibodies to thyrotropin receptors in the thyroid gland result in over stimulation of the gland and subsequent hyperthyroidism. Orbital manifestations result from pronounced inflammation, migration of T-cells, and deposition of glycosaminoglycans. This can lead to enlargement of orbital fat content and extraocular muscles, resulting in increased orbital pressure, proptosis, and possible optic nerve compression (Figure 7). Symptoms of Graves orbitopathy may include tearing, proptosis, diplopia, and visual loss. Graves disease can also be classified as either acute or chronic. Active inflammation for 6 to 18 months marks the acute phase; symptoms are initially treated with local conservative measures such as taping and lubrication. In severe cases, systemic corticosteroids or radiation may be considered. The chronic phase involves severe fibrosis of orbital contents and may respond to surgical management.37 Indications for endoscopic orbital decompression include visual changes as well as severe proptosis resulting in exposure keratitis or cosmetic deformity.

An orbital decompression is begun by performing a large endoscopic maxillary antrostomy to identify the infraorbital nerve coursing along the roof of the maxillary sinus. This is followed by a total sphenoethmoidectomy and possibly a frontal sinusotomy. Next, the lamina papyracea is gently removed with blunt dissection, taking care to avoid entering the periorbita of the orbit. After the entire medial orbital wall (lamina papyracea) is removed up to the skull base and down to the floor of the orbit, the dissection is taken to the posterior limit at the anulus of Zinn, just anterior to the face of the sphenoid sinus. Anteriorly, the dissection is continued to the nasal lacrimal apparatus. After this is completed, the orbital floor medial to the infraorbital nerve is removed through the maxillary antrostomy. A sickle knife is used to make several parallel incisions through the periorbita beginning posteriorly and superriorly, allowing the orbital contents to prolapse into the sinonasal cavities (Figure 8). Great care is taken to avoid injury to the extraocular muscles during this maneuver.37 Success rates of these procedures range from 22 to 89%.36,38,39 Ocular recession as a result of orbital decompression averages approximately 3.5 mm, with an additional 2 mm provided by the addition of lateral decompression.39 Complications of this technique include diplopia, bleeding, epiphora, CSF leak, and blindness.37 Of particular concern is chronic sinusitis, and specifically frontal...
sinusitis, occurring in the presence of prolapsed orbital contents scarring to the middle turbinate. Postoperative debridements are essential to help reduce this risk.

**Optic Nerve Decompression**

Endoscopic optic nerve decompression can be performed for both traumatic optic neuropathy (TON), as well as for relieving compression from fibro-osseous lesions and various neoplasms. The optic nerve may be injured in 0.5 to 1.5% of all cases of closed head injury that often involve the optic canal. The endoscopic approach offers several advantages over more traditional approaches, including decreased morbidity, preservation of olfaction, rapid recovery, no external scars, and less operative stress.

The optic nerve can be divided into three segments: intraorbital, intracanalicular, and intracranial; the main goal in optic nerve decompression is to relieve compression of the intracanalicular portion. The optic canal, which carries both the optic nerve and ophthalmic artery, is formed by the lesser wing of the sphenoid bone. The optic nerve is encased by the three meningeal layers within the canal. At the orbital apex, lies the fibrous anulus of Zinn, the most accessible site for nerve compression. Trauma to this fixed intracanalicular segment can be attributed to primary and secondary ischemic injury resulting from shearing and swelling. TON is a clinical diagnosis based on a thorough history and physical examination as well as a complete ophthalmologic examination. Once the diagnosis is suspected, high resolution CT scans of the orbit and sphenoid sinuses are invaluable in evaluating the optic canal for injury and neural impingement.

The treatment for TON is controversial; in fact, 20 to 38% of these patients will experience spontaneous recovery of vision. The benefit of intervention of any kind is unclear. Many authors recommend conservative treatment with corticosteroids to reduce edema and inflammation, while others recommend surgical decompression alone or in combination with corticosteroids. Several reports show a 31 to 82% improvement in vision in patients undergoing surgical intervention with or without corticosteroid therapy. Regardless, the treatment options and management strategies should be individualized to specific patients.

After adequate decongestion and infiltration with 1% lidocaine with epinephrine, a sickle knife or #15 blade is used to fashion a posteriorly placed mucosal flap over the lacrimal fossa. The nerve may be identified in a posterior to anterior direction toward the anulus of Zinn. The optic tube is a thick bony structure formed at the junction of the posterior part of the lamina papyracea and the anterior and lateral walls of the sphenoid sinus; this marks the location of the optic nerve foramen and anulus of Zinn. Once the thinnest portion of the sphenoid bone of the optic canal is encountered, a diamond burr is used to thin the canal medially, after which a microcurette is used to fracture and remove the thinned bone. The nerve is usually decompressed approximately 1 cm posterior to the face of the sphenoid. Although much controversy exists, the optic nerve sheath can also be opened; this is carefully performed with a sickle knife starting just anterior to the anulus of Zinn in the superomedial quadrant to avoid injury to the ophthalmic artery. Fibrin glue can be applied to the incision site to prevent CSF leak. Extensive packing is avoided so as to assure maximal decompression. The true success rate of optic-nerve decompression is difficult to quantify, as randomized, prospective studies are lacking; moreover, many patients have significant improvement in vision with observation. Complications of this procedure may include CSF leak, meningitis, and visual loss. Of particular concern is the risk of internal carotid artery injury given the proximity of the vessel to the nerve, and the presence of bony fragments in injuries of this type.

**Nasolacrimal Duct Surgery**

Historically, surgery for nasolacrimal duct obstruction mainly involved external techniques. In 1989, endoscopic dacryocystorhinostomy (DCR) was described by McDonogh and Miering. Initially, however, endoscopic techniques yielded somewhat lower success rates than traditional approaches; attributed to an early limited understanding of the anatomy, poor visualization, and suboptimal instrumentation. However, due to continued improvement in these areas, many studies have shown that endoscopic DCR now yields results that are comparable to external procedures.

Tearing epiphora results from either excess lacrimation or impairment of drainage. Epiphora can be unilateral, bilateral, constant, or intermittent. It can be associated with many conditions including, midfacial trauma, sinus disease or sinus surgery, as well as systemic disease. Several tests can be used for diagnosis of nasolacrimal duct obstruction: the dye disappearance test, lacrimal system irrigation/probing, scintigraphy, and contrast dacryocystography. The definitive treatment of this difficult problem is DCR.

Knowledge of the anatomy of the nasolacrimal system is of utmost importance when performing surgery on the lacrimal system. The lacrimal sac rests in an oval shaped fossa measuring approximately 15 × 10 mm. The anterior crest of the fossa is formed by the thick frontal process of the maxilla, whereas the posterior crest is formed by the thinner lacrimal bone. The suture line formed by these two bones corresponds to the important maxillary line. A landmark study by Wormald and colleagues in 2000 demonstrated that the lacrimal sac actually lies above the axilla of the middle turbinate rather than anteroinferior as previously believed. This anatomical knowledge has aided in the development of newer techniques in endoscopic DCR that allow for more complete bone removal superiorly and the creation of the largest possible opening in the lacrimal sac, ensuring adequate drainage and avoiding restenosis.

The endoscopic DCR technique begins with identification of the maxillary line, uncinate process, and middle turbinate as important landmarks. A sterile adequate decongestion and infiltration with 1% lidocaine with epinephrine, a sickle knife or #15 blade is used to fashion a posteriorly based mucosal flap over the lacrimal fossa. The incision is started 5 to 6 mm above the insertion of the middle turbinate and continued anteriorly for approximately 8 mm. A vertical incision is carried inferiorly to the midpoint between the

---

Figure 8 A sickle knife is used to make several posterior to anterior parallel incisions through the periorbita until a prolapse of orbital fat is visualized.

Figure 9 Coronal computed tomography scan showing injury and fracture of the left optic canal in a patient who sustained severe head trauma.
middle turbinate insertion and inferior turbinate, and finally posteriorly to the uncinate process. Next, a suction elevator is used to elevate the mucosal flap, identifying the important maxillary line. Once this is done, the thin lacrimal bone is removed with a curette, and the thicker frontal process of the maxilla is partially removed with a rongeur or punch. The remainder of the frontal process of the maxilla superior to the axilla of the middle turbinate may be removed with a powered diamond burr. After the lacrimal sac has been completely exposed, especially superiority, the inferior or superior punctum is dilated and the sac is cannulated with a lacrimal probe. When the probe is visualized tenting the sac medially, a vertical incision is made along the length of the sac, followed by superior and inferior relaxing incisions horizontally. The redundant anterior and posterior lacrimal sac flaps can either be resected or reapproximated with the original flap of nasal mucosa. After this is done, slilastic stents are placed within the lacrimal apparatus and secured intranasally. Complications are rare but may include surgical failure, chronic sinusitis, epistaxis, CSF leak, and orbital injury. Success rates for endoscopic DCR versus external approaches are equivalent (93.5 vs 95%). This can be attributed to a better understanding of the relevant anatomy ensuring adequate removal of bone superiorly, as well as advances in endoscopic equipment and instrumentation.

ENDOSCOPIC SURGERY OF BENIGN SINONASAL NEOPLASMS

In the mid-1980s, Kennedy and Stammberger first introduced the concept of endoscopic sinus surgery for benign, inflammatory sinus disease. Since then, “functional endoscopic sinus surgery” has become the standard of care for such disease processes. As expertise, instrumentation, and technology have advanced, so too have the applications of endoscopic sinus surgery. With the advent of tools such as powered instrumentation, angled burrs and curettes, and image-guided surgery, the endoscopic endonasal approach is now being used routinely for the resection of multiple types of benign sinonasal neoplasms. Inverted papillomas (IPs), fibro-osseous lesions, neural-related neoplasms, hamartomas, and vascular neoplasms have all been treated successfully with endoscopic resection. In selected patients, the endoscopic approach allows for complete tumor resection, shorter hospital stays, minimal blood loss, no external incision, and less overall morbidity as compared to more traditional open approaches. Endoscopes provide greater magnification and visualization of sinonasal lesions and enable a more precise resection as well as identification and preservation of certain vital structures. Endoscopic approaches can also be combined with open approaches for resection of tumors when absolute visualization and total resection may be anatomically impossible with an endoscopic-only resection. In addition, imaging studies such as MRI and CT can be employed along with endoscopic examination, allowing for improved evaluation of sinonasal lesions and selection of optimal surgical approaches. CT scans are used to evaluate bony involvement of lesions, while MRI is more useful in assessing the soft tissue characteristics of tumors, such as intra- cranial and intraorbital extension. Specifically, T2 weighted MRI images may differentiate brightly enhancing neoplasms and minor salivary gland tumors from other more intermediate-enhancing sinonasal neoplasms. T1 weighted images may be used to differentiate between postobstructive secretions and soft tissue. In addition, MRI can be used to differentiate between inflammatory and neoplastic lesions.

Benign sinonasal neoplasms are a diverse group that may have similar clinical presentations. Common presenting symptoms include nasal obstruction, epistaxis, epiphora, rhinorrhea, and recurrent sinusitis. Patients may also be asymptomatic, presenting with lesions discovered as incidental findings on imaging studies ordered for nonrhinologic purposes. Although several of these lesions may have characteristic presentations, as well as endoscopic and radiographic findings, final diagnosis rests on pathological analysis of a biopsy specimen. In general, benign sinonasal neoplasms can be divided into various categories: IPs, fibro-osseous lesions, neural-related neoplasms, hamartomas, and vascular neoplasms.

Fibro-Osseous Lesions

Three distinct clinical entities exist that can be classified as fibro-osseous lesions of the paranasal sinuses: osteomas, fibrous dysplasia, and ossifying fibroma. Although their appearance and presentation may be somewhat similar, their clinical implications vary tremendously. Osteoma is the most common tumor of the paranasal sinuses. Most commonly located in the frontal sinuses, osteomas have been reported to have been identified on 1% of routine sinus radiographs, and on as many as 3% of routine CT scans of the head and sinuses. Osteomas are slightly more common in men and usually present in the second and third decades of life. Most lesions are benign, but many exhibit a slow, steady progressive growth pattern with resultant local infiltration, cosmetic change, and/or postobstructive sinusitis. Recurrence after complete resection is very rare.

Gardner syndrome should also be considered when first evaluating patients suspected of having osteomas. Gardner syndrome is an autosomal dominant disorder characterized by multiple osteomas, soft tissue tumors (such as epidermal inclusion cysts or subcutaneous fibrous tumors), and colorectal polyposis. It is caused by a mutation in the adenomatous polyposis coli gene on chromosome 5q. Early diagnosis is crucial, as the colorectal polyps have a high incidence of malignant degeneration.

Although the exact etiology of osteomas is unknown, three accepted theories exist. In the developmental theory, the apposition of endochondral and membranous tissues traps embryonic cells, leading to osseous proliferation. This may explain osteomas occurring at the fronto-ethmoid suture line, as the ethmoid bone is endochondral bone and the frontal bone is membranous bone; however, this theory does not explain lesions located elsewhere in the body away from such sutures. The traumatic theory states that osteomas may occur as a result of localized inflammation. Miotto and colleagues reported that approximately 20% of sinus osteomas occur as a result of trauma. The resulting trauma may lead to an inflammatory response leading to the formation of osteomas. Similarly, Sayan and colleagues reported that osteomas of the mandible occur commonly in places where muscles insert into the bone; resultant muscle traction may incite minor trauma leading to inflammation and subsequent osteoma formation.

This theory, although explaining why males are more prone to developing osteomas, does not explain osteoma formation in older individuals who have not experienced traumatic injury. The infectious theory is similar to the traumatic theory and indicates that inflammation from chronic infection leads to osteoma formation. This, however, does not explain lesions developing in patients without a history of infection or osteitis.

In gross examination, osteomas may be sessile or pedunculated with their sinus mucosal covered surfaces being smooth and lobulated. Histologically, there are three types. The eburnated type, also known as the compact type, consists of dense bone, and lacks Haversian canals. The mature type is composed of cancellous bone. The mixed type contains elements of both the eburnated and mature forms. Figure 10. Osteomas are most commonly located in the frontal sinus (80%), with the remainder occurring in the ethmoid (20%), maxillary (5%), and sphenoid (rare). Symptoms from paranasal sinus osteomas commonly result from their “mass effect” on surrounding structures. Common symptoms include frontal pain and headache, as well as sinusitis and/or mucocoele formation from obstruction of adjacent sinus ostia.

Radiographically, osteomas appear as dense, homogeneous, well-circumscribed masses on both
CT and plain film radiographs (Figure 11). These lesions are usually found to be pedicled to relatively normal appearing adjacent bone although extensive lesions may cause some bone-thinning secondary to mass effect. M R I is recommended to evaluate lesions suspected of having extrasinus or intracranial extension; M R I also allows for differentiation of sinus secretions from mass lesions, brain parenchyma, and orbital structures. The primary dilemma in the management of osteomas is determining whether or not surgical resection is necessary. Many surgeons advocate observation with periodic CT imaging at 6-month intervals in asymptomatic patients. This allows decision making and surgical intervention prior to development of complications, should a lesion increase in size on serial imaging. While small, asymptomatic lesions may be observed, larger, symptomatic tumors should undergo surgical resection. Rapid growth, infection, compression of vital structures, severe pain, facial deformity, vision changes, mucocele formation, and intraorbital and/or intracranial complications are all indications for tumor resection. Several recommendations have also been proposed as indications for tumor removal in asymptomatic patients. These include a tumor occupying greater than 50% of the frontal sinus, having a posteriorly based frontal sinus lesion, and any osteoma occupying the frontal recess or ethmoid sinus cavity.

Multiple surgical techniques are available for resection of paranasal sinus osteomas. In general, approaches can be divided into three groups: endoscopic, open/external, or combined. Regardless of the approach chosen, the goals of surgery should include complete tumor removal with minimal damage to surrounding mucosa and vital structures. While most surgeons agree that most ethmoid lesions can be treated with endoscopic resection, frontal sinus osteomas may require further evaluation and surgical planning. Schick and colleagues recommend measuring the anterior-posterior dimension of the frontal sinus outflow tract to determine whether endoscopic instrumentation is feasible; endoscopic resection usually then requires a Draf 2 or 3 procedure. They also recommend that most lesions that are either anteriorly based or located lateral to the sagittal plane of the lamina papyracea should undergo an open osteoplastic procedure. Traditional past surgical techniques involved open approaches, such as the Lynch frontoethmoidectomy; however, due to postoperative vestogenesis of the frontal recess and visible scarring, other procedures were soon developed. A osteoplastic flap approach via a coronal, brow, or midforehead incision, allows for optimal direct visualization of the frontal sinus and its outflow tract. This technique also allows the option for other adjunctive procedures, such as sinus obliteration, cranialization, or CSF leak repair if deemed necessary. Although such open procedures do have their advantages, the disadvantages are obvious including the increased morbidity of a surgical wound, postoperative pain, scalp paresthesias, visible scars, and possible mucocoele formation.

Many tumors may lend themselves to combined “above and below” type procedures. Combined endoscopic and osteoplastic flap approaches are often used to gain optimal access to large frontal sinus osteomas. In addition, small frontal trephines may be combined with endoscopic approaches for smaller lesions that do not require a full osteoplastic flap but cannot be managed solely endoscopically. Chui and colleagues have proposed a grading system for frontal sinus osteomas (Table 1). They recommend endoscopic resection for grade 1 lesions; grade 2 lesions may require a trephine for an “above and below” type of approach. Lesions that are grade 3 and 4 usually require an external approach with or without endoscopic assistance.

A ll of the various complications of sinus surgery may occur with resection of osteomas of the paranasal sinuses. This, of course, includes injury to the orbit, optic nerve, and skull base. Should a CSF leak be encountered, it should be repaired at the time of surgery. Reactive bony hyperplasia may also occur with mucosal injury, leading to obstruction of sinus ostia and subsequent sinusitis. Postoperatively, patients should be followed and managed appropriately. After muco-cutaneous healing has taken place, CT scans at 6 to 12 month intervals can be used to monitor for tumor recurrence.

Fibrous dysplasia is another type of fibro-osseous lesion that can be found in the paranasal sinuses. Two forms of fibrous dysplasia exist: monostotic and polyostotic. Monostotic lesions (70 to 85%) involve only one bone, while the polyostotic form (15 to 30%) can affect multiple bones. The monostotic form involves the facial skeleton approximately 25% of the time, with the mandible and maxilla being the most common locations in the head and neck. Interestingly, the polyostotic form may present in patients with McCune-Albright syndrome; this syndrome also presents with precocious puberty in girls, abnormal skin pigmentation, and early skeletal bone maturation. While risk of malignancy is somewhat low in patients with the polyostotic form of fibrous dysplasia (0.5%), patients with McCune-Albright syndrome have an approximately 4% risk of malignant degeneration. Biopsy may not always be warranted as fibrous dysplasia has a characteristic “ground glass” appearance on CT scan. Fibrous dysplasia is usually present in younger patients, with growth actually decreasing around the age of puberty; because of this, treatment is usually conservative with surgical intervention reserved for symptomatic patients or those with cosmetic deformity.

Ossifying fibroma is the most concerning of the fibro-osseous lesions. Also known as cemento-ossifying fibroma, psammomoid ossifying fibroma, and juvenile-aggressive ossifying fibroma, differentiation from fibrous dysplasia is paramount as their management may differ. Radiographically, ossifying fibroma appears as a well-circumscribed lesion with an eggshell rim and central lucency, whereas fibrous dysplasia takes on its characteristic “ground glass” appearance. Ossifying fibroma presents as an expansive lesion with a definite demarcation from

Inverted Papilloma

IP is a benign epithelial growth in the underlying stroma of the nasal cavity and paranasal sinuses that is best known for its invasiveness, tendency to recur, and association with malignancy.\(^{63,65}\) IP has a long history which deserves discussion. In 1854, Ward first documented the occurrence of IP in the sinonasal cavity.\(^{86}\) However, in 1935, Reingertz histologically described the nature of the tumor and noted its classic inverted nature in underlying connective tissue stroma.\(^{87}\) Since then, this tumor which is characterized by its epithelial inversion into underlying connective tissue, has taken on many names: IP, inverting papilloma, epithelial papilloma, papillary sinusitis, Schneiderian papilloma, inverted Schneiderian papilloma, soft papilloma, transitional cell papilloma, cylindrical cell papilloma, polyp with inverting metaplasia, and benign transitional cell growth.\(^{56}\) Needless to say, there has been much confusion regarding the clinical and histological nature of this tumor. In 1971, Hymans reviewed several cases of this tumor at the Armed Forces Institute of Pathology; his report aided in solidifying the terminology and pathology of this distinct lesion. Here, sinonasal papillomas were subdivided into inverted, fungiform, and cylindrical cell types.\(^{63,89,90}\)

Pathologically, this tumor is distinct. Grossly, it appears to be exophytic, polyoid, and vascular. It is pink to gray in color, with frond-like projections extending from the bulk of the lesion.\(^{86}\) This benign tumor, which may fill the entire nasal cavity, usually emanates from a discrete pedicled site. It should also be noted that when the tumor rests on mucosa not intimately involved in the lesion, the native, uninvolved sinonasal mucosa remains normal.\(^{63}\) Histologically, the epithelium is distinct from the surrounding mucosa; the epithelium can be squamous, respiratory, or transitional.\(^{88}\) The epithelium of the tumor appears to be proliferative but different from surrounding tissues as it lacks mucus-secreting cells and eosinophils.\(^{51}\) The nuclear to cytoplasmic ratio is normal with few mitotic figures. Squamous metaplasia can occur, and the cells can become hyperkeratotic. In addition, the orderly maturation of the cells outward from the basal membrane is preserved. The epithelium rests on an intact basement membrane, with characteristic invaginations into the underlying connective tissue stroma (Figure 13). Diagnosis is established via biopsy.\(^{63}\)

The exact cause of IP is uncertain. The Schneiderian membrane, the embryologic origin of the sinonasal mucous membranes, is at risk for developing this epithelial lesion; therefore the etiology has been proposed.\(^{52}\) The role of allergy has been discounted secondary to the lack of allergic history in many patients with IP. Chronic rhinosinusitis has also been proposed as a possible etiologic factor due to a temporal relationship and the increased incidence of sinusitis on the opposite side from the lesion; however, it has also been proposed that chronic sinusitis develops in these patients secondary to the obstructive nature of the neoplasm itself.\(^{53}\) Additonally, there has not been any association found between IP and environmental chemical exposure. Due to the known relationship between common papillomas and human papilloma virus (HPV), a viral etiology has been sought.\(^{88}\) Interestingly, in situ hybridization techniques have isolated HPV DNA in IP similar to HPV types 6 and 11.\(^{63,85,96}\) The results and implications of these findings, however, are unfortunately still unclear.

The incidence of IP has been documented as approximately 0.6 cases per 100,000 people per year.\(^{97}\) It comprises 0.5 to 4% of all primary nasal tumors.\(^{91}\) Usually affecting patients in the fifth and sixth decade of life.\(^{89}\) Common symptoms include unilateral nasal obstruction, epistaxis, nasal drainage, bilateral nasal obstruction, nasal mass, and sinusitis.\(^{83,90}\) IP affects males more commonly with a male to female ratio of 3:1. Cases are usually unilateral with no side predilection although bilateral lesions do occur in 4.9% of patients.\(^{86}\) IP usually originates from the middle meatus or lateral nasal wall, involving at least one paranasal sinus 82% of the time: maxillary sinus (69%), ethmoid sinus (53 to 89%), sphenoid sinus (11 to 20%), and frontal sinus (11 to 16%).\(^{85,99}\)

Radiographic studies are commonly used to evaluate IP with CT and MRI being the most common. Bony changes, including a bowing of the bones located near the mass, are common CT findings (Figure 14). Tumors involving the maxillary sinus may lead to widening of the infundibulum on CT, making the uncinate process difficult to discern.\(^{100}\) Although the term “bony erosion” is often used to describe CT changes seen with IP, this term is usually reserved for true malignant lesions that grossly invade adjacent normal structures. “Bony remodeling” may be a better term to describe the changes that occur secondary to the constant pressure and mass effect on surrounding bony structures from IP\(^{101}\) commonly seen at the medial wall of the maxillary sinus and lamina papyracea.\(^{63,91}\) IP affecting the skull base may also have characteristic findings; it is postulated that the bony skull base may have a limited response to pressure, leading to more erosive changes rather than remodeling.\(^{63,101,102}\) In addition, contrasted CT may demonstrate slight enhancement and calcifications.\(^{101}\) On MRI, IP is hypo- to isodense on T1-weighted images and iso- to hyperdense on T2 weighted. Additionally, and most importantly, MRI scans with T1-weighted images with contrast and T2-weighted images can be used to differentiate between tumor mass and postobstructive secretions\(^{63,85,101,103,104}\) (Figure 15).

IP is a benign neoplasm with an association with squamous cell carcinoma. Krouse documents the occurrence of malignancy as 9.1% in all patients with IP.\(^{86}\) Although this association is real, the exact relationship is unclear. Squamous cell carcinoma may present in the setting of IP in three different circumstances. First, patients may present with IP with a small foci of squamous cell carcinoma within it. Patients may also present with malignancy as a separate synchronous lesion, with no evidence of malignancy present within the IP itself. Lastly, and thought to be least common, patients may present with metachronous carcinoma in areas of prior resection of benign IP.\(^{63,88,105}\)

This association with malignancy, along with a propensity for invasion and recurrence, drives the treatment paradigm for IP.\(^{51}\) Initially, IPs were excised via a transnasal closed approach with
CHAPTER 51 / Endoscopic Surgery of the Skull Base, Orbits and Benign Sinonasal Neoplasms

Figure 15  T1 weighted magnetic resonance imaging with gadolinium demonstrates an enhancing right-sided supraorbital inverted papilloma.

headlight illumination; in fact, these early procedures mimicked polypectomies. Although the intent of these procedures was curative, recurrence rates of 40 to 80% were unacceptably high. This, in turn, led to the use of external approaches, such as the Caldwell-Luc and external ethmoidectomy. Open approaches such as the lateral rhinotomy and midfacial degloving procedures allowed for increased tumor visualization and more complete resections with most of these resections usually involving some form of maxillectomy. In the review written by Wessler and colleagues, a recurrence rate of 71% was noted for closed intranasal procedures compared to 29% for open procedures (lateral rhinotomy and midfacial degloving). Open surgical resections such as lateral rhinotomy, were adopted as the standard of care for the treatment of IP.

Since the advent of functional endoscopic sinus surgery in the 1980s, advanced endoscopic techniques have been utilized for the resection of benign sinonasal neoplasms. Waizt and Wigand were among the first to publish their results comparing endoscopic resection of IP to traditional open procedures; they noted similar recurrence rates of 17% versus 19%, respectively, in a series of selected patients. Although several other studies have noted similar findings, it has been revealed that selection bias does exist with smaller, more limited tumors being managed endoscopically and larger, more extensive tumors managed with open approaches.

The success of endoscopic resection of IPs has been facilitated by the numerous advances in radiologic imaging, image guidance, and instrumentation such as angled burrs and micro-debriders. As more extensive sinonasal tumors are being managed endoscopically, the confidence of surgeons has increased. Complete resection of the neoplasm requires identification of the site to where it is pedicled to native mucosa. By debriding the bulk of the tumor first and retaining its pedicled attachment, the sinonasal cavities may be optimally visualized and inspected to allow for a more directed, complete tumor resection, while minimizing damage to surrounding structures and mucosa. Once the tumor has been removed, many advocate that the adjacent mucosa and underlying bone be drilled away with a diamond burr or the bone itself resected when needed. As endoscopic approaches are being used for resection of larger tumors, more advanced techniques and procedures are being developed, with the goal being adequate exposure for complete resection and postoperative endoscopic tumor surveillance. Determining the exact location of the tumor using radiologic imaging studies and preoperative nasal endoscopy allows the optimal surgical approach and technique to be planned ahead of time.

Adjunctive open procedures, such as Caldwell-Luc and maxillary canine fossa puncture, can also be added to endoscopic resection of IP of the maxillary sinus to maximize visualization and ensure complete tumor removal. Even with 45° and 70° angled telescopes, the entire sinus cavity is often difficult to visualize completely; these adjunctive open procedures may allow passage of both endoscopes and instruments transnasally and through the puncture site. Tumors of the posterior wall of the maxillary sinus may be best approached via a large middle meatal antrostomy, making sure that maximal bone is removed both posteriorly and superi orly to provide optimal visualization; a working port through a canine fossa puncture provides additional exposure. Tumors of the inferior, anterior, lateral, or medial walls of the maxillary sinus may also be resected via endoscopic medial maxillectomy. Here, the medial aspect of the maxillary sinus along with the lateral nasal wall is resected endoscopically. Sadeghi and colleagues have described an “en-bloc” tumor removal with this technique, and it appears to be more oncologically sound than piecemeal removal. Tumors of the frontal sinus may present more of a challenge for endoscopic resection. While limited involvement of the frontal recess lends itself to endoscopic resection, tumors of the frontal sinus itself may require advanced techniques. The endoscopic modified Lothrop procedure may be used in select cases where IP involves the frontal recess and frontal sinus. Frontal trephination may also be combined with endoscopic approaches to improve visualization and optimize tumor removal. For larger lesions involving the lateral part of the frontal sinus, an osteoplastic flap may be required for complete tumor extirpation; unless it is deemed absolutely necessary, obliteration is not carried out as an unobiterated sinus allows for easier clinical and radiographic tumor surveillance. In addition, a wide frontal sinusotomy at the time of surgery helps with endoscopic tumor surveillance.

As mentioned previously, selection bias exists when comparing recurrence rates of IP resected via open approaches versus endoscopically. In an attempt to standardize reporting and communication between investigators, Krouse has proposed a staging system for IP primarily based on disease extent, location, and presence of malignancy (Table 2). T1 tumors may be resected endoscopically without much bone removal, while T2 lesions may require more bony excision. T3 tumors may be resected endoscopically, if adequate visualization can be achieved; an open medial maxillectomy may be required. T4 tumors usually necessitate an open approach for maximal visualization and complete resection.

Other Benign Tumors

Numerous other less common benign sinonasal neoplasms occur. Neural neoplasms include meningiomas, schwannomas, and neurofibromas. Meningiomas arising from ectopic arachnoid tissue are rarely encountered in the nose and paranasal sinuses. Sometimes, sinonasal meningiomas can be difficult to differentiate from their intracranial counterparts; sinonasal tumors can have bowing of bone in the direction of an intact skull base. Neurofibromas may present along peripheral nerves in the sinonasal cavity, whereas schwannomas may present both in the region of the nasal septum along branches of the trigeminal nerve, as well as along peripheral nerves.

Hamartomas are nonmalignant lesions that represent congenital errors in development; they are extremely rare in the paranasal sinuses. While they are neither neoplastic nor inflammatory, they are characterized by an abnormal proliferation of tissue elements indigenous to a specific area of the body. Additionally, they do not have the capacity to metastasize and symptoms usually result from mass effect. Although rare, extension outside of the sinuses may give rise to orbital complaints such as proptosis or symptoms of ICP such as headaches. Differential diagnosis includes benign lesions such as IP as well as malignant lesions such as adenocarcinoma. A curative diagnosis is paramount, as hamartomas are benign lesions that should undergo conservative resection.

Juvenile nasopharyngeal angiofibroma is a benign, vascular lesion, most commonly seen in males during the second decade of life. Common presenting symptoms include nasal obstruction and epistaxis. These neoplasms are firm, well-encapsulated lesions, usually arising from the region of the sphenopalatine foramen.

Endoscopic techniques are commonly employed for resection of selected lesions; the endoscopic approach is advantageous for such lesions as external approaches with osteotomies may negatively impact facial growth in these young patients. In addition, preoperative embolization of the internal maxillary artery system may limit blood loss, aiding in endoscopic resection of these highly vascular tumors. Other rare benign vascular neoplasms include hemangiomas and hemangiopericytomas.

**Endoscopic Sphenopalatine Artery Ligation**

In all cases of benign tumor removal, adequate hemostasis is essential and may be aided by control of the sphenopalatine artery posteriorly. Pioneered in 1992 by Budrovich and Saetti, endoscopic sphenopalatine artery ligation or diathermy is useful as both a primary method of controlling posterior epistaxis, as well as an adjunctive procedure prior to more extensive and involved endoscopic surgical procedures.

This procedure is performed by first decongesting the nasal cavity and injecting 1% lidocaine with epinephrine into the mucosa of the lateral nasal wall adjacent to the posterior aspect of the middle meatus. A small vertical incision is made through mucosa and periorbitum 1 cm anterior to the posterior aspect of the middle turbinate. Alternatively, a middle meatal antrostomy is performed and carried posteriorly to the same location. Next, a suction elevator is used to raise a mucosal flap posterosuperiorly until the crista ethmoidalis is encountered just anterior to the sphenopalatine foramen (Figure 16). Once the sphenopalatine artery is identified, a vascular clip or bipolar cautery is applied to the vessel. Great care must be taken to ensure that all branches of the artery are identified exiting the foramen. Kumar and colleagues demonstrated that the success rates of hemaclip and diathermy approach 96% and 100%, respectively. Complications of this procedure are rare.

**ENDOSCOPIC SURGERY OF THE SKULL BASE AND PITUITARY GLAND**

The first transsphenoidal resection of a pituitary neoplasm via a lateral rhinotomy transethmoid approach was described by Schofer in 1907. A few years later in 1910, Cushing described the sublabial transeptal approach to the pituitary; with the advent of fluoroscopy, and more importantly, the operating microscope, the sublabial transeptal transsphenoidal approach soon became the standard approach for resection of pituitary tumors. In the 1980s, surgeons were introduced to endoscopic sinus surgery and provided with optimal optical illumination, magnification, and understanding of the paranasal sinus anatomy. In 1992, Jankowski described the first successful endonasal endoscopic resection of a pituitary tumor via a transsphenoidal approach. More recently, over the past decade, the endoscopic transsphenoidal approach has gained popularity and acceptance, with favorable complication rates as compared to traditional sublabial transseptal approaches.

Success of this procedure, however, requires close cooperation and coordination between otolaryngological and neurosurgical teams.

The pituitary gland is approximately 1 cm in size and rests in the sella turcica in the dorsal aspect of the sphenoid bone. The gland is composed of anterior and posterior lobes and is connected to the brain via the infundibulum. The sella turcica is in close proximity to the optic chiasm anteriorly, the clivus posteriorly, the cavernous sinus laterally, and the hypothalamus superiorly. The lateral walls of the sphenoid are in fact the medial walls of the cavernous sinus, and the various neural and vascular structures in the cavernous sinus can be identified in the lateral walls of the sphenoid sinus. The sphenoid sinus begins developing around 5 to 7 years of age, and it is variably pneumatized in adults. An intersinus septum usually separates the two sides of the sphenoid sinus; however, it is off midline in 60 to 70% of cases.

**Figure 17** Resection of the posterior-inferior third of the superior turbinate allows for optimal visualization and identification of the natural sphenoid ostium.

A team approach should be used when evaluating and treating patients with pituitary tumors. The multidisciplinary team should include an otorhinolaryngologist, neurosurgeon, endocrinologist, ophthalmologist, and radiation oncologist. Indications for resection of adenomas may include compressive symptoms, pituitary apoplexy, or severe headaches. Patients with active prolactinomas (prolactin-producing adenomas) are offered surgery only after failure of medical treatment, whereas patients with acromegaly, hyperthyroidism, and Cushing disease are offered surgery primarily. The preoperative evaluation must include an otolaryngologic evaluation, with complete sinonasal endoscopy and review of CT scans for image guidance to understand the patient’s individual anatomy. Ophthalmologic evaluation is also encouraged before any surgical intervention.

Minimally invasive pituitary surgery (MIPS) begins with the patient positioned in the “beachchair” position with the head rotated 15⁰ toward the surgeon. After registration of the image guidance scans, the face and abdomen are separately prepped and draped in sterile fashion, and the nasal cavities decongested. Hemostasis is achieved by injecting 1.5 mL of 1% lidocaine with 1:100,000 epinephrine transorally into the greater palatine foramina bilaterally. Lidoaine with epinephrine is also injected endoscopically into the tissues adjacent to the sphenopalatine foramen bilaterally. At this point, the most patent nasal cavity is selected, and the middle turbinate slightly lateralized. Next, the natural sphenoid ostium is identified postero-medially to the superior turbinate. After the posterior-inferior third of the superior turbinate is resected, the ostium is clearly identified and enlarged. Various forceps, rongeurs, punches, and drills are used to resect the bone of the sphenoid rostrum. Resection of the posterior aspect of the septum allows entrance into the contralateral sinus, thereby facilitating further removal of the rostrum and interseptal septum for maximal exposure of the posterior wall of the sphenoid sinus and sella. At this point, the endoscope is placed in a holder allowing for two-handed dissection. The mucosa overlying the sella is cauterized and the sella itself is entered with either a 4 mm chisel or drill. Wide resection of bone between the internal carotid arteries is achieved with Kerrison-like forceps.

The neurosurgical team takes over, cauterizing and entering the dura with a stellate incision (Figure 18). Once the tumor is identified usually bulging from the sella, a small piece is sent for both frozen and permanent pathologic diagnosis. At this time, suction-assisted resection...
A suction-assisted curette resection of a pituitary adenoma is performed.

Otoplasty is a common surgical technique primarily used to establish the normal anatomical relationships of the ear. Achieving an optimal result begins with understanding the three-dimensional anatomic relationships of the auricle. Over the past century and a half, numerous surgical techniques have been described, but recent trends have pointed to more conservative approaches that minimize risk and unnatural appearing outcomes.

In this chapter, the embryology and surface anatomy of the ear will be reviewed, along with the ideal anatomical relationships of the ear. Furthermore, common definitions of auricular abnormalities will be described followed by preoperative considerations. Finally, the four essential steps necessary for correction of the protruding ear will be discussed along with postoperative management, common pitfalls, and complications.

**EMBRYOLOGY AND SURFACE ANATOMY**

**Embryology**
The auricle is formed from six mesenchymal proliferations (hillocks of His) that originate from the first and second branchial arches. These six hillocks are thought to be the precursors for the tragus, helical crus, helix, antihelix, scapha, and the lobule, respectively. The first three hillocks are located anteriorly and they originate from the first branchial (mandibular) arch, whereas the last three hillocks are posterior and they originate from the second branchial (hyoid) arch. The hillocks first appear during the sixth week of gestational life and achieve final orientation by the twentieth week. By the end of development, the hillocks will have moved from their original position in the upper part of the future neck to a posterior cranial position at the level of the eyes.

**Surface Anatomy**
The auricle is a complex structure of fibroelastic cartilage with a thin overlying layer of skin. On its anterior aspect, the skin directly overlies the perichondrium. On its posterior aspect, a layer of connective tissue and fat separates the perichondrium from the skin. The helix forms a fold at the superior edge of the auricle extending from the crus helicus to a posterior-inferior arc that enters the lobule inferiorly as the cauda helices (Figure 1). The antihelical fold, or antihelix, runs parallel to the helix along its medial edge. The superior portion of the antihelix forms the superior and inferior crura divided by an area termed the fossa triangularis. The scapha is the depression immediately posterior to the antihelix. Medial to the antihelical fold lies the concha, a cavity that forms the deep cup-like appearance of the ear. The helical crus separates the concha into the cymba conchae and the cavum conchae.

The tragus is a cartilaginous projection that lies anterior to the external opening of the external auditory canal. Finally, the lobule is primarily made of fat and skin and is at the most inferior edge of the auricle. Sensory innervation of the auricle is through C3 (greater auricular nerve), C2 and C3 (lesser occipital nerve), cranial nerve X (Arnold nerve), cranial nerve V3 (auriculotemporal nerve), and cranial nerve VII. The predominant arterial blood supply of the auricle is through the posterior auricular and superficial temporal branch of the external carotid artery and a branch of the occipital artery.

**Categories and Definitions**
Perhaps the most common defect that presents for surgical correction is the prominent ear (alternatively, the outstanding, or protruding ear). The most common cause of this appearance is the lack of development of the antihelical fold. However, other pathologic features, most commonly a deep conchal bowl and/or a malpositioned lobule, can also contribute to the pathogenesis of the protruding ear. The prominent ear can also be described as an auriculomastoid angle greater than 30º. Patients with a prominent ear will have a positive family history, as the genetic transmission is autosomal dominant with variable penetrance.

---

**Figure 1** Auricular landmarks.
A second defect is known as the lob ear and is characterized by a thin, flat auricle with the helix acutely folded downward at the superior pole. The most common causes of this appearance are a poorly developed antihelix, excessive conchal cartilage, and an overprojected lobule.

A third defect is the cup (or shell) ear and is characterized by a smaller than normal ear with weak cartilage resulting in a cupping or deepening of the conchal bowl (Figure 2). The cause of this appearance is poor development of the superior pole with a short, thickened helix and deformed antihelix.

PREOPERATIVE CONSIDERATIONS

The timing of otoplasty remains a subject of debate. Typically, the optimal age for otoplasty is between 4 and 6 years of age. A study of 2,300 ears concluded that 85% of auricular development is complete at 4 years of age. Furthermore, the onset of psychological distress regarding physical appearance is typically thought to begin at 4 to 6 years of age, and there is no data to indicate that the psychological effect of otoplasty performed at age 3 years or younger is different than that when the operation is performed after 5 years of age. Also, an older child will be more capable of participating in the postoperative care of the ear and hence decrease the risk of postoperative complications. Finally, at this young age, the cartilage remains soft and pliable and is amenable to surgical manipulation.

The physical examination should focus on the absence of an antihelical fold, a determination of the conchal bowl size and projection, an assessment of the lobule size and position, and the degree of asymmetry between the right and left ears.

Indications for surgery include the absence or poor development of the antihelical fold with greater than 20 mm projection of the helical rim from the mastoid skin, a deep conchal bowl with an auriculomastoid angle greater than 30°, asymmetrically projecting ears, and a desire for correction by the patient. Contraindications for surgery include a child younger than 4 years of age, a history of keloid formation, and unrealistic surgical expectations.

Photodocumentation is essential for preoperative planning with standard frontal, lateral, and oblique views captured for all patients. Posterior and closeup lateral views are optional.

HISTORICAL PERSPECTIVE

Although the first known reference to an otoplasty was published in a book by Dieffenbach, Die Operativechirurgie, in 1845, an otologist named Edward Ely is widely credited for the first published description of the otoplasty technique. Early otoplasties described a multitude of techniques including skin excision, conchal cartilage remodeling, and manipulation of the angle between the auricle and the mastoid skin. In 1910, Luckett was the first to understand the connection between the auricle and the mastoid skin. In 1910, Luckett was the first to understand the connection between

CARTILAGE-INCISION VERSUS CARTILAGE-SPARING TECHNIQUES

The goal of all surgeons performing otoplasty is to establish normal anatomical relationships. However, there are both cartilage-incision techniques useful for stiff and thick cartilage and cartilage-sparing techniques that can be utilized in more soft and pliable cartilage. When treating a diverse patient population, the surgeon must realize that increasing age tends to bring stiffer cartilage that may need partial or complete cartilage resection for the creation of normal anatomical relationships. Stucker and colleagues found that in the adult population, 98.9% of patients required use of lateral conchal cartilage resection combined with a mattress suture technique. Alternatively, in the pediatric population, all patients required use of a mattress suture technique, and in 83.2% of selected cases, limited lateral conchal cartilage resection was required to obtain proper anatomical relationships. Cartilage-incision techniques either consist of a complete incision through the cartilage or a series of partial thickness incisions that cause the cartilage to bend away from the cut side. The drawback to this technique is that it may leave a sharp irregularity over the surface of the antihelical cartilage. Partial thickness incision techniques rely on several parallel incisions in the cartilage rather than one full thickness incision to minimize the risk of developing an irregular edge in the new antihelical fold. On the other hand, the partial thickness incision technique can lead to problems if the sutures used to establish normal anatomical relationships fail. Furthermore, any cartilage-incision technique can create unfavorable scarring.

Cartilage-sparing techniques were developed in part to minimize the risk of developing a sharp edge along the antihelix. Two other reasons were to avoid a technique that irreversibly changed anatomical landmarks and to minimize dissection of the ear. These techniques are most useful in patients with soft and pliable cartilage and utilize horizontal mattress sutures (M understes) to form the proper antihelical fold and create the appropriate conchomastoid angle (Furnas sutures) by bringing the conchal bowl to the mastoid peristomeum. One potential drawback to utilizing the M understes sutures is that the technique may create an antihelical fold that is too prominent if the cartilage is too thick. Therefore, surgeons utilizing this cartilage-sparing technique may have a more visible aspect of the cartilage in an effort to decrease the extra bulk, most commonly at the level of the superior crus.
**SURGICAL TECHNIQUE**

The surgical considerations and techniques outlined below are most applicable to the prominent ear deformity. Correction of other auricular deformities is beyond the scope of this chapter, but certain portions of the outlined techniques can be used for other auricular malformations. The six major goals of a successful otoplasty outlined by M. Dowell include: (1) correct protrusion in the upper third of the ear; (2) ensure that the helices of both ears are lateral to the antihelices on anteroposterior view; (3) create a helix with a smooth and regular contour; (4) avoid a markedly decreased or disturbed postauricular sulcus; (5) realize that the ear should not be placed too close to the head (especially in males); and (6) achieve symmetry between the two ears with no more than 3 mm difference at any given point.12

In essence, there are four major steps to correction of the prominent ear. Depending on the deformity, not all four steps are necessary to achieve an optimal result.

**Step 1: Skin and Soft Tissue Excision**

After local anesthesia is injected subcutaneously, an eccentric fusiform incision is made around the postauricular sulcus to address the undeveloped antihelical fold (Figure 3). This is preferable in situations where a very deep conchal bowl is the primary cause of the protruding ear; the subsequent conchomastoid (Furnas) suture placement and soft tissue excision aids in conchal setback. As the incision is made, more tissues are removed from the auricle than the mastoid area and the fusiform area is 10 to 12 mm at its widest point. Dissection is taken down to the perichondrium of the auricle and periosteum of mastoid bone with subcutaneous tissue, fat, and postauricular muscle excised with the overlying skin. If further lobule medialization is needed, a dumbbell-shaped incision (Figure 4). Although this dumbbell-shaped incision creates easier access to the antihelical fold for placement of Mustarde sutures, it does make conchomastoid suture placement more difficult. However, this pattern of incision aids in preventing the overcorrection of the middle portion of the auricle and the relative prominence of the superior and inferior poles known as the "telephone-ear" deformity which will be discussed below.

**Step 2: Correction of the Deep Conchal Bowl**

Once the dissection is at the level of perichondrium of the ear, the prominent posterior eminence of the conchal cartilage can be shaved off (in the shape of small disks) using a scalpel. This facilitates conchal setback and reduces cartilage bulk that prevents the auricle from lying closer to the head. It is important to remember that only a partial thickness excision is performed here to prevent overcorrection of the conchal bowl. Conchomastoid (Furnas) sutures are now placed in a horizontal mattress fashion using 4-0 mersilene (or clear nylon) suture in one or two locations to appose the conchal bowl to the mastoid perios- teum (Figure 5). The purpose of the sutures is to reduce the auriculomastoid angle to between 15 and 30°. Incorrectly placed sutures can project the conchal cartilage anteriorly, which can subsequently result in stenosis of the external auditory canal.13 This complication can be avoided by placing the mastoid end of the conchomastoid suture as far posteriorly as possible without distorting the entrance of the external auditory canal.

**Step 3: Creation of the Antihelical Fold**

Once the auriculomastoid angle has been corrected, Mustarde sutures are used to create the antihelical fold. As discussed previously, in the adult patient or in those patients with thick, inelastic cartilages, cartilage incision techniques can be used in conjunction with the Mustarde sutures to help form the antihelical fold. Horizontal mattress sutures (4-0 mersilene or nylon sutures) are placed in the auricular cartilage along the scapha to recreate the antihelical fold. The sutures should pass through posterior perichondrium, cartilage, and anterior perichondrium. Care should be taken to include the full thickness of the cartilage and lateral perichondrium without involving the lateral skin. Four to five sutures are usually needed to establish the natural curve to the antihelical fold. Knots should be tied sequentially from top to bottom after placement of all the sutures; this allows the tension from superior sutures to secure the optimal fold and allows the surgeon to adjust sequentially as he or she moves inferiorly. Overtightening or undertightening of these sutures will result in a suboptimal outcome. These sutures are vital to maintain the repair until enough scar tissue forms to maintain the new antihelical fold. Special attention should be placed on the superior pole as this is the most likely area for unraveling to occur.16,17

**Step 4: Lobule Repositioning or Reduction**

Once the antihelical fold is created, it is important to examine the lobule. The helix, antihelix, and lobule should all be in the same plane. Proper orientation of the tail of the helical cartilage can restore correct lobule position. A bursal lobule position can result in the "telephone-ear" and "reverse telephone ear" deformities. The conchal setback step may improve the lobule position without further intervention. However, overcorrection of the middle third of the ear via Mustarde sutures may accentuate a malpositioned lobule. Often, a protruding lobule results from a flared caudal helical cartilage. Alternatively, the lobule may be congenitally enlarged with excess fat and skin. If further lobule medialization is needed, incision of the caudal helicus or a horizontal incision is made...
mattress suture placed between the cauda helicis and the inferior conchal cavum may be necessary. Lobule reduction can be performed with a fusiform wedge excision at the posterior-inferior border of the lobule or a curvilinear excision along the inferior aspect of the lobule depending on the area of excess.

Once lobule repositioning is complete, hemostasis is obtained with cautery. The skin incision is closed in a single layer with interrupted 5-0 gut suture. The opposite ear is then addressed with the ultimate goal being to achieve proper symmetry between ears. Antibiotic ointment is applied to the incisional line. Cotton, saturated in mineral oil, is molded to the lateral surface of the ear and a pressure dressing is applied to decrease the risk of developing a hematoma. A drain is not required.

Figure 7 demonstrates a typical patient with prominent ears with poor antihelical fold development. Conchal bowl excess, lobule malpositioning, or excess lobule size was not appreciated in the preoperative condition. In this case, a dumbbell-shaped skin excision was used to facilitate the placement of the Mustarde sutures and to minimize the chances for a telephone-ear deformity. No conchal reduction or setback was necessary. The lobule-helix relationship was facilitated by the skin and soft tissue excision only.

In some instances, antihelical fold correction alone is insufficient. The patient in Figure 8 had some conchal bowl excess along with poor antihelical fold definition. An elliptical excision of soft tissue was performed along with conchal bowl shave, placement of conchomastoid and Mustarde sutures, and division of the cauda helices.

**Figure 7** (A) Preoperative and (B) postoperative photographs of a 12-year-old girl who underwent bilateral otoplasty.

**Figure 8** (A) and (B) Preoperative and (C) and (D) postoperative photographs of an 8-year-old girl who underwent bilateral otoplasty.
POSTOPERATIVE CARE

It is important to check for hematoma formation on the first postoperative day. The pressure dressing should be left on for 3 to 4 more days. After the pressure dressing is removed, a light head band should be worn at night for the next 4 to 6 weeks postoperatively.

PITFALLS AND COMPLICATIONS

Hematoma

Hematoma commonly presents with significant and persistent pain or "tightness." A tense swelling with or without ecchymosis is usually seen underneath the pressure dressing and necessitates immediate evacuation. The clot should be removed and the wound examined for any potential bleeding sources. If the hematoma is not removed quickly enough, the overlying cartilage and/or skin can necrose and chondritis may result.

Infection

Infection may result in permanent cosmetic deformity. Fortunately, it is rare because of the abundant blood supply to the head and neck region. Symptoms include fever, and the signs are erythema, swelling, and/or pus along the incision. Minor forms of cellulitis can be treated with broad-spectrum antibiotics that cover Staphylococcus aureus and Pseudomonas aeruginosa. If the infection fails to respond to oral antibiotics, the patient will need inpatient admission, wound irrigation, and parenteral antibiotics.

Hypertrophic Scar or Keloid Formation

Keloid formation more frequently develops in African-Americans than in Caucasians. One retrospective study involving 570 ears found keloid formation in 11% of African-American ears and 2.1% of Caucasian ears. Intraoperative considerations for prevention of keloid formation include conservative skin excision, adequate tissue mobilization, and tension free closure. Most early keloids can be treated with intradermal Triamcinolone injections.

External Auditory Canal Stenosis

A noted previously, this may result if the conchomastoid suture is placed too far anteriorly on the mastoid region. This complication can be treated directly with trimming of the redundant cartilage at the ear canal. Alternatively, the conchomastoid sutures can be repositioned to the more appropriate posterior position.

Aesthetic Complications

The most common complications relate to a suboptimal aesthetic outcome. Although some loss of correction is to be expected, thick auricular cartilage placed under excessive tension with Mustarde sutures may be the source of recurrence of the deformity. This undercorrection may also result if too few Mustarde sutures are used when creating the antihelical fold. Rates of relapse of auricular projection range from 2 to 13%.

Slight asymmetries in projection between the auricles are well tolerated and acceptable. However, greater than 2 mm difference between the helical rim projections from the temporomastoid surface of the skull will likely be noticeable and may warrant revision. Similarly, significant lobule position or size discrepancies should be revised.

The telephone-ear deformity results from either overcorrection of the middle third of the ear along with inadequate flexion at the superior and inferior auricular poles or excessive removal of postauricular skin or mastoid soft tissue. Prevention of this complication is best achieved by rechecking the suture tension immediately before wound closure. Treatment of this complication is problematic if it stems from overresection of conchal cartilage from the middle third of the ear. The upper third needs to be set closer to the mastoid and the lobule must be revised. The reverse telephone ear deformity results from overcorrection of the upper and lower poles of the ear and failure to address a deeply cupped conchal bowl.

Rhinoplasty and Septoplasty

Richard E. Davis, MD

THE ART AND SCIENCE OF AESTHETIC RHINOPLASTY

Fueled by the timeless and universal quest for human beauty, cosmetic rhinoplasty has become a permanent fixture of American cultural life. For some patients, the impact of cosmetic rhinoplasty can be remarkable, transforming the face from a collection of disjointed anatomic features to a harmonious and captivating blend, in which the cosmetic whole exceeds the sum of its individual parts. Moreover, unlike many cosmetic procedures, the effects of rhinoplasty are permanent and largely immune to the effects of aging. Owing to its durable, predictable, and dramatic surgical results, cosmetic rhinoplasty enjoys enormous popularity and remains an extremely gratifying cosmetic procedure for both patient and surgeon alike.

However, cosmetic nasal surgery is also among the most challenging of all cosmetic surgical procedures. Considerable harm can result when rhinoplasty is performed improperly, and the adverse effects can dramatically alter both facial cosmesis and nasal physiology. Although rhinoplasty ranks among the most commonly performed cosmetic operations, few surgeons ever master its numerous subtleties and peculiar nuances. No doubt, the difficulty of cosmetic rhinoplasty is attributable to the unique cosmetic, functional, and anatomic characteristics of the nose. In addition to its prominent cosmetic location, the nose is a complex three-dimensional organ with delicate tissues of varying histologic type; including skin, bone, cartilage, muscle, and nasal mucosa. The surgeon must execute exacting and precise changes to this complicated anatomic structure; these changes must remain stable over time, and they must not occur at the expense of satisfactory nasal airway function. “Do no harm” remains the cardinal rule of elective cosmetic surgery.

In addition to understanding all the many technical aspects of cosmetic nasal surgery, the accomplished rhinoplasty surgeon must also possess a strong artistic eye. Indeed, without accurate preoperative surgical strategy to accommodate hidden surgical findings. The nose is then surgically reconfigured by assembling a mosaic of dissimilar tissues and creating an attractive surface contour that blends harmoniously with the surrounding face. Even when this challenging task is executed to perfection, the result remains at the mercy of wound healing and potential distortions therein. Hence, the truly insightful surgeon will also anticipate unfavorable wound healing characteristics and employ effective countermeasures to mitigate these adverse effects. It is the unique blend of an artistic eye, a gentle and precise hand, and an analytical mind that makes the master rhinoplasty surgeon a rarity in the medical profession.

In addition to surgical and artistic skills, the accomplished rhinoplasty surgeon must also prove adept at psychological assessment and emotional support. Each patient must be carefully evaluated in terms of their motivations, expectations, goals, and apprehensions. The ethical surgeon must also explain the operation, its limitations, and its associated risks in an honest and candid manner, providing full disclosure and a realistic assessment of the anticipated cosmetic outcome. Reassurance, patience, kindness, and empathy are all essential components of the surgical process as a compassionate and supportive surgeon is greatly appreciated during the sometimes disconcerting adjustment to a new self-image. Likewise, the rhinoplasty surgeon must also remain vigilant for unrealistic patient expectations, inappropriate patient motives, and/or a lack of sincere commitment to the surgical recovery process. While the overwhelming majority of properly executed rhinoplasties result in a satisfied patient, the individual with unrealistic expectations, inappropriate motives, or psychological disorders may never reach contentment no matter how favorable the surgical result. When unhealthy motives are suspected, surgery should be avoided to prevent baseless claims of failed surgery and potential conflicts therein.

A further potential reason for avoiding rhinoplasty is an unacceptably high risk of wound healing complications. Although the vast majority of rhinoplasty patients heal favorably with good end results, a small subset of patients may exhibit aberrant wound-healing characteristics despite appropriate surgical strategy and sound surgical technique. In rare but extreme cases, this aberrant healing may manifest as severe subcutaneous fibrosis, aggressive scar contracture, and/or dense hypertrophic scarring that may dramatically impair the cosmetic outcome and lead to potentially permanent nasal deformity. While it is impossible to screen accurately all such predisposed patients, the accomplished rhinoplasty surgeon is distinguished from the novice by the ability to predict and mitigate these unfavorable healing characteristics in a majority of circumstances. The knowledgeable and prudent surgeon will also temper the expectations of scar-prone patients and decline surgery in those patients with an inordinate level of surgical risk.

Although the challenges of cosmetic nasal surgery are formidable, the rewards of a well-executed rhinoplasty are noticeably more attractive face, in which the eyes predominate and the newly shaped nose blends harmoniously and inconspicuously with the surrounding features. For the typical patient, modest cosmetic improvements produce a satisfied and more confident individual making rhinoplasty a rewarding and worthwhile endeavor. However, for the occasional patient, dramatic cosmetic improvements profoundly transform the self-image leading to equally dramatic increases in self-esteem, self-confidence, and sense of self-worth. For these rare patients, cosmetic rhinoplasty can represent a life-changing milestone in which a far more outgoing, self-assured, and confident individual results; and for the cosmetic surgeon, these patients can be especially gratifying.

ASSESSMENT AND HEALING

All human tissues are susceptible to the effects of aging and the nose is no exception. For individuals with naturally strong and stout nasal cartilage, age-related changes may be subtle or inconsequential since skeletal support is abundant. However, for individuals with naturally weak or flaccid nasal cartilage, the adverse effects of aging may be significant and premature. In severe cases, spontaneous age-related deterioration may even lead to progressive nasal tip ptosis, nasal sidewall collapse, and contour deformities of the alar cartilage. For these individuals, naturally weak nasal cartilage predisposes to loss of structural support ultimately leading to altered nasal contour and increased airway resistance. Indeed, the human
nose is in a perpetual state of decay with gradual loss of structural support as the natural byproduct of aging, disease, and/or injury.

Even though aging changes typically require decades to manifest fully, overly aggressive nasal surgery can instantly erode even the most robust skeletal support leading to progressive nasal airway collapse and conspicuous nasal contour deformities. In susceptible individuals, such as those with frail cartilage and naturally weak skeletal support, the consequences of surgical cartilage reduction can be devastating, resulting in profound cosmetic and functional disability. Indeed, the large number of cosmetic rhinoplasty patients seeking treatment for surgically induced nasal contour deformities underscores the importance of tissue conservation and the preservation of adequate skeletal support.

Although the rhinoplasty community has been slow to recognize the risks and adverse effects of aggressive cartilage excision, mounting evidence has condemned the practice of excessive cartilage reduction. Reliable and aesthetically superior results are now achieved by conserving structural elements whenever possible and by trimming oversized elements judiciously. Misshapen tip cartilages are now reconfigured using suturing techniques to retain intrinsic structural support, rather than by excising large portions of alar cartilage in a haphazard attempt to alter tip contour through partial collapse of the alar tripod. When cartilage reduction is unavoidable (as often occurs with nasal hump deformities), dorsal height is kept strong and augmentation grafts are often used, even in treatment of the oversized nose, to strengthen residual structural elements weakened by heredity, age, or surgical manipulation. It is this philosophical shift from “volume reduction” to “structural rhinoplasty” that has propelled contemporary cosmetic nasal surgery into a new era of enhanced precision, control, and efficacy.

Although the typical rhinoplasty patient desires immediate improvement following cosmetic nasal surgery, postoperative recovery is a slow and gradual process. A cute nasal swelling and inflammation typically persist for 4 to 6 weeks and complete recovery often requires up to 12 months, even in young healthy patients with favorable wound-healing characteristics. In most cases, gradual restoration of the lymphatic and capillary circulation leads to a progressive reduction in lymphedema and softening of the firm and contracted nasal soft tissues. This in turn gives rise to a thinner, more delicate, and more tightly adherent skin envelope, producing a more attractive and better defined nasal contour. While the speed and pattern of recovery varies widely even among healthy individuals, the recovery process is seldom complete in less than 1 year. Teenage patients with smooth healthy skin often recover faster than adults, but vigorous exercise, heavy sun exposure, prolonged dependent posture, excessive salt intake, or coexisting nasal allergies may prolong the presence of postoperative lymphedema. In contrast, older patients, patients with thick sebaceous skin, or patients with previously operated (scared) noses may require several additional months for complete healing even when the circumstances for recovery are optimized. Regardless of age, all patients should be counseled that a nose will seldom look perfect upon dressing removal due to the inevitable presence of edema. In fact, good rhinoplasty outcomes often look disappointing during the first few months following surgery since nasal contour is distorted by swelling; whereas noses that appear thin and delicate at the time of dressing removal may appear pinched, skeletonized, or overresected once all surgical edema has resolved.

Even though surgical edema typically resolves in the first year after surgery, for some rhinoplasty patients the inflammatory changes initiated by cosmetic nasal surgery may take much longer to manifest fully. Unlike patients with forgiving nasal skin, patients with contracture-prone skin may experience a slowly progressive distortion of the nasal framework which may continue for years, or even decades after cosmetic rhinoplasty. This unwanted complication, commonly called the “shrink-wrap phenomenon,” develops in susceptible individuals who have both weak cartilage and aggressive contractile tendencies. Naturally weak cartilage or excessive reduction of the cartilage framework results in poor skeletal support and predisposes to twisting, buckling, or migration of the cartilage elements. Initially the skeletal distortion may be concealed by surgical swelling; but, as edema subsides and contracture progresses, the shrink-wrap deformities become increasingly obvious and gradually more detrimental to the cosmetic outcome. For affected patients, progressive distortion may take years, or even decades to manifest fully, and the true impact of surgery cannot be determined until all manifestations of scar contracture are complete. Because shrink-wrap deformities are a byproduct of poor skeletal support, long-term structural integrity is now commonly acknowledged as a fundamental requirement of good rhinoplasty technique. Similarly, the importance of long-term patient assessment to confirm the ultimate impact of cosmetic nasal surgery cannot be overemphasized.

Because rhinoplasty is only partially understood, all practitioners should continually strive to increase their understanding of this challenging and sometimes mysterious operation. Even the accomplished rhinoplasty surgeon lacks complete understanding of rhinoplasty and can benefit from an objective self-assessment of his or her long-term surgical results. To facilitate self-assessment, the specifics of each operation are carefully recorded using a hand-drawn schematic rhinoplasty worksheet (Figure 1).

The rhinoplasty worksheet provides an indispensable reference document, which can be used to assess the long-term effectiveness of each individual surgical maneuver. By comparing the surgical worksheet to standardized “before and after” patient photographs, each long-term follow-up visit provides an opportunity to critique the surgical methodology, identify shortcomings, and continually refine one’s surgical technique and philosophy. It is only through continual and honest evaluation of the long-term cosmetic result that surgical excellence can be
achieved, and meticulous documentation of the surgical procedure is critical to the evaluation process.

Because rhinoplasty is a uniquely challenging and demanding operation, few surgeons can achieve consistent, state-of-the-art surgical results without specializing in this difficult procedure. For the surgeon who performs rhinoplasty only sporadically, consistently favorable results are seldom attained and complications are far more common. In contrast, the surgeon who restricts a large portion of his or her practice to the specialty of cosmetic nasal surgery will often develop a thriving practice based upon consistent and enviable surgical results. While devotion to this operation is necessary to achieve surgical mastery, no surgeon ever fully masters this complex and sometimes baffling procedure. Indeed, for the true devotee, rhinoplasty is a life-long quest for perfection which yields enhanced skill and improved outcomes, but only if diligently sought and studiously pursued.

THE NOMENCLATURE OF NASAL SURGERY

Cosmetic rhinoplasty has developed its own unique and somewhat unconventional medical nomenclature. Although this specialized nomenclature occasionally violates the traditional rules of anatomic classification, it is commonly accepted within the surgical community, and it appears throughout the medical literature. Any serious student of rhinoplasty must be familiar with the peculiarities of this unique terminology to comprehend fully the surgical concepts contained in this chapter and elsewhere. Hence a brief review of rhinoplasty nomenclature is in order. Terms fundamental to the nomenclature of rhinoplasty appear in italics throughout this chapter.

Owing to the atypical (oblique) alignment of the nose relative to the human body, the terminology used to describe the external nasal contour has been modified. For example, the outer nasal bridge, which protrudes from the ventral aspect of the human body, is commonly referred to as the nasal dorsum. Likewise, the superior (upper) aspect of the nasal framework is referred to as the cephalic aspect, whereas the inferior (lower) portion is commonly called the caudal aspect. Ironically, within the inferior (caudal) aspect of the nose, the nasal septum has both superior and inferior corners, known commonly as septal angles (Figure 2). The superior septal angle is known interchangeably as the anterior septal angle, and the inferior septal angle is also known interchangeably as the posterior septal angle. Owing to the unique anatomic references used to describe nasal anatomy, the nose has been said to have “its roots above, its wings below, and its front in back.”

In Figure 3, key surface landmarks are shown from the frontal and profile perspectives. While some of these landmarks are derived from cephalometric nomenclature, most are soft tissue landmarks critical to nasal analysis and surgical modification. Familiarity with these terms is essential for any serious student of cosmetic rhinoplasty who wishes to master the art of facial aesthetic analysis.

NASAL ANALYSIS

Atractive noses are widely variable in shape and do not conform to a single aesthetic ideal. What may appear attractive and harmonious on one face may appear obtrusive and unattractive on another. Although cosmetically appealing noses all share a common base architecture, individual variations in contour must complement the patient’s gender, bone structure, and ethnicity if the nose is to look natural and inconspicuous. Hence, a universal or “ideal” nasal contour does not exist. While classic aesthetic norms of Western civilization, for example, Greco–Roman aesthetic ideals, have traditionally served as the template for cosmetic enhancement of the nose, these aesthetic standards may not be appropriate for every patient, particularly those of minority ethnic heritage. For that reason, cosmetic rhinoplasty requires individualized facial analysis, and surgical objectives must be tailored to suit both the patient’s aesthetic preferences and the individual facial anatomy. Finally, the concept of nasal beauty varies widely among individuals, even those of the same gender and ethnicity, making the optimal nasal contour a highly personalized choice based upon widely varying individual tastes and preferences. Just as two people may have completely different tastes in clothing, jewelry, or hairstyle, so too the concept of nasal beauty is also widely variable among individuals. It is imperative that the rhinoplasty surgeon seeks to identify and respect the personal preferences of each patient to the greatest extent possible. Surgeons who habitually disregard the cosmetic desires of their patients will no doubt suffer the adverse consequences of these overbearing and paternalistic practices.

Figure 2 Cadaver specimen with the left nasal sidewall removed to reveal the cartilaginous nasal septum.

One of the most important components of a successful cosmetic rhinoplasty is accurate preoperative analysis. Almost any anatomic nasal deformity can be corrected by more than one surgical technique; and, while the choice of technique depends upon a host of different factors, all surgical techniques are predicated upon a proper understanding of the surface anatomy. In fact, correct aesthetic interpretation of the topographic anatomy is the first and, perhaps, the most critical step in planning cosmetic nasal surgery. In addition to shape, the surgeon must also evaluate the size and symmetry of each nasal component in relation to the surrounding facial features. Features that possess the proper shape and symmetry will appear unattractive if not in proper scale with the surrounding anatomy. Conversely, features with compatible size will also appear unattractive if lacking bilateral symmetry and a pleasing contour. A thoughtfully all humans can recognize an unattractive nose, few individuals can accurately identify the specific anatomic traits that are responsible for aesthetic disharmony. Although an “artistic eye” is an inherited talent that enables a surgeon to “see” aesthetic nasal disharmony, like any other natural talent, this unique skill must be actively cultivated to reach its full potential.

Once the surface deformities are properly identified, they must then be linked to the underlying skeletal anatomy to permit surgical modification of the nasal contour. Understanding how each surgical maneuver affects the surface topography, and faithfully executing these maneuvers, is the final piece of the surgical puzzle. Because the surgical game plan is entirely predicated upon the cosmetic analysis, a flawed analysis will inevitably result in surgical misjudgment, often leading to subsequent misjudgments and a domino effect of surgical errors. Perhaps the most common example of this phenomenon occurs when nasal hump size is misjudged, leading to overresection of the nasal dorsum. Because tip projection now appears to be excessive, the error is compounded when tip projection is aggressively reduced, further contributing to the
cosmetic deformity produced by dorsal overreduction. Historically, the overresected dorsum is one of the most common errors prompting patients to seek revision rhinoplasty, and while overresection of the nasal hump can also occur for technical reasons, failure of the surgeon to assess hump size properly is an all too frequent cause of the unsatisfactory rhinoplasty outcome. Although the vagaries of wound healing may occasionally spoil a properly executed operation, a flawed nasal analysis condemns the operation to failure from the very start and is a far more common cause of surgical disappointment. Thus, the importance of preoperative nasal analysis cannot be overemphasized.

**PATIENT PHOTOGRAPHY**

Patient photographs are an essential part of cosmetic rhinoplasty and should be included in the official medical record of all rhinoplasty patients. In addition to documenting the presenting nasal contour, patient photographs provide an indispensable and mandatory tool for preoperative nasal analysis and surgical planning. Patient photographs are also the primary means by which a surgeon can evaluate the surgical outcome and perfect his or her surgical technique. A series of standardized and uniform photographs have been proven more informative than the most carefully detailed notes, both as a planning and self-instructional device and as a necessary medicolegal record.²

Color photographs of the face can be taken with a 35 mm single-lens reflex camera equipped with a lens-mounted flash attachment. A portrait lens is used to prevent parallax distortion; and frontal, bilateral profile, bilateral oblique, base, and optional (profile) smiling views are obtained (Figure 4). Although conventional format cameras are still acceptable, digital cameras offer numerous advantages including instantaneous review of picture quality with deletion of unsatisfactory photos, immediate image access, electronic storage, and the absence of developing delays or processing costs. Patients should be comfortably seated in front of a sky-blue background with feet firmly positioned on the floor. Soft overhead lighting is used for general illumination and should be augmented with flash photography. Although the optimal focal length will vary according to camera format and lens size, the face should fill nearly the entire frame when the camera is held in the vertical “portrait” orientation. Once the focal length has been established, it should remain constant for all subsequent views (except the closeup base view) so that image size remains constant. To keep focal length constant, focusing is achieved by moving the camera back and forth until the image appears in sharp focus, rather than by adjusting the focusing ring. On both the right and left profile views, the head should be positioned with the Frankfort Horizontal line parallel to the floor (the Frankfort horizontal line extends from the upper tragus to the infraorbital rim). This alignment is maintained for all subsequent fullface views. Moreover, the patient should maintain a solemn facial expression for all views except for (optional) smiling profile views. For the oblique views, the patient is rotated approximately 45º from frontal plane until the inner canthus is vertically aligned with the ipsilateral oral commissure. On frontal view, the midsagittal plane is oriented perpendicularly to the floor, and the gaze is directed forward directly into the camera lens (primary gaze). Forward directed primary gaze should also...
are now available at the onset of the rhinoplasty process. Standardized high-resolution digital photographs of the nasal profile and upper vault are frequently obtained several days after the initial examination. Surprisingly, the traditional practice of analyzing color slides during the initial consultation has become obsolete. With the advent of digital photography and computer imaging technology, standardized high-resolution digital photographs are now available at the onset of the rhinoplasty consultation. This not only permits the surgeon to evaluate standardized photographs and nasal deformities in tandem, it also permits the patient to observe the evaluation process and better understand the cosmetic deformity. When subjected to computer-based analytical tools, even the slightest discrepancy in nasal symmetry, size, or shape becomes obvious, making digital photography a powerful tool in preoperative nasal analysis. Moreover, the contemporary rhinoplasty patient also participates in the evaluation process and bears witness to the anatomic deformities revealed by digital photography. Deformities that were previously unseen by the patient now become obvious, and the full scope of contour irregularities becomes evident to patient and surgeon alike.

In addition to static image analysis, the preoperative cosmetic evaluation is further enhanced by the use of computer morphing software. This technological innovation permits the skilled user to electronically edit digital photographs to produce life-like simulated images, which depict the effects of cosmetic nasal surgery (Figure 5). By incorporating input from the patient, morphing software permits the surgeon to electronically “design” a new nose, which reflects the patient’s aesthetic tastes and preferences. It also allows the patient to “preview” the new look and to approve recommended cosmetic changes. Alterations to the nasal contour can be added sequentially until both patient and surgeon are pleased with the proposed nasal contour, and the impact of deleting specific modifications can also be assessed. Although the surgeon must restrict the “design” process to changes that are both surgically realistic and aesthetically compatible, the result is a mutually agreeable blueprint from which the surgical plan is ultimately derived. Moreover, the ability to fade electronically between images in real time, that is, to “morph” between the original image and the simulated new nose, greatly enhances the analytical power of the computer imaging software. For the surgeon, the morphed image becomes a powerful assessment and planning tool, which unambiguously demonstrates the anatomic flaws so that appropriate surgical treatment measures can be devised. Aesthetic analysis is simplified since the extent of nasal hump reduction, tip projection, lobular narrowing, or other contour changes can be more accurately quantified. For the patient, real-time transformation provides immediate intuitive understanding of the cosmetic deformity and the proposed surgical corrections. Even subtle deformities become obvious and the surgical plan becomes exacting and tailored to the desires of the patient. While patients must be counseled that exact replication of the simulated images is seldom possible, a skilled surgeon can usually produce surgical outcomes that closely resemble the computer-generated simulations. This technology has greatly expanded the capacity to analyze complex nasal morphology and it is rapidly becoming a requirement of the typical rhinoplasty consumer.

**COMPUTER-GUIDED NASAL ANALYSIS**

Because nasal analysis is most accurate when applied to static images, the absence of patient photographs during the initial consultation was formerly a handicap in patient assessment. Fortunately, the traditional practice of analyzing color slides several days after the initial examination has become obsolete. With the advent of digital photography and computer imaging technology, standardized high-resolution digital photographs are now available at the onset of the rhinoplasty consultation. This not only permits the surgeon to evaluate standardized photographs and nasal deformities in tandem, it also permits the patient to observe the evaluation process and better understand the cosmetic deformity. When subjected to computer-based analytical tools, even the slightest discrepancy in nasal symmetry, size, or shape becomes obvious, making digital photography a powerful tool in preoperative nasal analysis. Moreover, the contemporary rhinoplasty patient also participates in the evaluation process and bears witness to the anatomic deformities revealed by digital photography. Deformities that were previously unseen by the patient now become obvious, and the full scope of contour irregularities becomes evident to patient and surgeon alike.

In addition to static image analysis, the preoperative cosmetic evaluation is further enhanced by the use of computer morphing software. This technological innovation permits the skilled user to electronically edit digital photographs to produce life-like simulated images, which depict the effects of cosmetic nasal surgery (Figure 5). By incorporating input from the patient, morphing software permits the surgeon to electronically “design” a new nose, which reflects the patient’s aesthetic tastes and preferences. It also allows the patient to “preview” the new look and to approve recommended cosmetic changes. Alterations to the nasal contour can be added sequentially until both patient and surgeon are pleased with the proposed nasal contour, and the impact of deleting specific modifications can also be assessed. Although the surgeon must restrict the “design” process to changes that are both surgically realistic and aesthetically compatible, the result is a mutually agreeable blueprint from which the surgical plan is ultimately derived. Moreover, the ability to fade electronically between images in real time, that is, to “morph” between the original image and the simulated new nose, greatly enhances the analytical power of the computer imaging software. For the surgeon, the morphed image becomes a powerful assessment and planning tool, which unambiguously demonstrates the anatomic flaws so that appropriate surgical treatment measures can be devised. Aesthetic analysis is simplified since the extent of nasal hump reduction, tip projection, lobular narrowing, or other contour changes can be more accurately quantified. For the patient, real-time transformation provides immediate intuitive understanding of the cosmetic deformity and the proposed surgical corrections. Even subtle deformities become obvious and the surgical plan becomes exacting and tailored to the desires of the patient. While patients must be counseled that exact replication of the simulated images is seldom possible, a skilled surgeon can usually produce surgical outcomes that closely resemble the computer-generated simulations. This technology has greatly expanded the capacity to analyze complex nasal morphology and it is rapidly becoming a requirement of the typical rhinoplasty consumer.

**COSMETIC ANALYSIS OF THE NOSE**

**Profile and Upper Vault**

The cosmetically pleasing nasal contour is characterized by a tall and straight dorsal profile terminating cephalically in a well-defined nasofrontal angle. Although the size of the nasofrontal angle varies widely in attractive people, the apex of this angle, the sellion, represents the nasal starting point, and should rest at or near the upper lid margin (Figure 6). Noses in which the nasal starting point is located inferior to this anatomic reference point possess a “deep” or “underprojected” nasal root (alternatively known as the nasal radix) forming an obtuse nasofrontal angle. Often, this deformity is accompanied by a weak underprojected rhinion, but a normal or overprojected bony dorsum may also be observed. The underprojected radix frequently results from a congenitally flat nasal dorsum, but a low nasal starting point may also result from acquired bone loss, such as occurs with overresection of a nasal hump deformity. Noses characterized by excessive width (the platyrhine morphology) typically lack strong dorsal projection and are often associated with...
noses (the leptorrhine mon to extremely wide noses, extremely narrow bone using powered instrumentation.5,6
deprojection requires removal of dense frontal or recess the nasal starting point. Typically, radix
is necessary to maintain position of the nasal starting point and eliminate the illusion of a nasal hump5 (Figure 8).

In contrast to the underprojected sellion common to extremely wide noses, extremely narrow noses (the leptomorphology) are often characterized by overprojection of the nasal dorsum, often with a cephalically displaced nasofrontal angle (Figure 7C). In this situation, profile aesthetics are restored by removing the dorsal hump and deprojecting the radix to lower or recess the nasal starting point. Typically, radix deprojection requires removal of dense frontal bone using powered instrumentation.5,6

While a properly positioned nasal starting point is appropriate for patients of either gender, the relationship of the nasal dorsum to the nasal tip often varies slightly between men and women. Even though a straight dorsal profile is universally acceptable, in the feminine nose the nasal tip often projects slightly above the dorsal line creating a subtle curvature at the supratip, known as retroussé or a supratip break (see Figure 6). In contrast, a masculine nasal contour may lack a supratip break, having a completely straight or even a slightly convex dorsal profile. While these profile characteristics represent commonly observed gender-based tendencies in the naturally attractive nose, there are also many attractive noses that defy these generalizations.

Surgery to alter the dorsal profile is a common objective of cosmetic rhinoplasty, making accurate cosmetic assessment of the nasal dorsum and nasofrontal angle a critical aspect of nasal aesthetic analysis. Moreover, dorsal profile analysis should precede analysis of the tip, since tip positioning must conform to proper dorsal height to achieve a natural-appearing nasal contour. Failure to recognize a malpositioned nasal starting point may significantly compromise the cosmetic outcome of profile surgery and may lead to overresection or underresection of the nasal dorsum and/or corresponding tip malformations.

**NASAL ANALYSIS**

**Profile and Lower Vault**

Profile analysis of the lower nasal vault is challenging and involves multiple aesthetic variables, including tip projection, tip rotation, columellaralar harmony, and the nasolabial angle. Tip projection refers to the extent of forward protrusion of the nose parallel to the Frankfort horizontal plane of the face. Patients may better understand this concept as the extent of “Pinocchio” elongation exhibited by the nose. Various mathematical formulas have been derived to calculate ideal tip projection, but these mathematical constructs serve only as approximate guides and do not supersede good aesthetic judgment. As a general rule of thumb, tip projection should be roughly equivalent to the vertical height of the upper lip. However, this rule does not apply in patients with the caudal excess deformity since lip height is artificially reduced. Fortunately, with the aid of modern computer imaging software, the aesthetics of tip projection are ultimately governed by the patient’s cosmetic preference as long as the desired projection falls within the scope of surgical feasibility.

Like its analog the nasolabial angle, the nasolabial angle, also known as the columella-labial junction, is an important parameter of profile aesthetics.7 Ideally, the apex of the nasolabial angle should rest on a horizontal line drawn through the lowest portion of the alar crease (see Figure 6). The apex should also rest slightly posterior to the labial tubercle creating a gentle backward slope to the upper lip. In patients with the caudal excess nasal deformity, the nasolabial apex is shifted both anteriorly and caudally, creating an obtuse or “webbed” nasolabial angle and foreshortening the upper lip.

In contrast to tip projection, tip rotation describes a change in tip configuration produced by movement along a fixed arc of rotation (Figure 9). When nasal tip position shifts caudally along this arc of rotation, the tip becomes counterrotated or ptotic. From the front view, the nostril openings become less visible or may be hidden entirely, and the distance from the sellion to the tip defining points, known as the dorsal line, increases in length. In general, a long dorsal line and ptotic nasal tip are associated with an aged appearance as nasal elongation is a common manifestation of human aging. In contrast, when nasal tip position shifts cephalically along the same arc of rotation, the dorsal line is shortened and nostril show is increased from the front.

Typically, the youthful, feminine nose will exhibit a greater degree of tip rotation, but care must be taken to avoid the overrotated nose with prominent porcine-like nostril show. In women,
a greater degree of tip rotation equates to a more obtuse nasolabial angle of approximately 95 to 110°, whereas in men a longer dorsal line with an acute nasolabial angle of 90° to 100° is typical. Although tip rotation can be gauged by nasolabial angle size, like tip projection, this method of assessment may prove unreliable in the presence of columellar retraction or nasolabial protrusion (webbing) as often occurs in the caudal excess nasal deformity.

Another aspect of profile aesthetics involving the nasal base is the columella-alar relationship. In the cosmetically appealing nose on profile view, the leading edge of the columella is visible as it protrudes slightly beyond the alar rim (see Figure 6). In women, and to a lesser degree in men, the columella has a gentle downward curvature, the so-called double-break, created by divergence of the underlying medial crura. In the cosmetically appealing nose, the alar rim possesses a reciprocal curvature resulting in 2 to 5 mm of columellar reveal, also known as columellar show. Disturbances in the columellar-alar relationship may result from a variety of deformities including excessive columellar show, columellar retraction, alar retraction, alar rim ptosis, or combinations therein (Figure 10). Both congenital anomalies and acquired deformities may account for disturbances in the columellar-alar relationship.

Frontal View and Upper Vault
In recent years, the cosmetic importance of the brow-tip aesthetic lines (BTALs) has been emphasized. These paired lines, formed by shadows of the nasal sidewall, should be parallel or slightly divergent as they extend inferiorly off the supraorbital rim (Figure 11). BTALs should also be smooth, symmetric, and unbroken, connecting the medial brow to the alar crease. For most patients, the optimal spacing between BTALs is approximately half of the intercanthal distance.

Width discrepancies between the upper bony vault, and the middle cartilaginous vault, are a common cause of disrupted BTALs. In severe cases, the pinched middle vault cartilages will produce a progressively narrow sidewall shadow that converges superiorly at the rhinion, the so-called inverted-V deformity (Figure 12A). Overresection of the nasal dorsum typically exacerbates width discrepancies and is commonly associated with formation of the inverted-V deformity. However, even a conservative hump reduction with a high residual profile can result in the inverted-V shadow if pinching of the upper lateral cartilages (ULCs) develops. Correction involves increasing separation of the pinched ULCs and/or reducing separation of the nasal bones (Figure 12B).

Frontal View and Lower Vault
The nasal tip, or lobule, is one of the most important cosmetic features of the nose. From the front, the lobule should be easily distinguished from the adjacent nostrils, separated by faint shadows that blend smoothly into the adjacent alar crease. The ideal lobular width varies considerably according to a host of aesthetic factors including personal preference, nostril size, and dorsal width; but as a rule, the lobule should be about 10 to 20% wider than the aesthetically pleasing nasal
dorsum. Lobular shape also varies considerably, but the attractive nasal tip typically possesses a symmetric diamond shape created by flaring of the underlying alar domes (Figure 13).

Overly broad nasal domes, excessive convexity of the lateral crura, or absence of domal divergence, result in broad, bulbous, or “uni” tip deformities, respectively. Excessive grooving between the alar domes, a condition known as bifidity, is common in patients with thin skin and strong, round alar cartilage. A modest degree of bifidity within the infratip lobule is cosmetically desirable, but conspicuous bifidity within the lobule itself is generally considered cosmetically undesirable.

The alae and nostril openings, comprise the remainder of the nasal base. In addition to symmetry, the nostril openings should be oblong with a gentle “gull wing” configuration from the front view (Figure 14). In most patients, the outer alar margin should fall within a few millimeters of the medial canthal line, equating nasal base width to the intercanthal distance. Although surgical narrowing of the nasal base is occasionally desirable, care must be taken to avoid nostril deformity by confining nasal skin excision to the nasal sill. Sagittally oriented fusiform excisions of the nasal sill effectively narrow the nasal base without distorting nostril shape. In contrast, skin excision from the lateral ala as with the so-called “Weir incision,” often results in unsightly blunting of the nostril/cheek interface and should be avoided in most circumstances. Moreover, because excessive tip width is often mistakenly confused with excessive alar width, alar base reductions are often performed unnecessarily.

Although refinement of the oversized lobule is a frequent objective of cosmetic rhinoplasty, overresection of the lateral crura in an ill-conceived attempt to narrow the lobule will frequently result in stigmatic deformity of the nasal tip. Typically, the overoperated tip is characterized by lobular pinching, excessive tip rotation, and cephalic migration of the lateral crura (Figure 15). In addition to pinching of the diamond-shaped lobule, cephalic malposition of the lateral crus typically results in a conspicuous notching of the nostril rim leading to unwanted distortion of the ideal “gull wing” configuration. In general, these tip deformities are best prevented by limiting excision of alar cartilage and preserving adequate crural strength.

**Base View**

Examining the nose from the base view can greatly augment the nasal analysis and reveal problems not always seen on the frontal or profile views. Hence, the base view remains a key component of the nasal analysis and should not be neglected. Ideally, when viewed from the basal perspective, the nose should conform to an equilateral triangle (Figure 16). Assuming that the nasal base width is approximately equal to intercanthal width, the triangular base configuration will provide a cosmetically acceptable tip configuration and insures a cosmetically pleasing degree of tip projection. However, as with all aesthetic guidelines, allowances must be made for morphologic variants such as the patient with extremely wide-set eyes or extremely narrow-set eyes. In both cases, the ideal nasal base width may not coincide with the existing intercanthal distance, and the nasal width should be calibrated to the overall facial bone structure for optimal cosmetic results.

Other important aspects of the nasal base analysis include the width and alignment of the columella, the columella to lobule ratio, and the shape
of the alar sidewall. Ideally, the columella lies in the midline and widens gently at its base due to the flared footpods of the medial crura. Columellar height should also be approximately twice that of the lobule, and the nostril sidewall should appear straight or very slightly concave without pinching or significant indentation.

SURGICAL ANATOMY OF THE NOSE

Upper Vault

The nasal bones are paired membranous bones arranged in a crude “A-frame” configuration. Distally the nasal bones are thin and delicate, whereas their dense cephalic union with the nasal process of the frontal bone is seldom prone to injury. Laterally, the nasal bones fuse with the nasal process of the maxilla at the lateral nasal suture line (Figure 17). Collectively, the nasal bones and the adjoining process of the maxilla comprise the bony (or upper) nasal vault. The nasal bones are supported in the midline, from beneath, by the perpendicular plate of the ethmoid bone; and they typically comprise approximately one-third of the nasal dorsum.

The union of the nasal bone with the maxilla lies medial to the nasofacial groove, which is formed by the anatomic junction of the nasal sidewall with the adjacent cheek. The misconception that the bony vault is composed entirely of nasal bone is dispelled by the presence of maxillary bone within the lateral most aspect of the nasal sidewall. Because optimal narrowing of the bony vault typically requires infracture of the entire nasal sidewall, the preferred placement for lateral osteotomy is typically within the nasofacial groove (Figure 17). Thus, lateral osteotomy bone cuts typically lie within the maxilla and only briefly traverse the nasal bone at its cephalic extent. During osteotomy of the nasofacial groove, dense bone of the anterior maxillary buttress located immediately lateral to the nasofacial groove, serves to help protect the adjacent lacrimal fossa from inadvertent injury.

Beyond the rhinion, the nasal bones give rise to the cartilaginous nasal dorsum, also known as the middle nasal vault. Similar to the A-frame configuration of the upper nasal vault (which is supported from beneath by the vertical ethmoid plate), the middle vault is formed by the ULCs which are supported from beneath by the quadrangular (cartilaginous) septum. Even though the right and left ULCs and quadrangular cartilage are individually named (inappropriately suggesting they are separate anatomic structures), in reality, these three plates of cartilage are a single anatomic structure. The cephalic margin of the ULC is tightly fused to the undersurface of the caudal aspect of the nasal bone, whereas the quadrangular cartilage and ethmoid bone are similarly fused. The resulting osseocartilaginous pyramid is a structurally uniform and anatomically contiguous vault, which constitutes the complete nasal dorsum.

The confluence of the nasal bones with the ULCs and the nasal septum occurs at the rhinion, which is sometimes referred to as the “keystone” or “K-area.” Complete disruption of the bony-cartilaginous union within the keystone area due to trauma or overaggressive surgery may lead to irreversible collapse of the nasal pyramid and should be avoided whenever possible. Nasal deformities affecting the keystone area are particularly challenging due to the increased potential for skeletal instability.

Internally, the junction of the paired ULCs with the midline dorsal septum, results in a critically important anatomic and physiologic feature: the nasal valve (Figure 18). The nasal valve is the narrowest segment of the human airway and it plays a vital role in creating sufficient airway
resistance to facilitate filtration, warming, and humidification of the inspired air. Typically, the ULCs attach to the dorsal septum at a 10º to 15º angle resulting in an internal cross-sectional airway dimension of only 55 to 73 mm².8,9

Of note, in nearly all healthy noses the quadrangular septum widens and flares at the junction with the ULCs. This anatomic widening of the dorsal septum increases the horizontal separation of the ULCs contributing to both improved nasal sidewall support and greater internal airway dimension. Because anatomic reductions in nasal valve cross-sectional area are associated with an exponential increase in nasal airway resistance, reductions in valve width as little as 1 mm can produce symptoms of nasal airway obstruction.10 Consequently, medialization of the ULC from a nasal hump reduction that reduces septal flaring may result in symptomatic nasal valve dysfunction. Therefore, in patients with weak cartilage or narrow noses predisposed to nasal valve collapse, compensatory surgical measures such as spreader graft placement or flaring sutures are sometimes necessary to prevent nasal valve obstruction secondary to pinching of the middle vault.

The lower lateral cartilages (LLC) are the most anatomically complex, and perhaps the most aesthetically important, skeletal structures of the nose (Figure 19). These paired, mirror-image cartilages are closely approximated within their medial (columnellar) segment, but fold sharply at the nasal tip diverging in nearly opposite directions to span the lower nasal sidewall. Each LLC or alar cartilage is arbitrarily subdivided into smaller anatomic segments for greater clarity. Although the nomenclature varies slightly among different authors, the designations lateral and medial crura are used commonly throughout the medical literature. Moreover, certain descriptive terms are used consistently across all classification systems and these include the nasal domes and the columnellar footpods. The nasal domes represent the acute angle formed by the junction of the medial and lateral crural segments of the LLC. Clinically, the nasal domes correspond to the point of maximum tip projection, and their shape and spacing govern the overall contour of the nasal tip or lobule. The lateral crura comprise the “alar wings,” which extend superolaterally, connecting the nasal domes medially to the pyriform aperture laterally, just above the alar crease. The strength and rigidity of the lateral crura are integral to the support and functional integrity of the nasal sidewall; and anatomic deformities, injuries, or improper surgical alterations can profoundly impair nasal breathing. Aesthetically, the lateral crura tend to be most pleasing when flat, and in large unsightly noses they often possess natural convex or concave curvatures in both their long and/or their short axes.

The anatomic junction of the lateral crus with the adjacent ULC forms a unique interlocking joint which amplifies strength of the nasal sidewall. This anatomic junction, commonly known as the nasal scroll, is formed by the cephalic margin of the lateral crus which curls internally to...
fuse with the externally curled caudal margin of the ULC (Figure 20).

The unique configuration formed between the upper and LLCs creates a tube-like strut which confers additional rigidity to the nasal sidewall. Analogous to an automotive roll bar, the nasal scroll resists inward collapse from transmural pressure generated by gentle (resting) inspiration. Since the nasal scroll defines the anatomic outer border of the nasal valve region and since the scroll supports the only mobile section of the valve perimeter, it also governs the threshold for dynamic nasal valve collapse during more vigorous inspiration. If the nasal scroll is damaged, such as may occur with aggressive “cephalic resections” typical of traditional reduction rhinoplasty, the remaining cartilage may be too weak to support the nasal sidewall. In addition to fixed anatomic narrowing of the nasal valve leading to an increase in airway resistance, a weakened nasal sidewall may lower the threshold for inspiratory collapse, permitting pathologic valve dysfunction, that is, dynamic collapse, even upon resting inspiration. External manifestations of static nasal valve dysfunction include lobular pinching, alar retraction, and dimpling of the alar crease.

Although contemporary rhinoplasty surgeons are slowly beginning to recognize the potential long-term implications of aggressive cephalic scroll resection, the practice remains widespread and the adverse consequences will no doubt manifest for decades to come. Fortunately, contemporary rhinoplasty techniques have since evolved which maintain lateral nasal sidewall support while permitting a cosmetically pleasing nasal contour.

At its medial end, the nasal scroll terminates 5 to 6 mm from the midline forming a small gap between the ULC, lateral crus, and anterior septal angle, known as the weak triangle. The inferior most aspect of the LLCs, the so-called medial crural footpods, are rounded (often flared) feet which rest on either side of the posterior septal angle and nasal spine (Figure 21). The anatomic complex formed by the footpods, nasal spine, and posterior septal angle is sometimes called the nasal pedestal. Undesirable widening of the nasal pedestal is commonly seen in the tension nose deformity in which excessive anterior septal projection causes tenting of the lower part of the nose and upper lip.

Starting with the crural footpods below, extending to the nasal domes above, are the medial crura. The medial crura are the paired, conjoined, sagittally oriented segments of the LLC, which give rise to the columella and infratip lobule. For purposes of further differentiation, some authors have proposed subdividing the medial crura by renaming the infratip lobular segment as the intermediate or mesial crus. While the medial crura are nearly parallel in the columellar segment, they diverge just above the nostril, giving rise to a flared infratip lobule on front view and a columellar double-break on profile view.
anatomic deformities of the nasal airway. Nasal such as mucosal contact headaches, epistaxis, or result in secondary side effects such as dry mouth, edly unpleasant, and chronic nasal obstruction may nasal respiratory physiology. The nasal airway is plasty is not complete without a brief review of A meaningful discussion of contemporary rhino-

NASAL PHYSIOLOGY

A meaningful discussion of contemporary rhino-plasty is not complete without a brief review of nasal respiratory physiology. The nasal airway is the body’s preferred conduit for ordinary respira-
tion. Inability to breathe through the nose is decid-
edly unpleasant, and chronic nasal obstruction may result in secondary side effects such as dry mouth, sore throat, snoring, anosmia, sinus dysfunction, or sleep disturbance. Other pathologic conditions such as mucosal contact headaches, epistaxis, or eustachian tube dysfunction may also result from anatomic deformities of the nasal airway. Nasal valve dysfunction is also associated with corre-
spoding reductions in disease-specific quality of life measures as determined by validated psycho-
logical assessment questionnaires, and surgical correction of nasal valve deformities correlates closely with improved quality of life measures.

Much of the body’s total airway resistance is generated by the nose as a consequence of spe-
cial adaptations which warm, humidify, and clean the air we breathe. Beyond the skin-lined nostril or nasal vestibule, the nasal passage tapers at the limen vestibuli to form the bottleneck of the human airway—the so-called nasal valve (Figure 23). Some authors prefer to subdivide the nasal valve into the external and internal segments since these represent two anatomic sites where airway dimensions fluctuate during the normal respira-
tory cycle, a valve-like phenomenon. However, in the healthy nose, the external nasal valve contributes little to airway resistance because of its comparativelarge size; whereas the internal nasal valve constitutes the narrowest segment of the human airway and is responsible for nearly half of all airway resistance. Moreover, the internal valve has the capacity to reduce its size to increase nasal resistance and further restrict nasal airflow. Hence, the nasal valve is the physiologic spigot that controls the rate of airflow through the nasal cavity en route to the lungs.

Beyond the internal nasal valve, the nasal cavity, also known as the nasal cavum, is some-
what conical in shape, enlarging as it extends to join the nasopharynx. Mucosal-covered shelves of bone called conchae, protrude from the outer sidewall of the nasal cavum giving rise to the infe-
rior, middle, and superior nasal turbinate. These unique anatomic structures serve to increase the mucosal surface area within the nasal cavity and enhance contact between inspired air and the sticky, moist nasal mucosa. In addition, the inferior turbinate impinges upon the lower nasal valve region where its specially adapted erectile tissues serve to regulate airflow within the nasal valve and facilitate heat and moisture exchange. Although airflow dynamics are critical to the physiology of a properly functioning nose, considerable contro-
versy remains among experts regarding the pre-
cise nature of normal nasal airflow. The character of nasal airflow (turbulent versus laminar) and the principal path of airflow through the nasal cavity remain topics of controversy. However, turbulent airflow does appear to play a role in normal nasal physiology and the inferior turbinate appears to participate in the generation of turbulent airflow. Moreover, some investigators have observed a combination of laminar and turbulent airflow occurring at different phases of the normal inspira-
tory cycle. Increase in nasal turbulence has also been observed in association with the nasal cycle and with increased physiologic demand, such as occurs with exercise.

To regulate nasal airflow, the nasal valve increases the transit time of inspired air to permit sufficient warming, humidification, and cleansing of the air destined for the sensitive lower airway. Shaped as a slit-like triangular opening, the internal nasal valve is bounded mostly by rigid skeletal structures including the quadrangular septum medially, the pyriform aperture inferiorly, and the head of the inferior turbinate bone infero-
laterally. Although these skeletal structures are rigid and unyielding, the overlying mucosa of the anterior septum and inferior turbinate contain specially adapted erectile tissues composed of multiple venous sinousoids that can be quickly filled or drained to permit rapid variations in cross-sectional area of the nasal valve with corresponding variations in airflow resistance and nasal airflow. Because these unique vascular structures are also covered by only a thin layer of respiratory mucosa, they efficiently transfer both moisture and heat to the inspired air as it transits the nasal cavity. Hence, the nasal valve serves a dual purpose: the regulation of airflow through the nasal cavity and the transfer of moisture and heat to the inspired air.

While the regulatory mechanism of the nasal airway is only partially understood, it is pre-
dominantly under the domain of the sympathetic nervous system, with additional input from the parasympathetic nervous system and numerous vasoactive peptides. Nasal airway resistance in healthy individuals is also influenced by a wide range of exogenous factors, such as posture, ambient temperature, ambient humidity, activity level, alcohol ingestion, and various medications. In a large percentage of healthy humans, mucosal shrinkage (vasoconstriction) and swelling (vaso-
dilation) occur in a cyclic pattern alternating between the right and left nasal passages, a process known as the nasal cycle. Presumably this permits one side to perform the physiologic work of filtration, humidification, and warming, whereas the opposite side is protected from overdrying and per-
mitted to self-cleanse. The nasal mucosa also pos-
posses a specialized mucous bilayer for filtration of inspired particulate debris. Debris such as dust or pollen are entrapped within the sticky mucous layer and transported from the nose propelled by a wave of beating microcilia. The mucous stream eventually reaches the pharynx where entrapped pathogens are swallowed and neutralized by the harsh pH of the stomach. However, mucocili-
ary dysfunction resulting from genetic disorders or toxic ingestion such as cigarette smoking may impair this natural cleansing mechanism.
While the medial and inferior borders of the nasal valve are rigid and stationary, the lateral border is composed of thin, flexible cartilage that is far less rigid and easily deflected by external compressive forces. When high inspiratory flow rates produce transmural pressures that exceed lateral sidewall support, inward collapse of the nasal sidewall results in dynamic nasal valve collapse. Although dynamic nasal valve collapse is normal in healthy individuals during periods of high ventilatory activity such as exercise, nasal valve collapse should not occur at rest with gentle inspiration. However, various abnormal conditions may compromise nasal sidewall support leading to pathologic valve collapse and symptomatic nasal airway obstruction. Anatomic alterations that weaken the nasal sidewall, such as those caused by overzealous cosmetic rhinoplasty, are a frequent cause of nasal valve dysfunction.

**SURGICAL FUNDAMENTALS OF RHINOPLASTY**

**Anesthesia**

Rhinoplasty may be performed comfortably under either general anesthesia or conscious sedation, alternatively known as "twilight anesthesia" or "intravenous sedation." Both options have advantages and disadvantages, and surgeon preference will usually dictate the anesthetic approach used. Regardless of the approach chosen, infiltration of the nasal soft tissues with epinephrine-containing local anesthetic is necessary to prevent excessive surgical bleeding. Premixed anesthetic solutions containing 1% lidocaine and epinephrine in a concentration of 1:100,000 are commercially available for soft tissue injection. For twilight anesthesia, infiltration of local anesthetic is preceded by topical anesthetization of the nasal mucosa, augmented by regional nerve blocks to enhance pain control; whereas for general anesthesia, regional nerve blocks are typically omitted. To prevent systemic side effects and limit unwanted hydrostatic tissue distortion, care must be taken to monitor vital signs during injection and restrict the volume of local anesthetic administered.

**Surgical Approaches**

Cosmetic rhinoplasty is accomplished via the artistic and structurally sound alteration of the nasal skeleton. To that end, surgical exposure must permit satisfactory access to the misshapen anatomy, while minimizing unwanted surgical morbidity. Two surgical approaches to the nasal skeleton are currently used for cosmetic rhinoplasty: the open (or external) approach and the closed (or endonasal) approach. In the closed rhinoplasty approach, all incisions are confined to the nasal vestibule and surgery is conducted entirely through the nostrils. The closed approach offers several advantages over open rhinoplasty, including the absence of visible incisions and limited disruption of the skin-soft tissue envelope. The absence of external incisions shortens closure time, while the limited tissue disruption not only minimizes acute swelling and ecchymosis but also proportionately limits the potential for scar contracture or subcutaneous fibrosis. Because the endonasal approach does not require elevation of a pedicled skin flap, distortion of the nasal skin is minimized, and cosmetic changes to the nasal skeleton are more easily appreciated. Although reduced access to the nasal skeleton does not facilitate suture fixation of grafts or implants, the closed approach does permit creation of "precise pockets" to stabilize onlay grafts and limit unwanted graft migration. Despite these many advantages, the limited surgical exposure typical of endonasal rhinoplasty prevents the application of many advanced operative techniques, making closed rhinoplasty poorly suited to complex revision procedures. Nevertheless, endonasal rhinoplasty remains the preferred approach for numerous cosmetic surgeons, particularly in the previously unoperated nose (primary rhinoplasty) or for limited revision ("touch-up") procedures.

Presently, most endonasal rhinoplasty is performed using the delivery method of alar cartilage exposure in which intercartilaginous (IC) and marginal incisions are combined to externalize or "deliver" the alar cartilage as a bipedicled chondrocutaneous flap (Figure 24). The IC incision divides the attachment of the upper and LLCs at the nasal scroll, then extends medially past the anterior septal angle where it continues along the leading edge of the caudal part of the septum and divides the attachment of the upper and LLCs at the nasal scroll, then extends medially past the posterior septal angle. In addition to permitting access to the nasal tip, the IC incision also permits surgical access to the nasal bridge for alterations of the dorsal profile (Figure 25B).

![Figure 24](image)

**Figure 24** Intraoperative view of alar cartilage delivery technique. (A) Right alar cartilage delivered as chondrocutaneous flap via right nostril. (B) Both alar cartilages delivered via the right nostril for suture approximation.

![Figure 25](image)

**Figure 25** Cadaver specimen with skin partially removed. (A) Endonasal view of the intercartilaginous rhinoplasty incision. (B) "Intercartilaginous" knife cut dividing the lower lateral and upper lateral cartilages for access to the upper part of the nasal dorsum.
In contrast to the IC incision which follows the cephalic border of the alar cartilage, the marginal incision follows the caudal border (or “margin”) of the alar cartilage giving rise to the name “marginal” incision (Figure 26). Since the caudal border of the alar cartilage runs oblique to the nostril rim, the marginal incision should not be confused with the seldom-used rim incision which runs parallel to the inner nostril rim. Use of the rim incision is discouraged owing to its characteristically conspicuous and unsightly appearance and the increased risk of nostril stenosis.

Although the marginal incision is mandatory for delivery of the tip cartilage, it is also the principal incision used in the external rhinoplasty approach. Bilateral marginal incisions are connected by a single bridging incision of the columellar skin, the so-called transcolumellar incision (Figure 27). Usually less than 5 to 7 mm long, the transcolumellar incision is typically located at the mid-columella and is often irregularized to improve camouflage and minimize scar contracture. While this incision results in a potentially visible scar, it also permits wide-field surgical degloving of the nasal framework for dramatically improved access to the nasal skeleton. Moreover, when repaired properly, the transcolumellar scar is frequently indiscernible.

Because the external approach obviates the need for IC incisions, both the mucosal envelope and nasal scroll remain intact. Thus, contamination from the underlying nasal cavity is minimized, and structural support to the nasal sidewall is preserved. The open approach also facilitates en bloc elevation of the skin-soft tissue envelope, thereby limiting disruption of the cutaneous capillary and lymphatic networks. Perhaps most importantly, the external approach offers vastly improved surgical exposure resulting in better diagnostic accuracy, diminished distortion of the exposed skeletal anatomy, and direct access for suture fixation of most grafts or implants (Figure 28). Although endonasal rhinoplasty is still in widespread use, the external approach has become the procedure of choice for complex structural reconstruction of the collapsed nasal framework. Owing to its greater diagnostic accuracy and therapeutic versatility, external rhinoplasty will no doubt remain the workhorse of revision nasal surgery.

Fundamentals of Tip Rhinoplasty

Regardless of the surgical approach selected, the objective of cosmetic rhinoplasty is the controlled and artistic reconfiguration of the nasal framework. For the nasal tip, a wide variety of techniques have been devised to modify the LLCs and improve tip contour, projection, and/or rotation. Because many of the early refinement techniques relied solely upon alar cartilage excision to partially collapse the alar tripod, cosmetic results were often unpredictable and frequently disappointing. Even satisfactory cosmetic results were too often prone to delayed shrink-wrap deformities and eventual nasal sidewall collapse. Despite the large number of tip refinement techniques described to date, few methods have withstood the test of time, and many have been abandoned or condemned due to consistently poor surgical results.

While considerable disagreement exists among accomplished surgeons regarding the optimal method of tip enhancement, all successful tip-plasty techniques share several common...
characteristics. Perhaps the most important universal element in a successful tip-plasty is adequate preservation of structural tip support. Without effective support of the nasal tip, the lobule eventually succumbs to the persistent forces of muscle movement, gravity, or aging; and an elongated, counterrotated, and/or underprojected nose ensues. Indeed, poor tip support is frequently a causative factor, not only in the failed rhinoplasty, but also in the naturally unattractive nose as well.

Another important characteristic of successful tip modification is an aesthetically pleasing separation of the nasal domes. Whether from congenital malformation or failed surgical intervention, tightly approximated nasal domes produce an objectionable “pinched” or “unitip” appearance. Moreover, noses with this appearance are frequently plagued by functional collapse of the nasal airway, making the combined aesthetic and functional deficits a common motive for seeking corrective surgery. Like the overly narrow nasal tip, excessive domal width is also highly disruptive to cosmetic harmony, and both a wide ball-like lobule or a bulbous tip are highly undesirable and conspicuous features that often prompt cosmetic rhinoplasty. Although a large nasal tip does not guarantee satisfactory nasal airway function (since it may also conceal functional deformities of the underlying nasal passages), progressive narrowing of the nasal tip is limited by continued patency of the nasal airway. Hence, all effective tip reduction techniques must precisely narrow tip width without invoking functional encroachment of the nasal airway. Since divergence of the medial crura and separation of the nasal domes are mandatory attributes of any attractive nasal tip, all effective tip modification techniques must also preserve these critically important aesthetic features.

Finally, the last element common to all effective tip-plasty techniques is versatility. Because virtually no two noses are alike, surgical alteration of the nasal tip must be able to accommodate individual variations in tip morphology including projection, rotation, symmetry, and width. Furthermore, because maneuvers which enhance nasal contour from one perspective, may disrupt nasal aesthetics from another, all effective tip-plasty techniques must be able to compensate for unwanted secondary or tertiary effects of cartilage reshaping. The result should be a stable, natural, and attractive tip contour when viewed from all angles. Although it has been stated that mastery of the tip equates to the mastery of rhinoplasty, this represents a gross oversimplification of the numerous challenges and complexities of cosmetic rhinoplasty. Nevertheless, no rhinoplasty can be considered truly successful if an attractive tip is lacking, and achieving a cosmetically pleasing tip contour can present one of the more daunting facets of cosmetic nasal surgery.

The Wide Tip. Refining the overly wide tip involves narrowing broad domal arches, reducing excessive interdomal space, and restoring domal symmetry. However, before the naturally attractive nasal tip can be replicated, the surgeon must first understand the skeletal configuration which characterizes the naturally attractive nose.

The ideal nasal tip framework is typified by angular, V-shaped domal apices oriented slightly oblique to the sagittal midline (Figure 29). The caudal border of the domal apex is separated from its counterpart by several millimeters, whereas the cephalic margins are typically in close approximation. The resulting divergent configuration creates a diamond-shaped surface contour which surrounds a small interdomal cleft. Ordinarily the cleft is filled with supportive ligaments and other fibromuscular tissues, resulting in a smooth, slightly convex, external contour. When domal spacing is ideal, this configuration leads to a slender and elegant lobule with distinct, individual domal highlights.

However, domal spacing alone does not assure an attractive nasal tip. In addition to optimal domal spacing, the ideal tip configuration is also characterized by flat, straight, and symmetric lateral crura. Although modest convexity may be tolerable in the wide nose, a flat, uniplanar lateral crus typically provides the most appealing nasal shape.

While virtually no two noses are exactly alike, variations of this alar cartilage configuration are found in virtually all naturally attractive noses. While the angle of divergence will vary according to the desired tip width, the presence of a diamond-shaped lobule and smooth, flat lateral crus are essential to an attractive tip contour, and all tip-plasty techniques either mimic or recreate these crucial skeletal features.

In the broad nasal tip deformity, wide, rounded domal arches result in excessive separation of the alar domes (Figure 30). In the thick-skinned patient, the large interdomal space is typically filled with fibromuscular tissue, but lobular bifidity may also be observed in the absence of thick nasal skin. From below, the broad nasal tip appears trapezoidal in shape rather than the preferred equilateral triangle, and the lateral crura are generally flat or gently convex presenting a conspicuous bulbous appearance.

Refining the boxy tip involves creating a more angular domal arch to narrow the excessive interdomal space. Typically the lateral crus require very little modification other than modest cephalic resection at the “paradomal” region to eliminate supratip fullness in the nasal profile.

Figure 29 Natural configuration of tip cartilages in the aesthetically pleasing nose. Note the divergent mesial crura, diamond-shaped lobule, and flat lateral crura.

Figure 30 Examples of the broad nasal tip deformity. Note the wide interdomal spacing, linear alar sidewall, and trapezoidal tip configuration on base view. (Note postoperative views at the bottom)

In contrast to the broad tip, the classic bulbous nasal tip deformity is characterized by unusually broad and widely separated domal arches exacerbated by overly round, convex lateral crus (Figure 31). Refinement of the bulbous tip deformity involves narrowing the overly wide tip (as described above for the broad-tip deformity) followed by flattening of the convex lateral crura. Eliminating convexity in the cupped and bowed lateral crus without compromising nasal sidewall support can be extremely challenging and may require a combination of cartilage excision, suture modification, and/or cartilage grafting techniques.
Finally, in the asymmetric tip deformity, the domal arches lack mirror image symmetry due to inconsistencies in domal contour, projection, and/or rotation (Figure 32). Modest domal asymmetries are often evident in the misshapen lobule, and the deformities described above are commonly observed in combination. Although the malpositioned alar cartilage often responds favorably to repositioning, correction of congenital size discrepancies between LLCs is far more challenging and may require augmentation, unilateral cartilage excision, and/or camouflage grafts for correction.

Because excessive tip width is a common feature of the misshapen nose, a number of techniques have been described to address the wide lobule. Perhaps the most effective approach for tip refinement is suture modification of the alar tripod. Suture-based refinement techniques rely upon cartilage reshaping, rather than the traditional technique of cartilage excision, to reconfigure the oversized lobule. These techniques permit narrowing of the domal arch, reduction of the interdomal space, or combinations therein, while simultaneously conserving structural support and minimizing the risk of contracture-mediated deformities.

Typically, suture-based techniques are performed as a two-step procedure. In the first step, each dome is individually narrowed using a horizontal mattress “dome-unit” or “dome-binding” suture (Figure 33). To create the desired V-shaped domal configuration, scoring of the domal apex is often necessary to break the “spring” of the alar arch. When simultaneous increases in tip projection and rotation are also needed, the hinge-point can be repositioned laterally, outside the existing dome, to increase length of the medial element. In the second step, the newly narrowed domal arches are then coapted with a third “interdomal” mattress suture, placed between the domes, to control precisely the extent of interdomal separation and diminish lobular width. As with the ideal (natural) dome configuration, the cephalic aspects of the domes are positioned in close approximation while the caudal ends remain separated by up to several millimeters (see Figure 32). This is accomplished by angling the interdomal suture with the caudal segment placed away from the domal apex. The result is a natural-appearing diamond-shaped lobule that avoids the pinched “unitip” deformity resulting from complete coaptation of the nasal domes.

While suture techniques provide an effective means of refining the wide nasal tip, the bulbous nasal tip deformity normally requires additional measures to address the broad, convex lateral crura. Typically, bulbous alar cartilages are strong and stiff as a consequence of their cupped, convex shape. Obtaining a smooth, flat crural contour is often challenging and various ancillary techniques such as curetting, augmentation grafting (eg, lateral crural strut grafts), or sculpting sutures may be required to achieve the desired nasal contour. However, stubborn convexities may also require judicious excision of the cephalic part of the crus in order to sufficiently flatten the cupped alar cartilage. Since bulbous alar cartilages are generally more resistant to cartilage excision, the volume of excised tissue is typically greater than that necessary for the average nose. Nevertheless, the bulbous nose is also subject to the same requirements of adequate structural sidewall support, and overexcision is ill-advised.

Although conservative excision of the lateral crus is sometimes necessary to shape the unusually strong alar cartilage or to refine the supra-tip profile, the practice of subtotal lateral crural resection (eg, the “rim strip”) is seldom justified and should be abandoned. While this technique has been taught as a reliable means of achieving tip rotation or tip narrowing, loss of crural rigidity is commonly associated with buckling of the residual cartilage producing a host of associated deformities including bossae, lobular pinch- ing, alar dimples, and/or domal asymmetries (see Figure 31). Moreover, in contracture-prone patients, the skeletal void created by the missing cephalic segment leads to cephalic migration of the remnant cartilage producing a conspicuous retraction of the nostril rim. Because alar retraction is difficult to reverse, excision of the cephalic margin, particularly within the nasal scroll, should be avoided whenever possible. Fortunately, the traditional practice of subtotal crural excision has fallen into disfavor, and numerous, far more effective and reliable alternatives to “excisional” rhinoplasty, such as suture-based cartilage reshaping, have been developed.

The Ptotic Tip. Another frequent challenge of tip rhinoplasty is eliminating the ptotic nasal tip deformity. The ptotic tip deformity stems from compromised tip support and is characterized by a counterrotated and often underprojected lobule (Figure 34). Causes for inadequate tip

Figure 31 Examples of the bulbous nasal tip deformity. Note the broad convex lateral crura, pronounced interdomal bifidity, and exaggerated trapezoidal shape on base view.

Figure 33
support include widely spaced medial crura, buckled medial crura, short medial crura, and/or excessive activity of the depressor septi muscles (Figure 35).

Because the ptotic tip lacks adequate projection and sufficient rotation, treatment mandates correction of both deficiencies. As with tip narrowing, a wide range of procedures have been devised to rotate and project the ptotic nasal tip. Techniques include coaptation of the medial crura, augmentation of medial crural strength, extension of medial crural length, suspension of the alar cartilage, and/or reduction of the over-sized alar arch.

Perhaps the most common technique for treatment of the ptotic tip is placement of a columellar strut graft (Figure 36). Fashioned from septal cartilage to create a long flat strip of rigid tissue, the columellar strut graft behaves as a structural pillar to enhance tip recoil and lengthen the central limb of the tripod. Although septal cartilage is often preferred, the graft may also be fashioned...
from conchal cartilage, rib cartilage, or irradiated rib cartilage when autologous septal tissue is unavailable. Sandwiched between the medial crura, the graft is coapted with multiple transfixed suture techniques, functionally uniting the three separate skeletal components into a single reinforced structural element. Normally the graft terminates above the crural footpods and is supported by a sling of intercrural ligamentous tissue which prevents direct articulation with the nasal spine. However, this type of “floating” strut design may lose projection when subjected to extreme loading forces typical of the severely underprojected nose. In contrast, the articulated columellar strut, which rests directly upon the nasal spine via a variety of complex fixation techniques, provides rigid unyielding structural support and is preferred for the severely underprojected or overrotated nose. However, maintaining secure midline fixation upon the nasal spine is challenging and muscle activity produced by smiling may displace the articulated strut from the nasal spine if secure fixation is lacking. Nevertheless, the extended columellar strut is often the only effective means of forcibly reprojecting the scarred or severely hypoplastic tip.

Regardless of strut design, the strut profile can be angled by 10° or 15° to simulate a columellar “double break” when a feminine profile is desired. Similarly, by adjusting the extent of caudal projection, columellar profile disturbances such as columellar retraction or an overly acute nasolabial angle can also be eliminated. Although either an open or closed rhinoplasty approach can be used to insert a columellar strut graft, secure fixation of the articulated strut usually necessitates the external approach. In both cases, the columellar strut graft is initially overprojected, then sequently trimmed until the desired profile aesthetics are achieved (Figure 37). Because the residual strut protrudes beyond the underprojected alar domes, a unitip deformity is temporarily produced and additional measures are needed to restore tip fullness (Figure 38). Using the strut as a fulcrum, the alar cartilages are then pulled forward and sutured to the distal graft to project the alar tripod, camouflage the protruding graft, and create a natural and cosmetically appealing tip contour. When the alar domes are too short to reach the newly designated tip, recruitment techniques, such as the “lateral crural steal,” are used to relocate the alar domes and increase projection of the alar arch. This technique increases tip projection and rotates the lobule by repositioning the dome apices laterally and “stealing” lateral crura to lengthen the medial element. When used in combination with a columellar strut graft, the tip, pother, and underprojected lobule can be narrowed, rotated, and projected simultaneously (Figure 39). Although placement of a columellar strut will result in palpable rigidity of the nasal tip, it also confers a potentially permanent increase in tip support to maintain appropriate rotation and projection of the poteic lobule indefinitely.

**Tip Grafts.** Often, the severely underprojected nose is only partially corrected with the application of a columellar strut graft. Although recruitment techniques, such as the lateral crural steal, are capable of yielding additional tip projection, these increases may be prevented by overrotation of the lobule. Thus, when columellar struts and recruitment techniques fail to achieve the desired tip projection, tip augmentation techniques may be used to achieve additional projection. Although various tip graft configurations have been described, the infratip “shield” graft is by far the most popular option. Fashioned to mimic the diamond-shaped lobule and its divergent domes, the heart-shaped graft is secured to the infratip lobule for a simultaneous increase in nasal length and tip projection (Figure 40). Care must be taken to bevel the outer graft edges for satisfactory camouflage and to ensure that the lateral crura blend smoothly with the graft shoulders. When crafted properly, the shield graft provides a cosmetically pleasing lobular contour and a sizeable increase in tip projection. Moreover, graft shape can be adjusted to suit the desired tip width, and graft length can be adjusted to modify the columellar profile. Since the shield graft also functions as a mechanical gusset plate, stability of the alar tripod is greatly enhanced with shield graft placement.

Another popular tip augmentation graft is the cap or supradomal augmentation graft. Like the shield graft, the cap graft is used to increase tip projection by lengthening the domal apices (see Figure 40). As with all onlay grafts, the edges are beveled to enhance camouflage and care is taken to ensure a smooth transition with the surrounding cartilage. However, unlike the more commonly used shield graft, the cap graft does not alter tip rotation since dorsal length remains constant. Hence the cap graft is a useful adjunct for the underprojected nose in which counterrotation is not desired.

**Tip Extension Grafts.** The successful application of a columellar strut graft requires an elastic skin-soft tissue envelope that can stretch to accommodate the newly projected nasal framework. For the ptotic nasal tip deformity, the increase in tip projection is offset by the decrease in nasal length and the skin envelope can generally stretch to accommodate the reconstructed tip tripod. However, when attempting to increase tip projection in patients with scarred or contractured nasal skin, the absence of skin elasticity leads to excessive cephalic displacement of the strut, and tip projection gives way to an overrotated, underprojected lobule with excessive nostril show.

To prevent unwanted rotation of the lobule, the cephalic aspect of the graft may be extended into the membranous septum and overlapped with the caudal L-strut. This type of modified strut can be sutured to the caudal septum to stabilize the central tripod and prevent unwanted strut displacement. By using both the caudal septum and the nasal spine as a mechanical buttress, the extended columellar strut, also known as a septal extension graft, achieves maximum structural stability and permits forceful elongation of the nasal skin envelope to increase projection dramatically while simultaneously maintaining appropriate rotation of the lobule. Although the septal extension graft is a powerful tool in revision rhinoplasty, in severely inelastic noses, careful excision of subcutaneous fibrous tissue may be needed to enhance skin elasticity further and permit adequate tip lengthening.

![Figure 37](image1.png) Intraoperative photographs showing (A) initial installation of a floating strut prior to final shaping, (B) final strut contour reflecting the desired profile aesthetics.

![Figure 38](image2.png) Intraoperative photographs showing (A) initial installation of a floating strut prior to final shaping, (B) final cartilage configuration after domal advancement with interdomal suture placement.
This technique and its variations, including various grafts anchored to the nasal septum, have been described in which tip support is augmented using various grafts. Lengthening of the septum with cartilage grafts can be used to correct a host of nasal deformities including severe retraction, septal overresection, or the congenitally short nose. While many of these techniques employ single or bilateral spreader grafts to stabilize the domal arch, they all rely upon the nasal septum to buttress the nasal tip in a more projected or counterrotated configuration.

A further accepted method for addressing the ptotic tip deformity is the technique of vertical dome division. This technique and its variations vertically divide the alar cartilage adjacent to the existing dome to increase medial crus length (Figure 42). A portion of the divided lateral crus is then recruited to lengthen the foreshortened medial crus, simultaneously increasing both tip rotation and tip projection. Tip support is further enhanced by coapting the medial crus with transfixion sutures, with or without an intervening columnar strut graft. Vertical division of the alar cartilage also serves to “break the spring” of the domal arch contributing to tip refinement from narrowing of the lobule. Although vertical dome division may be performed via the external rhinoplasty approach, it is most commonly performed using an endonasal (delivery) approach and can be embellished with the addition of onlay grafts or conservative alar cartilage excision.

While vertical dome division is commonly used to increase tip projection, segmental excision of the alar arch using “vertical” incisions can also provide a powerful means of reducing the overprojected nasal tip (Figure 43). By reducing all three limbs of the alar tripod simultaneously, segmental excision of the alar domes produces a controlled reduction in tip projection. Moreover, by simultaneously adjusting the relative length of the medial and lateral tripod legs, concomitant changes to tip rotation can also be achieved. Hence, vertical dome division is a versatile technique that may be used to alter tip projection and rotation in a variety of combinations.

A further method of simultaneously improving tip projection and tip rotation is the “tongue-in-groove” setback technique. This powerful technique, applicable only to overly long noses, achieves simultaneous tip projection and tip rotation by cephalically repositioning the alar tripod upon the caudal aspect of the septum (Figure 44).

The technique requires surgical separation of the membranous septum and medial crura, followed by a “setback” repositioning and imbrication of the medial crus upon the caudal aspect of the septum to stabilize the repositioned tripod. In this manner, the caudal aspect of the septum functions as a columnar strut to support the newly projected tip and cephalically repositioned alar tripod. The result is a shortened nose with greater tip projection (Figure 45). In addition to increasing tip projection, the tongue-in-groove technique can also be used to decrease tip projection by altering juxtaposition of the alar tripod relative to the caudal aspect of the septum. Hence, the tongue-in-groove technique is a versatile method for cosmetic tip refinement in the overly long nose; and tip rotation, tip projection, or tip deprojection may all be accomplished with this technique.

Finally, the ptotic tip can also be addressed with the crural overlay technique in which the lateral crura are vertically divided, shortened or overlapped, and reconstituted with suture (Figure 46). Typically, the lateral crura are divided well lateral to the nasal dome in the mid to lateral segments, although the precise location is often governed by the shape and strength of the alar cartilage. While the lateral crural overlay technique rotates the lobule effectively, unlike many of the aforementioned techniques, the lateral crural overlay does not increase tip projection. For this reason, the lateral crural overlay is often preferred for the overprojected ptotic nose. In cases of severe overprojection, medial crural overlap can also be used to optimize deprojection while avoiding overrotation.

**Tip Surgery and Nasal Skin Thickness.** Regardless of the craftsman’s skill, the quality of the final product is only as good as the materials used in the construction process. In the case of cosmetic rhinoplasty, time-honored methods used in the hands of a master surgeon cannot always overcome the constraints of unfavorable tissues. Perhaps the most daunting challenge is the wide nose with thick sebaceous skin and naturally weak cartilage. As a strong and rigid nasal framework is needed to shape forcefully the thick, amorphous skin, weak, flexible cartilage is ill-suited to a well-defined nasal contour. The problem is compounded by excessive nasal size since an oversized sebaceous skin envelope seldom conforms to a reduced skeletal framework in a favorable manner. Moreover, even when favorable results are achieved, the healing process usually takes much longer to conclude. Since a large, shapely nose is generally preferable to a small misshapen one and since the large thick-skinned nose may respond poorly to size reduction, contour enhancement should take priority over size reduction in the oversized nose with heavy nasal skin. If existing septal tissues lack sufficient rigidity or are in short supply, rib cartilage grafting may be necessary to achieve a strong and aesthetically pleasing skeletal framework and to stretch the thickened nasal skin forcibly for a well-defined nasal contour.
In contrast to the thick-skinned patient, patients with extremely thin skin lack the subcutaneous camouflage necessary to conceal minor topographic flaws in the nasal framework. Often the thin-skinned nose may appear skeletonized and vascular dyschromias are frequent after surgical intervention. For patients with pathologically thin nasal skin, subcutaneous augmentation grafts of dermis, perichondrium, superficial musculoaponeurotic system tissue, or fibrous tissue are necessary to achieve a smooth and even surface contour by increasing skin thickness. Although graft viability is tenuous in the smoker or diabetic, in healthy young patients, permanent augmentation is typical. Intermediate skin thickness is generally preferred since it conceals minor skeletal imperfections, while adhering faithfully to the underlying skeletal anatomy to yield a well-defined and elegant nasal contour. However, even patients with optimal skin thickness may also experience cosmetic derangements as a result of excessive subcutaneous fibrosis or scar contracture. Although healthy intermediate-thickness skin with a clear complexion and firm symmetric cartilage has the best prognosis for a favorable surgical outcome, no patient is immune from potential wound-healing derangements, and all prospective patients should be counseled accordingly.

Dorsal Hump Reduction

Perhaps the most common maneuver in cosmetic rhinoplasty is nasal hump reduction. Although realignment of the dorsal nasal profile is often regarded as a comparatively simple maneuver, in reality, the flawless execution of a dorsal hump reduction is a demanding and exacting surgical procedure that may take years to master fully. This is attributable to the complex and delicate anatomy of the nasal dorsum, comprised of widely dissimilar tissues, all of variable thickness and consistency. Moreover, because the nasal bones are obscured by the overlying soft tissues, "blind" hump reduction adds to the challenge of precise profile alignment. Indeed, many expert rhinoplasty surgeons regard hump reduction as one of the most challenging maneuvers in cosmetic rhinoplasty.

In humans, the nasal bridge is seldom more than one-third bone, and the typical nasal hump is usually composed mostly of cartilage (Figure 47). Although most humps project only a few millimeters above the cosmetically ideal profile, overresection of the dorsum is an all too common tendency among novice rhinoplasty surgeons. Even extremely large nasal humps seldom require more than 3 to 4 mm of bony deprojection to achieve a satisfactory profile alignment. Although a straight dorsal profile is the goal in almost any hump reduction, naturally increased skin thickness at the nasal root (sellion) and supratip require preservation of a slight skeletal convexity at the rhinion to achieve a straight and attractive surface contour. However, in all noses, a smooth transition from cartilage to bone is essential to avoid step-off irregularities of the dorsal profile.

Hump reduction begins with composite elevation of soft tissues off the dorsal crest. Sufficient exposure is needed to visualize and remove the bony and cartilaginous humps, but care must be taken not to elevate all of the lateral nasal bone periosteum as these attachments are needed to maintain support following bony infracture. Prior to hump removal, the surgeon must carefully plan the height and angulation of the cartilaginous and bony profiles to achieve the desired cosmetic changes. In most noses, bony hump reduction requires only a triangular wedge resection, beginning at the rhinion and tapering at the radix (see Figure 47). While the length, width, and thickness of the bony wedge may vary, the overall shape is remarkably consistent in most noses. In contrast, the cartilage fragment will often vary in both size and shape since the dorsal septum has widely variable morphology. In patients with an overprojected rhinion and a normally projected anterior septal angle, the cartilage fragment will be tapered, thinnest at its caudal end. Alternatively, in patients with an overprojected anterior septal angle, the resulting fragment may have a more rectangular shape. Because the desired skeletal contour will determine the position and angulation of the tissue cuts and because there is a wide variation in size, shape, and composition of nasal humps, the parameters of hump reduction will vary significantly for almost every patient. Nevertheless, skeletal tissue should be conserved in all patients since a strong and prominent dorsum is both aesthetically pleasing and functionally advantageous. The novice surgeon should also remember that surprisingly little bone removal is usually sufficient to achieve a satisfactory cosmetic outcome. Clearly, the ability to properly judge and execute the tissue resection is fundamental to a successful surgical outcome and is typically far more challenging than many surgeons realize. Good aesthetic...
judgment is predicated upon careful preoperative analysis that is well worth the time invested. The sequence of cartilage and bone removal is at the discretion of the surgeon. Likewise, the use of scalpel or scissor to resect the cartilage hump is also a matter of surgeon preference. However, most surgeons prefer to reduce the cartilaginous dorsum first and then set the bony profile to complement the newly aligned middle vault. While some surgeons prefer to resect the ULC and dorsal septum in a single cut, in practice the middle vault cartilage often flexes making a precise cut difficult. As an alternative, many surgeons prefer first to separate the ULCs from the dorsal septum and then resect each element individually. Regardless of the method chosen, the final result should be a straight, smooth cartilaginous vault in which the cut upper edges of all three elements are equal in height.

Once the cartilage reduction is complete and the desired cartilaginous profile has been achieved, the bony hump is removed. Traditionally, a medium to large bony hump is resected en bloc using a sharp osteotome, whereas smaller humps are reduced using manual rasps. Because the bony hump represents a U-shaped plate of membranous bone of varying density, guiding the osteotome in a perfectly straight path to cleave the overprojected bone is a formidable task. Not surprisingly, this method of blunt force bone reduction is fraught with numerous potential complications such as overresection, undersection, asymmetry, and/or bony comminution. Although minor residual bony abnormalities can be eliminated with the manual rasp, these defects must be addressed prior to lateral osteotomy which destabilizes the bony pyramid and prevents effective rasping.

Because blunt force bony hump removal is associated with a host of potential complications, the powered reciprocating rasp offers a less traumatic and more precise alternative to the traditional method. Using the reciprocating power rasp, bone is removed sequentially with minimal trauma to the overlying soft tissues. Small humps, minor asymmetries, and surface contour imperfections are all easily eliminated with the power-assisted rasp while blunt force trauma is avoided. The resulting bony pyramid can also be “sculpted” to create a more natural skeletal contour. Although lateral osteotomies are still required in most cases to narrow the widened vault, the power-assisted rasp facilitates a polished, smooth, and straight bony contour for more predictable cosmetic outcomes.

Although a well-executed bony hump reduction immediately improves the nasal profile aesthetics, the realigned profile occurs at the expense of altered frontal aesthetics. Since lowering the nasal bridge leads to increased separation of the nasal bone remnants, the upper BTALs appear significantly wider following nasal hump removal. Typically the additional width is considered undesirable since humped noses are often too wide from the start. Moreover, the gap separating the cut edge of the nasal bone and the adjacent ethmoid complex, the so-called “open roof deformity,” creates a flat and unnatural appearance, further contributing to the adverse cosmetic impact of hump removal. To compensate for the cosmetic deformity produced by hump reduction, dorsal osteotomy is usually followed by (bilateral) infracture of the nasal sidewall. This is accomplished by detaching and medializing the bony sidewall using curvilinear bone cuts positioned within the nasofacial groove, a procedure commonly known as a lateral osteotomy. Although osteotomy releases

more than just the nasal bone remnants (since the lateral nasal sidewall includes the nasal process of the maxilla), the upper nasal vault can be narrowed to compensate for iatrogenic widening of the BTALs. Traditionally, the lateral osteotomy is performed in a subcutaneous plane with a sharp narrow osteotome through a small endonasal incision. However, instead of a continuous subcutaneous osteotomy, some surgeons prefer interrupted "postage stamp" osteotomy cuts via a percutaneous approach. While both approaches have advantages and disadvantages, the traditional osteotomy is far more commonly used.

The traditional osteotomy begins at the pyriform aperture just above the attachment of the inferior turbinate bone. This starting point is approximately halfway along the pyriform aperture allowing effective narrowing of the bony vault without functional narrowing of the nasal airway. Osteotomy cuts that begin lower on the pyriform aperture are ill-advised since medialization of the inferior turbinate will assuredly obstruct the nasal airway. Initially the osteotomy is directed superolaterally toward the pupil until the dense bone of the anterior maxillary buttress is reached (see Figure 26). The osteotomy cut is then redirected approximately 90º superomedially toward the nason where the cut follows the nasofacial groove along the medial edge of the anterior maxillary buttress. As the cut extends cephalically its course curves gently toward the radix and terminates at the interpupillary line. Because the traditional lateral osteotomy begins high on the nasal sidewall, then continues low into the nasofacial groove and then terminates high on the nasal root, this type of lateral osteotomy is often termed a "high-low-high" lateral osteotomy. When performed in conjunction with a bony hump resection, the high-low-high osteotomy releases the bony sidewall remnants from all adjacent bony attachments leaving the nasal bones suspended by the attached periosteum and overlying soft tissues. However, if upper vault narrowing is desired in the absence of a bony hump reduction, medial osteotomies are necessary to release the intact (medial) attachments of the nasal bones to the central ethmoid complex. Medial osteotomies are performed much like the lateral bone cuts using a narrow sharp osteotome directed along the lateral aspect of the central ethmoid complex (see Figure 26). Typically the medial and lateral cuts meet at the interpupillary line, but lateral cuts can be truncated whenever bony vault instability is a concern.

Like the dorsal osteotomy, the lateral osteotomy is also associated with potential complications. In addition to asymmetric cuts, comminution, or sidewall collapse, the mobilized bone fragments may heal unevenly leading to a crooked bony vault. Often this complication results from unrecognized deviation of the perpendicular ethmoid complex, emphasizing the importance of the bony septum to the symmetry of the bony vault. Skeletal irregularities resulting from untreated injuries to the bony vault may necessitate aggressive countermeasures including intermediate osteotomies to eliminate severe convex or concave deformities of the bony sidewall.
As multiple osteotomies are employed to restore symmetry and produce a cosmetically pleasing nasal contour, the stability of the nasal pyramid is diminished and the likelihood of collapse, asymmetry, or deviation increase as the extent of destabilization increases. Care must be taken to protect the union of the cartilage and the bony framework, particularly at the keystone area and the junction of the nasal bones with the ULCs. In both anatomic areas, the fused junction between cartilage and bone is difficult to restore once disrupted, and profound nasal collapse can ensue. While obtaining a straight and symmetric nasal pyramid is a worthwhile goal, aggressive destabilization of the skeletal framework with multiple blunt force osteotomies may not always produce reliable and predictable results. In the severely traumatized nose, alternative techniques such as camouflage (onlay) grafts and/or power-assisted rasping offer a safer and equally effective means of achieving the desired nasal contour.

The Inverted-V Deformity

One of the most common cosmetic side effects of nasal hump reduction is the inverted-V deformity. The inverted-V deformity is a V-shaped shadow produced by a skeletal step-off formed between the wide bony nasal vault and the narrow middle nasal vault (see Figure 12). Formation of a bony-cartilaginous step-off results from either excessive width of the nasal bone remnants and/or pinching of the middle vault cartilage. Although the step-off deformity is a common complication of the overresected nasal hump (since overresected nasal bones can seldom be narrowed sufficiently), the deformity can also be seen in patients with a normal rhinion projection. Patients with normal rhinion projection develop the inverted-V step-off deformity when cartilage hump resection narrows the dorsal septum giving rise to medialization of the ULC remnants. In these patients, the stable bony vault remains wider than the pinched cartilaginous vault producing a disparity in nasal width. The resulting upside down V-shaped shadow disrupts the parallel BTALs producing a discontinuity of the normally continuous sidewall shadows.

Treatment of the inverted-V deformity involves restoration of dorsal height (when appropriate) and elimination of the nasal sidewall width discrepancy. This can be achieved by physically narrowing the bony vault if bony infrastructure is cosmetically acceptable. Alternatively, the cartilaginous sidewall can be repositioned using cartilage augmentation grafts to eliminate pinching of the middle vault.

Spreader Grafts

Perhaps one of the most versatile and important grafts in rhinoplasty is the spreader graft. In addition to restoring ULC width for elimination of the inverted-V deformity, spreader grafts can also be used to straighten a deviated dorsal septum, widen a pinched nasal valve, elongate the short nose, and/or correct minor saddle nose deformities. Fashioned from autologous septal, conchal, or rib cartilage, spreader grafts are long thin strips of cartilage placed in a submucosal pocket alongside the dorsal septum (Figure 48). When placed endonasally, spreader grafts are immobilized by creating a precise longitudinal pocket beneath the upper septal mucoperichondrium. When placed via the external rhinoplasty approach, spreader grafts can be sutured directly to the dorsal septum with mattress sutures at both ends. In patients with weak nasal cartilage who are susceptible to mid-vault pinching, “prophylactic” spreader grafts are used at the time of cartilage hump resection to prevent inverted-V deformities from scar-induced pinching of the ULCs. In revision rhinoplasty, depending upon the deformity at hand, grafts can be applied to one or both parasagittal spaces to provide increases in mid-vault width, improved rigidity or alignment of the dorsal septum, or small increases in height of the dorsal septum. When extended caudally, the spreader graft becomes a septal extension graft capable of elongating the foreshortened nose. Although spreader grafts have numerous cosmetic applications, placement of bilateral spreader grafts will do little to increase nasal valve patency in patients with lateral nasal sidewall collapse since only modest lateralization of the upper nasal sidewall is achieved. However, a variation of the conventional spreader graft, known as the butterfly spreader graft, uses an oval or trapezoid-shaped cartilage onlay graft to lift the collapsed lateral nasal sidewall using the inherent spring of the flexed cartilage graft. The butterfly spreader graft may also be used to augment the middle-vault profile in patients with modest saddle nose deformities.

Dressing

Once the various maneuvers of the surgical procedure are complete and wound closure has concluded, dressing of the nose is performed promptly to restrict swelling and maintain alignment of the delicate nasal framework. Sterile tape is applied across the dorsum and around the lobule followed by a molded plastic or contoured aluminum splint. Blood pressure control is closely maintained and anti-emetic precautions are continued. Ice packs are applied intermittently for 1 to 2 days, and elevation of the head is continued for 2 to 3 weeks. Vigorous exercise, heavy sun exposure, sunglasses, and platelet-inhibiting medications are all avoided for several additional weeks until acute inflammation subsides.

Revision Rhinoplasty

Without doubt, some of the most vexing problems in nasal surgery result from the need for revision rhinoplasty. Severe collapse of the nasal skeleton, often accompanied by symptomatic nasal airway obstruction, can challenge even the most gifted rhinoplasty surgeon. However, even daunting anatomic deformities can be overshadowed by the turbulent emotional issues which attend the patient needing revision. Instead of the promised outcome of an attractive new nose, the patient must first cope with the initial shock and disappointment of a newly acquired physical deformity. Coupled with sizeable investments in time and money, the resulting emotional responses range from shame and embarrassment to anger and distrust of the medical community. Moreover, many patients report serial rhinoplasty failures, having undergone multiple unsuccessful revisions, each one more disfiguring and more disappointing than the last. Not surprisingly, most patients needing revision rhinoplasty are apprehensive and reluctant to risk further nasal surgery without sufficient justification, support, and encouragement.

Sadly, the overwhelming majority of failed rhinoplasties are the result of surgical error, whereas poor healing tendencies account for the remainder. Although an incomplete operative procedure is occasionally responsible for the unsatisfactory outcome, (for example, a residual hump,) overaggressive excision of the nasal skeleton is a far more common cause of the unsatisfactory rhinoplasty result. Indeed, badly misshapen cartilage, gross skeletal asymmetries, and overresected bony remnants are the usual findings in the multiply operated nose. In addition to a paucity of skeletal support, the patient needing revision may also present with severe soft tissue fibrosis, epithelial adhesions, and disfiguring scar contractures compounding the skeletal deficiencies. To make matters even worse, surplus septal or auricular cartilages necessary to graft the collapsed nose are often absent, having been depleted during previous attempts at surgical restoration. Because misguided attempts at surgical repair only magnify the surgical challenge, complex revision surgery should be reserved for the accomplished rhinoplasty surgeon with abundant experience in revision rhinoplasty. For complex

![Figure 48](image-url)
The external rhinoplasty approach is also preferable since it spares the patient from the morbidity of a second operation. Although the nasal septum is prone to trauma in nearly all individuals, deformities of the anterior part of the nasal septum may cause nasal airway obstruction from unsightly skeletal collapse. Augmentation grafts are associated with donor site morbidity and are typically in short supply, the experienced surgeon will use these materials in a creative and sensible manner to conserve tissue and optimize the surgical outcome. Moreover, the effects of preexisting scar tissue must be anticipated, and compensatory measures must be implemented whenever possible to prevent delayed septal distortion from shrink-wrap contracture. Although failed rhinoplasty appears to be a growing problem worldwide, the vast majority of revision patients can be restored to a normal, if not attractive nasal contour, when appropriate reconstructive techniques are undertaken. However, a “perfect” nose is all but impossible, and careful assessment of the deformity, tissue characteristics, healing capacity, and patient motivation are necessary to determine the prognosis for a successful outcome.

Of note, a small minority of revision rhinoplasty patients possesses unusually poor healing characteristics and may experience unfavorable results even when the operation is executed properly. Signs of unfavorable healing response, such as hypertrophic scarring, cicatricial stenoses, ischemic tissue loss, and so forth, should be diligently sought; and, when identified, these patients should be counseled accordingly. On the other hand, patients with favorable healing tendencies have an excellent prognosis when proper surgical technique is combined with abundant and quality graft materials. For this reason, surgical consent for all anticipated graft materials is essential.

SEPTAL SURGERY

Septal surgery is an integral component of both cosmetic rhinoplasty and functional nasal airway surgery. The time-honored adage “as goes the septum, so goes the nose” underscores the importance of correcting septal deformities to achieve a symmetric and cosmetically appealing nasal contour. Because a neglected septal deviation may prohibit proper realignment of the scoliotic nose, septal deformities are best corrected prior to management of the deviated bony vault. The cosmetic rhinoplasty surgeon who is unable to eliminate coexisting septal deformities is severely handicapped; and, because septal deformities often contribute to the unattractive nose, this limitation will frequently compromise the cosmetic result. Septal surgery has been traditionally regarded as a functional discipline, but its mastery is equally important for the cosmetic surgeon.

Because the nasal septum supports both the internal nasal airway and the external nasal framework, deformities of the nasal septum may cause functional disturbances, cosmetic disturbances, or combinations therein. When confined to the internal nasal septum, functional disturbances are usually treated via septoplasty without alteration of the external nasal contour. In contrast, functional disturbances of the septum are frequently accompanied by visible deformities of the outer nose, and rhinoplasty techniques may be required to eliminate both the functional and aesthetic problems. In either case, care must be taken to preserve adequate septal support since an overaggressive septoplasty or an overzealous rhinoplasty can lead to symptomatic nasal obstruction from unsightly skeletal collapse. Although cosmetic and functional disturbances of the septum may occur independently, they are frequently observed in tandem. Since joint cosmetic and functional disturbances are anatomically interrelated, combined treatment with septrhinoplasty typically provides the most effective means of evaluating and eliminating complex septal deformities. Moreover, because reduction rhinoplasty will inevitably diminish breathing space, correction of coexisting airway blockage is sometimes needed to prevent symptomatic nasal airway obstruction arising from a purely aesthetic procedure. Combined treatment is also preferable since it spares the patient from the additional discomfort, down-time, and expense of a second operation. Although the nasal septum is commonly regarded as a functional entity, complex septal deformities almost always affect nasal cosmesis, and correction of external septal deformities usually improves nasal contour. Clearly, septoplasty and rhinoplasty are permanently intertwined, and septal deformities should be regarded as anatomic malformations with variable cosmetic and functional manifestations.

The nasal septum is a skeletal partition that bisects the nasal cavities in the midline sagittal plane. Composed of cartilage anteriorly and the fused vomer and ethmoid bones posteriorly, the nasal septum is an aesthetically prominent and functionally important nasal structure that is often subject to blunt force injury. However, the “normal” nasal septum, found within a healthy nose, is seldom perfectly straight. Minor septal irregularities are typical and should be considered surgically inconsequential provided they create no symptomatic obstruction and produce no external nasal deformity. The exception to this rule is the functionally sensitive nasal valve region where even minor septal deformities can produce significant increases in nasal airway resistance.

The external border of the upper part of the nasal septum, known as the dorsal septum, is also prone to anatomic deformities resulting in columellar asymmetry, nostril deformity, or retraction of the columella. Typically, visible deformities of the outer aspects of the nasal septum are also linked to hidden internal septal deformities that severely constrict nasal airflow. Thus, a thorough endonasal examination is mandatory for all patients undergoing skeletal surgery of the nose.

Symptomatic internal deformities of the nasal septum are common and are known generically as a “deviated septum.” Septal deformities comprise a wide range of anatomic irregularities, including deviations of the bony-cartilaginous junction, dislocation of the quadrangular cartilage from the nasal spine and/or maxillary crest, accordion-like folds within the quadrangular cartilage, cartilage duplications, or spurrs anywhere within the septal partition (Figure 49). Complex obstructing septal deformities are frequently the result of trauma, but childhood growth disturbances, failed surgical manipulation, or combined causes, may also result in septal irregularities. Because septal deformities are sometimes congenital, and because the septum is prone to trauma in nearly all individuals, the exact cause of the deviated septum is often difficult to determine. While comparatively large deformities of the posterior part of the nasal septum are necessary to occlude airflow within the nasal cavum, a comparatively modest deformity of the anterior part of the nasal septum may cause severe nasal airway obstruction. Anterior septal deformities, particularly high septal deviations, obstruct the already narrow internal nasal valve, making the septal deformities the most common cause of nasal valve dysfunction. Despite the importance of anterior septal deformities, their presence is often overlooked on endonasal examination since the obstruction is frequently bypassed upon insertion of the nasal speculum. While the diagnosis of a large posterior septal deformity is comparatively straightforward, the diagnosis of nasal valve narrowing requires...
(speculum-free) inspection of the valve inlet within the posterior part of the nasal vestibule. In addition to deflections of the anterior part of the nasal septum, the season examiner routinely inspects the posterior part of the nasal vestibule for related signs of nasal valve dysfunction such as dynamic nasal sidewall collapse, lateral crusal cartilage recurvature, or cicatricial stenosis of the vestibular epithelium.

**Septoplasty**

In general, septal surgery should conserve skeletal support via the strategic resecting of deviated elements, rather than endanger skeletal support via the reckless excision of vital structural components. Complications of overaggressive septoplasty, such as saddle deformity, columellar retraction, compromised tip support, nasal airway collapse, and septal perforation, are all exceedingly rare when septal support is conserved, but the cavalier excision of essential structural elements is certain to invoke unwanted complications. Care must also be taken to protect blood supply to the septal cartilage by limiting mucosal elevation to a single side whenever possible and by coopting elevated flaps securely to facilitate rapid flap readherence. Nutrient blood supply to the septal cartilage can be temporarily interrupted in the healthy individual with minimal risk of ischemic injury; but the threshold for cartilage resorption is unpredictable, and limited mucosal elevation is a far safer practice.

Corrective septal surgery may be performed via a number of well-known surgical approaches including the direct (Killian) incision, the hemitransfixion incision, or even the external rhinoplasty approach. Each option has inherent pros and cons, and surgeon preference will generally dictate which approach is preferred. Regardless of which approach is selected, the successful septoplasty requires powerful fibroptic illumination and effective vasoconstriction to facilitate direct visualization. Topical anesthetization and decongestion precedes injection of the septal mucosa with a standard solution of 1% lidocaine containing epinephrine. In addition to intensifying the vasoconstriction produced by topical decongestion, the injection serves to “hydro-dissect” (or hydraulically elevate) the injected mucoperichondrium to facilitate rapid and bloodless flap elevation. Once skeletal modifications are undertaken, the skeletal anatomy and the surrounding nasal airway are both repeatedly assessed, since septoplasty is a dynamic process in which each step will often dramatically influence the next.

The simplest technique for minor septal deformities is the direct (Killian) approach, in which an L-shaped mucosal incision is made immediately anterior to the septal deformity for direct access. The septal deviation is then exposed by elevating the overlying mucoperichondrium and/or mucoperiosteum behind and above the L-shaped access incision. Typically the skeletal malformation is then removed with care to preserve the opposite mucoperichondrium; however, shaving, curetting, or morcelizing the deviated segment are acceptable alternatives as long as a flattened septal partition results. Recently, endoscopic elimination of septal spurs has been advocated using powered microdebriders (commonly used for sinus surgery) via a Killian-type incision. While this “minimally invasive” approach to minor septal surgery has several advantages including limited dissection and improved visualization, copious instrumentation is required, rendering this method impractical unless concurrent sinus surgery is planned. Regardless of the method chosen for skeletal correction, care must be taken to avoid or repair opposing mucosal tears to prevent iatrogenic septal perforation. While the direct (Killian) septoplasty is still widely used today, it is only suitable for focal septal deformities involving the central nasal septum, thereby limiting its widespread use. However, for small protrusive spurs, such as those producing mucosal contact headaches or obstruction of the middle meatus, the Killian septoplasty remains an excellent technique.

Perhaps the most commonly used approach for nasal septoplasty is the hemitransfixion approach. This technique employs a unilateral mucosal incision spanning the caudal aspect of the septum for broad surgical exposure. For most surgeons, the hemitransfixion incision is placed within the left nasal vestibule to facilitate right-handed surgical dissection, although some surgeons prefer placing the incision on the concave side of the septal deformity to facilitate easier flap elevation. Mucoperichondrial and/or mucoperiosteal flaps are then elevated until all of the deformities are exposed. Elevation is begun in the submucoperichondrial plane at the leading edge of the caudal aspect of the septum using a flat, semisharp elevator such as a Cottle or Freer. A nasal speculum is also used to keep the partially elevated flap under tension, thereby facilitating both dissection and visualization. A broad-based flap is recommended to enhance exposure and reduce perforation risk, but flap elevation is confined to essential areas to minimize disruption of the blood supply (Figure 50).

Once the correct subperichondrial plane is established, the healthy flap can be quickly elevated using a top to bottom sweeping action with a #10 Frasier suction tip. However, for complex deformities, the dissection is sometimes hindered by the presence of fracture adhesions, cartilage duplications, or severe scarring. In such cases, the stubborn area is encircled from above and below until retrograde dissection can complete the flap elevation. A gain, care is taken to avoid mucosal tears during dissection to minimize perforation risk. The creation of fenestra during flap elevation is not unusual, especially at the apex of sharp deflections or with complicated septal deformities. Small unopposed fenestra can be ignored as they provide an escape route for submucosal blood accumulations, but large fenestrations must be repaired with small caliber absorbable suture to prevent iatrogenic septal perforation, especially if opposing tears are present.

Although a variety of published methods have been described for the elimination of skeletal deviations, excision of the deviated septal segment (known as a submucous resection) provides excellent long-term results as long as adequate structural support is preserved. Typically, this is accomplished by maintaining an outer rim of healthy residual cartilage containing the interconnected dorsal and caudal struts. Collectively, this outer rim forms an L-shaped strut, commonly called the “L-strut” (Figure 51).

As long as a sufficient L-strut is preserved, surplus cartilage can be removed from behind and
beneath the L-strut, whether for septal straightening, cartilage graft harvest, or combinations therein. Since structural integrity of the L-strut will vary according to intrinsic cartilage strength, the L-strut is always kept as wide as possible, particularly with naturally weak or flaccid cartilage, so that adequate long-term structural support is assured. However, in cases where L-strut augmentation grafts (eg, spreader grafts, septal extension grafts) are also used, the additional structural support gained through augmentation grafting may permit safe L-strut width reductions allowing more extensive cartilage removal.

Once septal straightening is complete, the mucosal leaflets must be coapted to prevent septal hematoma and ischemic insult to the exposed cartilage. Typically, this is accomplished with absorbable transseptal quilting sutures and/or with gentle compression using soft septal splints with or without temporary nasal packing material (Figure 52). When quilting sutures are used, nasal packing can usually be removed within 24 hours to restore comfortable nasal breathing.

Perhaps the most challenging septal deformities are those that involve malformations of the septal L-strut (Figure 53). Deformities involving the dorsal part of the septum, anterior septal angle, and/or caudal aspect of the septum are not amenable to submucous resection since structural support to the middle vault, nasal tip, and/or columella would be jeopardized, respectively. To maintain vital structural support provided by the L-strut, alternative techniques to realign and/or reinforce the deformed septum are necessary. For deformities affecting the caudal aspect of the septum, the cause is frequently a vertically overgrown caudal segment or a traumatic deviation of the caudal aspect of the septum. For the overgrown caudal segment, the elongated cartilage is frequently bowed and dislocated from the nasal spine. Treatment involves trimming the posterior septal angle to permit straightening and midline repositioning of the septum. Often a figure of eight suture is used to anchor the newly shortened caudal segment. This approach is commonly known as the “swinging door” technique since the septum is analogous to a swinging door that must be trimmed just enough to clear the metaphorical “septal hinge.”

Correction of the severely deviated caudal septum necessitates bilateral elevation of mucoperichondrium followed by release, repositioning, and fixation of the deviated segment. In rare cases the L-strut may require partial or even complete division at its junction with the dorsal part of the septum to eliminate stubborn angulations occurring at the anterior septal angle. However, complete division of the L-strut destabilizes support to both the dorsum and the columella, and suture reconstitution of the L-strut, with or without onlay graft reinforcement, is required to maintain adequate structural support. A less alternative technique, serial (incomplete) “picket fence” incisions along the deviated L-strut segments may be used to straighten a scoliotic L-strut. While this method can realign a warped or deviated L-strut, the use of multiple incisions may also destabilize the L-strut and lead to persistent deformity. In cases of aggressive L-strut manipulation, septal splints are placed bilaterally and secured with a temporary transfixed suture to serve as bookends and lend temporary support during the first week after the operation.

Although the hemitransfixion approach to the nasal septum can be safely used in conjunction with external rhinoplasty, the nasal septum can also be accessed through the external rhinoplasty approach without the need for a hemitransfixion incision. Instead, the caudal aspect of the septum is exposed in a submucosal dissection plane by separating the membranous septum via the trans-columellar incision. For removal of large septal cartilage grafts or bone fragments, the ULC must be divided from the dorsal septum to create satisfactory egress. Because this approach demands considerable dissection within the columella and membranous septum, it is not suitable for all patients. Nevertheless, the external rhinoplasty approach is an excellent alternative for patients with complex deformities of the L-strut since exposure of the nasal base is optimized.

**CONCLUSIONS**

Rhinoplasty is a complex and demanding operation with many intriguing peculiarities. While the dedication required to achieve mastery in rhinoplasty is formidable, transformation of the human nose from a missshapen appendage to an attractive facial attribute is a uniquely gratifying experience. For the beginner, mastery of nasal analysis and relentless self-assessment will pave the way for a long and rewarding career in nasal surgery.

Nasal Reconstruction
Shan R. Baker, MD

Over the last decade, reconstruction of the nose has reached a high level of sophistication with enhancement of aesthetic results.\textsuperscript{1,2} This has been achieved by emphasizing the need to replace surgically ablated tissue with like tissue. Skin is replaced with skin that matches in color and texture as closely as possible. Cartilage and bone are replaced and mucosa is used to replace any loss of the nasal lining. The concept of nasal aesthetic units has emerged with an emphasis on reconstructing an entire unit, if the majority of the unit is missing. Another important concept that has led to enhancement in the results of restorative surgery of the face has been the emphasis on the placement of incisions for local flaps along borders of aesthetic regions or units to maximize camouflage of scars. Whenever possible, local flaps are designed so that they are not transferred across the borders of aesthetic regions, particularly if the border has a concave topography. An example of such a border is the alar facial sulcus which represents a concave border between three aesthetic facial regions: the nose, the cheek, and the upper lip.\textsuperscript{3,4}

FACIAL AESTHETIC REGIONS

The face can be divided into topographical regions, each with its individual intrinsic characteristics of skin color, texture, contour, and hair growth.\textsuperscript{5,6} Each has an individual shape created by the underlying facial skeleton. The nose is one of the aesthetic regions of the face and can be divided into several aesthetic units (Figure 1). Each unit may be proportionally over- or under-developed relative to other noses, but there is a consistent general configuration from nose-to-nose.\textsuperscript{3} There are nine aesthetic units of the nose identified by distinctive convex or concave surfaces, including the tip, dorsum, paired sidewalls, paired alae, paired nasal facets, and the columella. In general, the shape of the nasal tip is determined, by the size and contour of the alar cartilages, and specifically by the domal portion of the alar cartilages. It is covered by relatively thick sebaceous skin. The skin of the dorsum tends to be less thick and sebaceous than the tip, becoming progressively thinner as it ascends to the rhinion and thickens again as it approaches the glabella. The nasal bones together with the upper lateral cartilages and cartilaginous septum provide skeletal support for the dorsum. The nasal sidewalls are most often a combination of convex and concave elements extending laterally from the dorsum to the junction of the nose with the cheek. Structurally, the sidewalls are supported by the nasal bones, and upper lateral cartilages, and the medial extensions of the frontal processes of the maxillae. The skin of the sidewalls is thin and less sebaceous than that of the dorsum and tip. Inferiorly, the skin of the sidewall becomes progressively thicker. The alar unit is covered with thick sebaceous skin similar in texture and porosity to the skin of the tip and adjacent superior melolabial fold. The structural support of the ala is provided by thick fibrofatty tissue which does not contain cartilage.

The soft tissue facets contribute to a portion of the nostril margin and span the arch between intermediate and lateral crura of each lower lateral cartilage. They are covered by thin, nonsebaceous skin and have only a small amount of fibrous connective tissue for structural support. The columella, like the tip and dorsum, is a non-paired aesthetic unit extending from the inferior aspect of the infratip to the upper lip. It is covered by the thinnest of nasal skin and structurally is supported by the medial crura. The lining for each of the nine aesthetic units of the nose is also distinctive.\textsuperscript{2} Thin nonhairbearing skin lines the tip, while the nasal facets and alae are lined by thicker skin, the caudal aspect of which is hair bearing. The columella is backed by the membranous septum, which is covered by thin nonhair-bearing skin. At the piriform aperture, the lining transitions to mucosa which lines the dorsum and sidewall units.

Menick has stressed that the goal of restorative nasal surgery is not simply to fill a defect.\textsuperscript{2} Depending on the extent of the defect; wounds should be altered in size, configuration, and depth to allow reconstruction of an entire unit. If the majority of the surface skin of a unit is lost, resurfacing the entire unit is usually preferable. This is accomplished by discarding the remaining skin of the unit and designing the flap used to resurface the defect so it will compensate for the discarded skin. This arrangement places the scars in the junction between units where they will lie in depressions or along shadow lines, maximizing scar camouflage. By placing the scars in these junctions, they tend to blend with the normal contour lines of the nose and will not distract the viewing eye. Menick has noted that resurfacing the entire unit also takes advantage of the mild trap door scar contraction phenomenon, which causes the entire unit to bulge slightly, simulating the normal convexity of the tip, dorsum, and alae.\textsuperscript{2} However, more important than resurfacing...
an entire nasal unit is the creation of the proper contour of the covering flap so that it exactly replicates the normal topography of the unit.

The surface area and pattern of each nasal aesthetic unit should be restored as accurately as possible. Because the nose is a three-dimensional structure, each reconstructed unit must duplicate normal contour. This is accomplished by concomitantly integrating structural support in each step of the repair. Reconstructed skeletal elements must be attached to a stable foundation such as remaining nasal cartilages or the bone of the maxilla. This will prevent collapse or distortion during the healing process.\(^1\) When a nasal defect is full thickness; nasal lining is replaced with mucoperichondrium from the septum or mucosa of the turbinates when possible. Similar to surface defects, lining defects are repaired with tissue that has the same surface areas as the defect. Application of the nasal aesthetic unit principles provides a logical cognitive approach to nasal reconstruction. Missing tissue is replaced with like tissue in a quantity and quality that exactly replicates the pattern, surface area, and contour of the absent unit.

### LINING FLAPS

Burget and Menick have described a bipedicled flap of vestibular skin and mucosa based medially on the septum and laterally on the floor of the nasal vestibule.\(^1\) Such a flap can be elevated off of the undersurface of the lateral crus and mobilized inferiorly to resurface the lining of the absent unit. In instances of alar reconstruction, this is required in order to support the nostril rim and prevent migration upward of the nostril margin during wound healing (Figure 5).\(^2\) In instances of alar reconstruction, this usually means employing a cartilaginous strip that spans the distance from junction of the alar base with the cheek to the region of the nasal facet, even though the alae do not normally contain cartilage. This is required in order to support the nostril rim and prevent migration upward of the nostril margin during wound healing (Figure 5).

The function of the grafted framework is to provide contour and maintain a patent airway. Framework grafts are used at the time of initial reconstruction and consist of grafts which, as nearly as possible, replicate the exact size, shape, and contour of the missing framework. When covered by a thin, conforming cutaneous flap, the contour of the framework is distinctively

**Figure 2** (A) Unilateral septal mucoperichondrial hinge flap developed by incising mucosa and perichondrium along floor of nose and 1.5 cm below and parallel to the cartilaginous dorsum. Parallel incisions are connected to the vertical posterior incision over the bony septum. (B) Flap is dissected from superior to inferior and from posterior to anterior. Anterior dissection remains 1 cm posterior to caudal border of septum and 1.5 cm posterior to nasal spine. (C) Hinged on the caudal septum, the flap is reflected laterally to line the caudal nasal vault. (D) Cartilage graft provides nasal framework. Lining flap secured to framework with a few mattress sutures. (Reproduced with permission from reference 6.)
manifested and produces a normal appearing restoration of the missing part. Framework grafts fix in place the soft tissues used in nasal repair by virtue of providing skeletal support for both lining and cover.

Bone and cartilage are the tissue grafting materials available to the surgeon for replacing the framework of the nose. The framework of the nasal dorsum may be replaced with bone or cartilage. Cranial bone grafts are the preferred material for more cephalic skeletal defects and are anchored to the frontal bone with miniplates. Limited caudal dorsal skeletal defects are best replaced with septal or auricular cartilage when available. When the entire dorsum is absent, costal cartilage is the preferred grafting material. The dorsal framework prevents cephalic contraction and subsequent shortening of the nose. It also provides shape and projection to the bridge.

The framework of the sidewalls can be replaced with septal bone and cartilage or cranial bone contoured into a trapezoid shape and fixed to the dorsum and maxilla. Costal cartilage may also be used. Sidewall skeletal grafts support the middle vault and prevent collapse. They also serve as a

covering flaps

Small defects of the nasal skin 2 cm or less in size can sometimes be repaired with local flaps harvested from the remaining nasal skin, if there is sufficient redundancy of the skin. Most notable of the local flaps is the bilobe flap as modified by Zitelli. The bilobe flap was originally designed for repairing nasal tip defects. Each lobe of the flap and the defect were separated by 90° for a total transposition over a 180° arc. Whereas this recruited skin is at some distance from the defect, it also maximized the standing cutaneous deformities (SCDs) and the likelihood of development of a trap-door deformity or pinching of both the first and second lobe of the flap. Zitelli emphasized the use of narrow angles (45° angles) between lobes so that the total arc of tissue transferred occurs over no more than 90 to 100°. This flap design reduces the SCD and pinching effects. Bilobe flaps are double transposition flaps which transfer the wound closure tension from the defect through a 90° arc to the donor site areas. A major disadvantage of using the bilobe flap to repair nasal skin defects is the formation of extensive incisional scar that does not fall along borders of nasal aesthetic units. However, postoperative dermabrasion is very helpful in obscuring the scar.

Whenever possible, the nasal bilobe flap is designed laterally. Medial-based flaps are hard, although the vascular supply is not as abundant as those based laterally. Bilobe flaps are ideally suited for repairing defects less than 1.5 cm in maximum dimension, located on the central or lateral nasal tip and without extension to the ala. Ideally, the defect should be at least 0.5 cm superior to the margin of the nostril. The flap recruits skin from the mid and upper dorsum and sidewall, where more generous skin laxity is present. Defects of the cephalic one-half of the nose are not well suited for reconstruction with a bilobe flap unless they are 0.5 cm or less in size. This is because bilobe flaps harvested in this area necessitates use of skin from the region of the medial canthus, which is thin and immobile. Bilobe flaps are most useful in patients with thin skin and an ample degree of skin laxity along the nasal sidewall. The surgeon may estimate laxity by pinching the lateral nasal skin between the thumb and index finger. Patients with thick sebaceous skin have a higher risk of developing flap necrosis, trap-door deformity, and depressed scars.

Bilobe flaps of the nose must be geometrically precise and are designed using the following method (Figure 6). The radius of the defect is measured. For laterally based flaps, a point lateral to the border of the defect is marked in the alar groove that is the distance of the length of the radius. This point is used for designing both lobes of the flap. Two arcs are drawn with their centers at the marked point. The first arc passes through the center of the defect, and the second makes a tangent with the border of the defect most distal to the point. Calipers and rulers are not used to draw the arcs because these devices measure straight-line distances. In contrast, the topography of the nose is convex in the area of the tip and dorsum. Therefore a flexible measuring device is used. A needle with an attached suture is passed full-thickness through the nose at the point marked in the alar groove. A knot is tied in the suture inside the nasal vestibule. The suture is draped from the point across the defect, and a clamp is applied to the suture at the center of the defect. The clamp with attached suture is then rotated about its pivotal point to indicate the first arc, which is marked with a pen. The clamp is advanced along the suture to the most peripheral point of the defect, and a second arc is drawn tangent to the peripheral border of the defect and parallel to the first arc. The base of the two lobes rests on the first arc. The height of the first lobe extends to the second arc so its height is equal to the distance between the two arcs. The width of the first lobe is equal to the width of the defect. The width of the second lobe is slightly less than the width of first lobe. The height of the second lobe is approximately 1.5 to 2.0 times greater than the height of the first lobe. The first lobe has the configuration of the defect, and the second lobe is triangular. The linear axis passing through the center of each lobe is positioned at approximately 45° from each other, with the axis of the first lobe positioned 45° from the central axis of the defect. This orientation of the lobes inevitably positions the axis of the second lobe along the center of the nasal sidewall or diagonally at the junction of the sidewall with the dorsum. The design also creates a triangular peninsula of skin between each lobe with a 45° angle. A triangle representing the eventual SCD resulting from the pivot of the first lobe is marked with its apex pointing laterally and one side parallel to or in the alar groove. The base of the triangle is the lateral border of the defect, and the height of the triangle is equal to the radius of the defect.

The flap is elevated after local anesthetic is injected. Like other nasal cutaneous flaps, it is dissected in the tissue plane between the nasal muscles and underlying perichondrium and periosteum. The flap and the remaining skin of the entire nose are completely undermined, sometimes extending the dissection into the cheek a short distance. Wide peripheral undermining of all the nasal skin is essential to reduce wound closure tension, facilitate flap transfer, and minimize trap-door deformity (Figure 7). The donor site for the second lobe is closed first by primary approximation of the muscle layer. The first lobe is then transposed to the nasal defect and secured with a few deep dermal sutures. Next, the SCD is removed in or cephalad and parallel to the alar groove. The second lobe is transposed, trimmed of its excess height so that it fits snugly without redundancy in the donor defect of the first lobe.

subcutaneous tissue pedicle

mechalial interpolated flap

The ala is best resurfaced with cheek skin from the area of the melolabial fold. The sebaceous quality of the skin of the fold closely resembles that of the ala. Menick has noted that as melolabial flaps contract, they become rounded resembling the...
is a lengthy period for the patient to endure the initial transfer to the nose. Although 3 weeks time of pedicle detachment and flap inset. This delay reduces the wound tension on the flap at the time of initial transfer.

A fashioned template of the ala or defect, if it extends beyond the ala, is placed on the melolabial fold so that the center of the template is positioned slightly above the horizontal plane of the oral commissure. The template is positioned so that the medial border of the designed flap lies in the melolabial crease. This arrangement insures that the flap is harvested from the cheek, not from the lip, and that the donor site wound closure will lie within the melolabial crease, providing maximum scar camouflage. The flap is designed to pivot 90° toward the midline in a clockwise direction when harvested from the left cheek and counterclockwise when harvested from the right cheek. Thus, the template is positioned to design the flap with a specific orientation. As the flap is pivoted and transferred to the recipient site, the medial border of the in situ flap is sutured to the cephalic border of the nasal defect. This in turn causes the inferior border of the in situ flap to join the anterior border of the defect. The lateral border of the in situ flap becomes the inferior border of the reconstructed ala.

A tracing is made around the template. A triangle of skin is marked superior and inferior to the tracing in order to fashion a crescentic island of skin. The two triangles extending from the template tracing represent SCDs that will form when the cheek donor site is closed. The inferior triangle of skin is excised and discarded at the time of flap transfer, and the superior triangle of skin is transferred with the flap and is excised and discarded at the time of pedicle detachment and inset of the flap. The superior triangle of skin is minimized to reduce loss of tissue from the superior melolabial fold where the fold is well developed. Removing skin from the superior portion of the fold may result in considerable asymmetry of the medial aspects of the cheeks.

The flap is incised, and the distal portion is elevated in the subcutaneous plane. The distal third of the flap is thin, leaving 1 to 2 mm of subcutaneous fat attached to the undersurface. As the dissection proceeds superiorly, the plane of dissection extends deeper to facilitate development of the subcutaneous tissue pedicle. The pedicle of fat is freed from the surrounding cheek fat by incising through borders of the pedicle perpendicularly to the surface of the skin. The depth of the incision is carried to the level of the superficial surface of the zygomatic major and levator labii muscles. On reaching the zygomatic major muscle, blunt dissection continues upward on the surface of the muscle, releasing the attachments of the pedicle to deeper structures until the flap can reach the recipient site without undue tension. To aid in reducing tension, it is sometimes helpful to place a 4-0 polypropylene suture between the superior skin edge of the donor incision and the alar base. This has the effect of pulling the pedicle upward toward the ala without the need to place additional traction on the subcutaneous tissue pedicle. The suture is released when the pedicle is divided at the time of flap inset.

To close the donor wound following transfer of an interpolated cheek flap, the skin adjacent to the incision is undermined peripherally for a distance 2 cm in the superficial subcutaneous tissue plane, and the SCD that develops inferiorly from advancement of wound margins is removed. Depending on the shape of the flap, the lateral border of the donor site may be considerably longer than the medial border. If this is the situation, it may be necessary to excise an additional SCD (Burow’s equalizing triangle) at right angles to

Figure 6 (A) and (B) Suture rotated about pivotal point used to mark two arcs for design of bilobe flap. (C) and (D) Width of defect equals width of first lobe. (Reproduced with permission from reference 9.)

contour of the normal ala. Skin of the melolabial fold is limited, and its use can flatten the fold causing marked asymmetry of the face. Nor can it easily be transferred to the nasal tip or dorsum. Skin of the melolabial fold is transferred to the ala as an interpolated flap, the pedicle of which crosses over but not through the alar facial sulcus. The pedicle is superiorly based and may consist of skin and subcutaneous fat or subcutaneous fat only (Figure 8). It is detached from the cheek 3 weeks after the initial transfer to the nose. Although 3 weeks is a lengthy period for the patient to endure the deformity caused by the flap, this interval allows the surgeon to defat aggressively and sculpture the flap both at the time of the flap transfer and at the time of pedicle detachment and flap inset.

When reconstructing the ala, the entire ala is resurfaced with the cheek flap, except for 1 mm of alar skin just anterior to the alar facial sulcus. This small skin tag preserves the alar facial sulcus and often provides a better scar than when the flap extends to the sulcus. This approach is similar to the method recommended by Sheen and Sheen for performing a type II Weir excision to reduce the size of the nasal base. Maintaining the excision outside of the alar facial sulcus lessens the risk of developing a depressed scar. This approach also avoids the technically challenging requirements of integrating the flap into the nasal sill at the time of flap inset. When using cheek flaps for repair, I often delay excising the extreme lateral portions of the residual alar skin until the time of pedicle detachment and flap inset. This delay reduces the wound tension on the flap at the time of initial transfer.

A fashioned template of the ala or defect, if it extends beyond the ala, is placed on the melolabial fold so that the center of the template is positioned slightly above the horizontal plane of the oral commissure. The template is positioned so that the medial border of the designed flap lies in the melolabial crease. This arrangement insures that the flap is harvested from the cheek, not from the lip, and that the donor site wound closure
the axis of the melolabial wound closure. This is accomplished at the inferior pole of the wound.

Cheek flaps are detached 3 weeks following transfer. For subcutaneous tissue pedicled flaps, the pedicle is transected at the base, and the cheek skin is undermined for a distance of 2 cm around the periphery of the amputated pedicle. After freshening the skin margins with a scalpel, the wound is closed by advancing the borders together. As this is accomplished, it is usually necessary to open the superior end of the donor site scar to facilitate excision of redundant subcutaneous tissue and a small SCD that often forms as the wound margins are approximated.

The lateral portion of the flap attached to the nose is released from attachments to the adjacent nasal skin for a distance of 0.5 to 1.0 cm to achieve sufficient freedom to unfurrow the flap. Release enables the surgeon to remove excessive subcutaneous fat not trimmed at the time of flap transfer. The residual skin of the alar facial sulcus is preserved. The flap is precisely trimmed to fit the skin defect and sutured in place. When the alar base is absent, the flap is tailored to replace the missing base and is integrated with the nasal sill. When the sill requires reconstruction, the flap is trimmed so that it has a tapered end that may serve as the sill. The end is turned medially and sutured to the upper lip.

**CUTANEOUS PEDICLE MELOLABIAL INTERPOLATED FLAP**

In most of the cases, I prefer to design cheek flaps on a subcutaneous tissue pedicle because this design limits the quantity of skin in the superior aspect of the melolabial fold that is included in the flap or excised to facilitate closure of the donor site. The island design has a greater freedom to pivot on its pedicle and may have a better blood supply by incorporating within the pedicle of the flap a greater number of perforating vessels arising from the angular artery. The pedicle of the island flap does not require tailoring and inset following detachment of the flap. The subcutaneous pedicle is simply excised, and the skin edges surrounding the pedicle are freshened and the wound closed primarily. However, harvesting the island flap is technically more difficult than harvesting a cutaneous pedicle flap because the plane of dissection is considerably deeper, placing the branches of the facial nerve supplying the zygomatic major and minor muscles at greater risk of injury.

A cutaneous pedicle interpolated melolabial flap is a peninsular flap with a linear axis centered on a cutaneous pedicle that connects the flap to the cheek. This is in contrast to the subcutaneous tissue pedicle (island) flap, which does not

Figure 8: (A) Full thickness defect of ala that does not extend cephalically more than 1.5 cm may be lined by bipedicle advancement vestibular skin flap based medially on septum and laterally on floor of nasal vestibule. Extended intercartilaginous incision necessary to develop flap. (B) Bipedicle flap advanced caudally and donor site covered with thin full thickness skin graft. (C) Remaining skin of ala discarded (arrow). A uricartilage provides structural support to nostril margin. have a cutaneous pedicle and is connected to the cheek by subcutaneous fat. Whether a peninsular or island flap, the pedicle is developed at the superior aspect of the melolabial fold.

The peninsular flap depends on the dermal and subdermal vascular plexes of the cutaneous pedicle to provide vascularity to the distal flap. The cutaneous pedicle must have sufficient width and depth to ensure this vascularity. When designing a peninsular flap, the orientation of the template remains the same as for designing an island flap. The width of the cutaneous pedicle is approximately the width of the template, although it may be narrower than the template when a wide (more than 2 cm) flap design is required. The peninsular flap is elevated in a subcutaneous tissue plane, maintaining 3 mm of fat on the undersurface of the cutaneous pedicle. This is in contrast to the island design, based on a subcutaneous tissue pedicle that may be as much as 1.5 cm thick. Thus, the plane of dissection for the cutaneous pedicle flap is considerably more superficial. Like the island flap, the peninsular flap pivots 90° toward the midline and is sutured to the nose in a similar fashion. Care is taken not to kink the pedicle on transferring the flap. Like the island flap, the distal half of the peninsular flap may be thinned as necessary to replicate the thickness of the recipient site. The proximal portion of the flap bridging between cheek and nose is not thinned to insure a sufficient vascular supply.

Similar to the island flap, the peninsular flap remains attached to the cheek for 3 weeks to enable the establishment of collateral vascularity. The pedicle is divided at a second stage, and the proximal portion of the pedicle is inset in the cheek by opening the superior portion of the donor site scar 1 to 2 cm. The wound edges are spread widely, creating a space to accommodate the proximal pedicle. The skin adjacent to the opened wound is undermined for 2 cm. This allows the cheek skin to retract, assisting in enlarging the wound. The pedicle stump is then trimmed to fit the wound precisely and inset in the melolabial fold, creating a V-shaped wound closure. Returning most of the skin of the proximal pedicle to the cheek helps maintain the natural fullness observed in the upper portion of the melolabial fold. Alternatively, the proximal pedicle may be amputated in an elliptical configuration, and the cheek wound closed primarily. This has the advantage of a linear donor site scar within the melolabial crease. The distal portion of the flap left attached to the nose is thinned and inset using methods similar to those for the island flap. Less aggressive sculpturing of subcutaneous fat from the flap is recommended both at the time of flap transfer and at the time of flap inset for patients who use tobacco products.

**PARAMEDIAN FOREHEAD FLAP**

A number of studies of the vascular anatomy of the forehead have been reviewed by Baker and Alford. These studies confirm that the supratrochlear artery is the primary axial blood supply of midforehead flaps, which include the median and paramedian vertically oriented flaps. Additionally, the studies have shown that in the medial canthal region a rich anastomotic network exists among the supratrochlear, supraorbital, and angular arteries. Identification of this vascular network and the surgical techniques of flap harvest that preserve this regional blood flow have allowed surgeons to harvest paramedian forehead flaps based on pedicles narrower than those used for medial forehead flaps. The narrower pedicle enables the flap more freedom to rotate about its pivot point, and therefore provides more effective flap length. At the same time, this design reduces the donor site deformity in the glabellar area which results from the transfer of the flap. When the paramedian forehead flap is based on the supratrochlear artery and its anatomoses to surrounding vessels, the flap is an axial pivotal interpolated flap with an abundant blood supply that allows transfer without delay.

The paramedian forehead flap may be designed with the assistance of a Doppler probe to localize the supratrochlear artery, but the author has not found this to be necessary. The base of the pedicle is usually centered over the supratrochlear
artery on the same side as the majority of the nasal defect for which the flap is intended for repair. The vertical axis of the supratrochlear artery is 2 cm lateral to the midline, which corresponds to the medial border of the eyebrow. Therefore, the base of the flap is centered over the medial border of the eyebrow. The width of the pedicle is designed 1.5 cm wide and is not flared as this restricts the pivotal movement of the flap.

The cutaneous defect is outlined by squaring off the corners of the defect with a skin marker. Giving the defect angular rather than curvilinear borders reduces the propensity for developing a trap-door deformity. If the defect occupies more than 50% of the surface area of a given nasal aesthetic unit, the remaining skin of the unit is marked for removal. When a unilateral cutaneous defect encompasses one-half or less of the surface area of the nasal tip, the defect is usually enlarged only to the degree that the enlargement creates a hemi-tip defect. This will limit the size of the forehead flap necessary for reconstruction which in turn, minimizes the deformity of the forehead. The aesthetic result of resurfacing a hemi-nasal defect with a paramedian forehead flap is equally pleasing as resurfacing the entire nasal tip.14

The nasal dorsum is an exception to the rule of resurfacing the entire nasal unit when the defect occupies one half or more of the surface area of the unit. When cutaneous defects occur on the dorsum, the thin skin of the rhinion is never removed unless required for tumor ablation.14 In most patients; the intrinsic thickness of forehead skin is greater than that of the native skin covering the rhinion. Even with removal of all the subcutaneous tissue from a forehead flap, the thickness of the flap may not match the thinness of the intact skin and muscle of the rhinion. In this region, contour outweighs the advantage of placing the borders of the flap along the junction of aesthetic units. It is wise to leave this skin intact and resurface only the caudal dorsum than resurface the entire dorsal nasal aesthetic unit.

Similar to the rhinion, the skin of the nasal facies is delicate and thin. It is supported only by fibroconnective tissue. Forehead skin cannot replicate the delicate nostril margin in this area of the nose. Nasal tip defects requiring a forehead flap as a cover should be enlarged only to a line along the superior border of the facet. This line corresponds to the caudal border of the intermediate crura of the lower lateral cartilages.

A three-dimensional template exactly duplicating the surface area and contour of the region to be resurfaced is fashioned from a foil or a thin sheet of foam rubber. The author prefers foam rubber because it has the flexible qualities of skin and easily conforms to the convex and concave contours of the nasal topography.14 The final defect to be resurfaced is marked on the nasal skin, outlining additional skin removal to square off the defect or to remove the remaining cutaneous portions of the aesthetic unit. The template is designed before the defect is enlarged because once the additional skin is removed the wound will spread and the defect will appear larger than it is. For this reason, if the nasal defect involves an aesthetic unit that has an intact counterpart, the intact unit is used to design the template because it will give a more accurate measurement of surface area. The template is then reversed to design the flap. When the defect involves an aesthetic unit that is unpaired, the template is designed as an ideal size for the specific patient. When dealing with large surface defects, it is helpful to suture the rubber foam template to the margins of the defect to assist with fashioning the template more precisely. Cartilage grafts are required to replace missing framework, and the template is designed after the grafts are in place.

The template is used to design the flap on the forehead skin. The center of the template is positioned approximately 2 cm lateral to the midline. At a minimum, the upper border of the template is positioned at the frontal hairline unless the patient has a receding hairline or frontal balding. The length of the flap is measured by a length of suture extending from the distal end of the positioned template to the level of the medial eyebrow. Holding the forehead skin, the suture is rotated 180° in the coronal plane toward the midline to the most distal recipient site on the nose. If the suture does not reach this point, the template must be repositioned higher on the forehead, or the pedicle must be lowered by extending it below the level of the eyebrow. By using this method of determining flap length, a decision can be made concerning the necessity of placing a portion of the template over hair-bearing scalp. The flap is then precisely outlined on the forehead with a skin marker, following the exact shape of the template.

Paramedian forehead flaps are usually dissected using local anesthetic and intravenous sedation14 (Figure 9). One percent lidocaine with 1:100,000 concentration of epinephrine is injected circumferentially and deeply about the surgical defect. The skin along the entire length of the supraorbital bony rims is infiltrated to the level of the periorbital septum. Particular attention is given to a broad vertical band of skin in the axes of the supratrochlear and supraorbital nerves. The anesthetic is injected into the subcutaneous tissue plane because this is the location of the nerves and vessels supplying the forehead skin. The base of the flap and skin over the root of the nose are also injected. Intravenous dolasetron mesylate is administered to control postoperative nausea commonly associated with the procedure. To avoid oversizing the flap, incisions are made inside the lines of the designed flap. The flap is incised through the skin, subcutaneous tissue, muscle, and fascia. The flap is elevated from superior to inferior in the subfascial plane, just superficial to the periorbitalseptum of the frontal bone. Rapid dissection may be performed in this plane until the corrugator supercilii muscle is encountered, at which point the muscle is dissected away from the underlying periosteum bluntly with scissors or a periosteal elevator. If it is necessary to extend incisions of the pedicle below eyebrow level, it is accomplished with a scalpel cutting through skin only. Blunt dissection by spreading tissue with a hemostat is then performed to mobilize the pedicle away from the medial bony orbit. The supratrochlear artery may sometimes be visually identified in the area on the deep surface of the frontalis muscle just as it exits over or through the corrugator supercilii muscle and before passing deep to the orbicularis oculi muscle to enter the orbit. A dequacket flap mobilization usually requires complete sectioning of the corrugator muscle to achieve sufficient flap length. Blunt and sharp dissections are used to continue flap elevation downward into the root of the nose or until sufficient pedicle length and flap mobilility have been attained to allow tension-free wound closure. Hemostasis along the border of the flap is achieved with electrocautery applied judiciously.

The forehead flap is covered with a damp sponge and reflected downward to allow repair of
the donor site. Donor site closure is accomplished by extensive undermining of the forehead skin in the subfascial plane from the anterior border of one temporalis muscle to the other. A few parallel vertical galeatomies 2 to 3 cm apart may be made to facilitate primary repair of the superior portion of the donor site if the donor defect is large. Galeatomies should be made just through the galea to the level of the muscle and removed from the vertical corridor of the supraorbital and supratrochlear nerves. The deep branch of the supraorbital nerve can readily be seen through the galea as it travels superiorly just medial to the temporal line, and it should be protected when performing galeatomies.

Horizontal incisions along the hairline to facilitate closure of the donor site are not performed. This would increase anesthesia of the anterior scalp by cutting through the distal branches of the supraorbital nerves and create an additional visible scar on the forehead. As the wound edges are advanced, a SCD of scalp tissue occurs at the superior apex of the flap donor site defect. This is excised completely by extending an incision sufficiently superiorly in the scalp to enable excision of the tissue cone.

The forehead donor site wound is repaired before the flap is sutured in place. The thickness of the flap is tailored by thinning the distal portion. This usually requires removal of the muscle and most of the subcutaneous fat in order to match the depth of the nasal defect. When necessary, all but the subcutaneous fat immediately attached to the dermis may be removed. If the vertical height of the nasal defect is less than 2 cm, the portion of the flap covering the entire defect may be thinned at the time of initial transfer. For larger defects, the proximal flap covering the more cephalic portion of the defect is left with all of its muscle and subcutaneous fat intact and is thinned at the time of pedicle division. If necessary, the muscle and galea may be removed from the entire length of the flap beginning 1 cm superior to the point at which the supratrochlear artery pierces the frontalis muscle. Any hair follicles transferred with

the flap should be individually cauterized with a fine-pointed electric cautery or removed manually. The distal flap, appropriately thinned, will be sufficiently supple and thin to conform to the nasal framework and manifest its contour.

After thinning, the flap is pivoted either clockwise or counterclockwise in an arc toward the midline and reflected downward toward the nasal defect. The distal flap is sutured in position with interrupted vertical mattress cutaneous sutures. Deep dermal or subcuticular sutures are not used. Following placement of vertical mattress sutures, a single running 5-0 fast absorbing plain gut suture on a fine-tipped needle is used to precisely approximate the epidermis by placing the suture in the superficial plane of the skin.

Pedicle separation is accomplished under local anesthesia 3 weeks following initial flap transfer (Figure 10). One percent lidocaine containing epi-nephrine is injected into the base of the pedicle and circumferentially around the flap where it attaches to the nose followed by the usual sterile preparation and draping. The pedicle is separated with a scalpel at the superior margin of the defect.
Figure 12  (A) Patient with a 1.5 x 1.5 cm deep skin and soft tissue defect of ala. (B) Remaining alar skin marked for resection. Interpolated subcutaneous tissue pedicle melolabial flap designed for external cover. Proximal and distal horizontal lines represent standing cutaneous deformities (SCDs) that will form as donor site is closed. Distal SCD excised at time of wound closure. (D) Flap based on subcutaneous tissue pedicle. (E) Flap resection. Interpolated subcutaneous tissue pedicle melolabial flap designed for external cover. Proximal and distal horizontal lines represent standing cutaneous deformities (SCDs). (F) Three weeks following flap transfer. (G) Immediately following flap inset. (H) Seven months postoperative.

Typically, the medial aspect of the eyebrow on the flap side is displaced inferiorly as a result of secondary movement from flap transfer. The brow must be mobilized sufficiently to correct misposition. This is accomplished by converting the proximal pedicle of the flap into a small triangular flap incorporating in its base the medial aspect of the eyebrow on the donor side. To accommodate for scar contraction and inferior migration of the eyebrow during healing, the flap is mobilized upward until the level of the horizontal axis of the medial aspect of the eyebrow on the flap side is positioned 2 mm above the level of the horizontal axis of the opposite eyebrow. Pedicle tissue should not be returned to the forehead beyond what is required to position the donor side eyebrow properly. Excess pedicle tissue above the portion of the triangular flap necessary for securing the medial eyebrow in proper position is resected and discarded. To facilitate superior advancement of the triangular flap, and thus the medial aspect of the eyebrow on the donor side, it is sometimes necessary to excise a small crescent or triangular segment of skin just lateral to the base of the flap along the superior medial border of the eyebrow.

DEFECTS EXTENDING BEYOND THE NOSE

Cutaneous defects that involve the nose and significant portions of the medial cheek or upper lip are reconstructed in stages. The first surgical stage is directed toward repair of the cheek and lip to provide a stable foundation for subsequent reconstruction of the nose. The surgical plan of first restoring the foundation on which to place the constructed nose, before initiating nasal reconstructive flap, is used whenever a sizeable full thickness defect of the cheek or lip is associated with a full thickness nasal defect. For example, when there is a full thickness loss of the ala or columella and adjacent upper lip, it is prudent to delay reconstruction of the nose until the lip is repaired and scars have contracted to their maximum propensity.

In contrast to full thickness nasal defects, defects of the nose which are not full thickness and which extend into the lip or cheek can usually be reconstructed concurrently. This is because there is less scar contracture surrounding the nose during the healing stages compared with repair of full thickness nasal defects. Thus there are fewer problems with distortion of the construct segments of the nose. Keeping with the principle of repairing each portion of a defect involving multiple facial aesthetic regions with an independent covering flap, individual flaps are used to reconstruct the cheek, nose, and lip if all three aesthetic regions are involved by the defect. The most common circumstance leading to defects involving the nose, lip, and cheek are skin malignancies arising from the ala and extending into the alar facial sulcus with subsequent growth into the medial cheek and upper lip. A nother common circumstance is for the malignancy to arise from the nasal sidewall and extend across the nasal facial sulcus into the medial cheek. The cutaneous defect resulting from resection of this type of neoplasm should be reconstructed with two independent flaps. In such instances, the cheek defect is typically reconstructed with a cheek advancement flap. The flap is advanced medially to the nasal-facial sulcus. The leading border of the flap is secured to the periosteum of the ascending process of the maxilla to prevent the flap from migrating laterally during the healing process. The cheek flap is secured in place first before designing a template for the paramedian forehead flap which is used to resurface the nasal sidewall. If periosteal sutures are inadequate to hold the advancement flap in place, holes are drilled in the exposed bone along the pyriform aperture. These holes are used for anchoring sutures placed along the advancing border of the cheek flap.

DEFECT CLASSIFICATION

Defects of the nose may be classified accordingly to location, depth, and size. Skin only defects are repaired with full thickness skin grafts, local flaps (if the defect is small), or skin transferred form the cheek or forehead. Defects involving loss of skeletal structure require replacement with like tissue. Full-thickness defects of the nose require replacement of the missing lining with flaps harvested from the interior of the nose whenever possible. These defects always require...
replacement of the missing skeletal framework and thus should be resurfaced with an interpolated paramedian forehead or melolabial flap.

The size of the nasal defect determines the source of the covering flap. In the case of defects greater than 2.0 cm in greatest dimension, there is rarely sufficient residual nasal skin for closure by a local flap of nasal skin without creating undue wound closure tension. Thus, the forehead or cheek is used as a donor site unless the defect is superficial and favorable for repair with a full thickness skin graft.

Reconstruction of Columella
The columella is the most difficult region of the nose to reconstruct. Small defects limited to 1.5 cm in greatest dimension can occasionally be repaired with composite grafts from the auricle in patients who do not use tobacco products or have peripheral vascular disease. The grafts are chilled with ice compresses for 3 days following transfer and systemic steroids are administered for 1 week. It is preferable to allow the initial defect to heal by secondary intention and then...
perform the composite graft after preparing a fresh recipient site by removing all scar and neoepithelialization. The graft is oversized by 2 mm to accommodate for wound contraction.

Depending on extent of tissue loss, larger defects of the columella are best repaired with unilateral or bilateral superiorly based interpolated melolabial flaps. Septal cartilage grafts are utilized for the framework. The initial flap transfer will create a thick columnella, which will require a contouring procedure following inset of the flap. Defects that extend into the tip from the columnella require structural support with cartilage grafts and an interpolated paramedian forehead flap for cover. By extending the incision for the forehead flap into or below the eyebrow, the flap can be made to reach the upper lip without excessive wound closure tension.

Full thickness defects of the columnella and tip are best reconstructed with a tilt out, hinge composite nasal septal flap. Mucosa of the flap is peeled downward bilaterally to provide internal lining. Auricular cartilage grafts are attached to the composite flap to provide structural support.
used routinely along the margin of the nostril when the defect extends from the tip into the nasal facet. This is in addition to any missing lower lateral cartilage which is replaced as well.

Bilateral full thickness defects of the nasal tip are repaired with a tilt out hinged composite.

**Reconstruction of Nasal Tip**

Small skin-only superficial defects of the nasal tip may be repaired with a nasal bilobe flap as described in detail earlier or a full thickness skin graft. However, an interpolated paramedian forehead flap will usually give a more natural result, because the entire aesthetic unit can be covered by the flap, placing scars in borders of aesthetic units (Figure 11). Cartilage grafts are used routinely along the margin of the nostril when the defect extends from the tip into the nasal facet. This is in addition to any missing lower lateral cartilage which is replaced as well.

**Figure 14** (A) Patient with a $3 \times 3$ cm skin defect of sidewall with extension to ala and dorsum. Skin of remaining ala and sidewall aesthetic units removed. Auricular cartilage graft in place along margin of nostril. Interpolated paramedian forehead flap designed for external cover. (B) Forehead flap transferred. (C to F) Preoperative and 5 years postoperative. Contouring procedure to create alar groove performed.
Defects confined to the ala with or without limited extension into the nasal tip or sidewall are best resurfaced with an interpolated superiorly based melolabial flap. The melolabial flap based on a subcutaneous pedicle is preferred, since this design minimizes the amount of skin that is disturbed in the superior melolabial fold. Preserving the superior fold is paramount in maintaining symmetry of the cheeks following reconstruction of the ala with a cheek flap. Cartilage grafts are used when repairing alar defects. This is because most lesions involving resection of alar skin also require removal of the underlying firm fibrofatty subdermal tissue which provides the ala with form and structural support. This support is replaced by cartilage to prevent upward migration of the ala or medial constriction of the margin of the reconstructed nostril.

Internal lining for full thickness alar defects is provided by a bipedicle vestibular skin flap or unilateral hinge septal mucoperichondrial flap as discussed. Occasionally an additional contralateral hinge mucoperichondrial flap, as discussed in the earlier portion of this chapter, may be necessary. This flap is required when the vertical height of the lining defect is such that an ipsilateral hinged mucoperichondrial flap will not provide sufficient tissue to replace the entire missing lining. When ipsilateral flaps are used to line defects of the ala or tip, they traverse the nasal passage and block the airway. To restore the airway, the pedicle is detached from the septum 3 weeks following transfer of the flap. Redundant tissue is trimmed and the distal portion of the flap is left in situ.

Reconstruction of Nasal Dorsum

The nasal dorsum is perhaps the least complex portion of the nose to reconstruct. Forehead skin in the form of an interpolated paramedian forehead flap is usually preferred for resurfacing skin-only defects of the caudal dorsum. However, bilobe flaps or full thickness skin grafts may also be used. Likewise, skin defects of the cephalic dorsum can be repaired with glabellar flaps such as the dorsal nasal flap or full thickness skin grafts, but interpolated paramedian forehead flaps are preferred for extensive defects that involve cartilage or bone and for large defects with loss of most of the skin of the dorsum. Small defects of the dorsal framework are replaced with septal cartilage grafts. More extensive defects of the nasal skeleton extending from the frontal bone to the tip are best replaced with calvarial bone grafts secured to the frontal bone or remaining nasal processes of the maxilla with plate and screw fixation. Costal cartilage grafts may also be used for this purpose. To prevent medialization of the nasal sidewall during wound healing, structural defects that extend into the nasal sidewall require replacement concurrent with replacement of the dorsal framework. Septal cartilage or additional cranial bone grafts plated to the dorsal graft work well for this purpose. Internal lining for full thickness dorsal nasal defects can usually be provided by mucoperichondrial hinge flaps reflected laterally from the exposed dorsum so long as there is sufficient height to the remaining septum. Unilateral or bilateral hinge septal mucoperichondrial flaps based on the caudal septum and including the septal branch of the labial artery can sometimes be used for lining when there is considerable loss of septal height. A tilt out composite septal flap, as discussed earlier in this chapter, is used to provide lining and structural support for the nasal bridge in extensive bilateral full thickness dorsal nasal defects. In instances where this approach will not provide sufficient tissue, bilateral paramedian forehead flaps are recommended. One flap provides internal lining and the other provides external coverage. A cranial bone graft is placed between the flaps for structural support.

Reconstruction of Nasal Sidewall

Reconstruction of the sidewall of the nose, is relatively uncomplicated. Small skin-only defects may be repaired with a bilobe flap harvested from the remaining nasal sidewall skin. Full thickness skin grafts harvested from the clavicular area of the anterior chest also provide a reasonable option for covering defects located in the superior portion of the sidewall, because of the thin skin in this location. Larger surface defects are best covered with an interpolated paramedian forehead flap. When structural support is absent from the cephalic one-third of the nasal sidewall, it is replaced with a calvarial bone graft, while the caudal two-thirds of the sidewall skeleton is best replaced with septal cartilage grafts. Unilateral full thickness sidewall defects can be lined using contralateral hinged septal mucoperichondrial flaps based on the nasal dorsum and delivered through a superiorly positioned nasal septal fenestrum. For more caudally located full thickness sidewall defects, a unilateral mucoperichondrial flap hinged on the caudal septum may provide sufficient lining. This arrangement, however, requires subsequent detachment of the pedicle. It is usually necessary to use both a contralateral dorsally based flap and an ipsilateral caudally based septal flap to provide lining for full thickness defects that involve the ala and extend cephalically to include the entire length of the nasal sidewall.

Facial Fractures
Paul J. Donald, MD

High-speed auto travel, increased sports participation by people of all ages and both genders, and the high incidence of violent crime continue to make facial fractures important injuries in our society. Contrary to the pattern of care in other countries, the management of facial fractures in the United States spreads across the disciplines of oral surgery, plastic surgery, and otolaryngology. Due to the comprehensive training in head and neck anatomy and physiology, the otolaryngologist is uniquely prepared to deal with these injuries. It is vitally important for the otolaryngologist to have a working knowledge of dental occlusion, facial esthetics, and an understanding of the healing of membranous bone.

The first encounter with the patient with a facial fracture is usually in the emergency department. A attention to the standard airway-breathing-circulation of emergency medical management must be invoked immediately. The patient is often the victim of an accident that involves many body systems, and almost always, attention to these injuries takes precedence. Addressing the impaired airway is preeminent. Extensive soft tissue contusion, bilateral mandibular bone fractures, and Le Fort fractures of the maxilla can all result in airway obstruction. In mandibular fractures, a nasotracheal intubation is appropriate; however, in maxillary fractures there is always a risk of fracture to the cribriform plate or the fovea ethmoidalis. Since intubation by the nasal route presents the danger of intracranial passage of the tube, oral intubation, cricothyroidotomy, or tracheostomy should be used to secure the airway. Fractures of the facial skeleton rarely present with life-threatening hemorrhage. The only time in the author’s experience, in which a problem of serious hemorrhage occurred, was in an instance of a Le Fort III fracture in which both internal maxillary arteries were severed. A nasal fracture of the temporal bone rarely ruptures the petrous portion of the internal carotid artery and a fracture through the basi-phenoid bone rarely tears the cavernous portion of the internal carotid artery.

A “C” collar is most often immediately placed on the patient to prevent displacement of a possible cervical spine fracture. After the patient’s condition has been stabilized, careful physical and radiographic examination of the cervical spine must be performed to rule out cervical spine injury. At this point, a careful evaluation of the other important systems is performed.

Treatment of the patient with facial trauma should include a thorough history and physical examination to determine the location and extent of all injuries. The goal of treatment of patients with craniofacial fractures should be reconstitution of all injured regions. Both soft tissue and bony injuries should be assessed, and a treatment plan should be established. The goals of treatment should be the restoration of function and appearance. The pre-morbid form and function of dental, skeletal, and soft tissues should be reestablished as much as is possible. Recent photographs and dental records, if available, are most helpful to establish the pretraumatic appearance.

If the initial injury involves skin or mucosal lacerations, attempts should be made to utilize these lacerations when possible for the approach to fracture repair. If no epithelial injury is present, approaches to fractures should attempt to maximise exposure, while minimizing scarring and risk to adjacent neural and vascular structures.

As much as possible, a thorough history is taken. Often, these patients have suffered multiple injuries and may be either unconscious or intubated. Information may be gleaned from friends or relatives at the scene or the police or ambulance attendants. Physical examination includes a careful inspection of dental occlusion, examination of the facial contour, and palpation of the facial bones. A computed tomography (CT) scan of the facial skeleton is crucial in securing the correct diagnosis.

After fracture diagnosis is completed, a systematic treatment plan is established. Surgical treatment of facial fractures involves adequate exposure, meticulous reduction, and stable fracture fixation. Surgical approaches should utilize transmucosal incisions or incisions that are camouflaged in relaxed skin tension lines (RSTL) or at the junctions of facial aesthetic units. The incision and approach chosen must not compromise the basic principle of providing adequate exposure for diagnosis and treatment of any fracture. After exposing the facial fracture, meticulous reduction must be performed and maintained until adequate fixation of the fracture can be done. Precise reduction is imperative when rigid fixation is utilized. Fixation techniques should allow for complete bone healing with reconstitution in three dimensions: height (superior-inferior), width (lateral-medial), and depth or projection (anterior-posterior).

Repair of soft tissue injuries is often as important as fracture treatment in the complete restoration of the patient with craniofacial injuries. This is especially true in the periorbital region, where injuries such as telecanthus, enopthalmos, and dysopsia often accompany the skeletal injury. Complete treatment of facial injuries requires attention to these soft tissue injuries and the accurate reattachment of soft tissue facial layers after fracture repair.

The basic principles of diagnosis and initial treatment of patients with facial fractures are listed in Table 1. The principles of fracture repair are listed in Table 2. Adherence to these principles will maximize function and appearance.

DENTAL OCCLUSION

The key to proper fracture reduction is the restoration of the patient’s premorbid occlusion. Understanding dental occlusion is an essential element in the management of facial fractures. Dental occlusion is the relationship of the maxillary to the mandibular teeth with regard to their cutting and grinding surfaces. This relationship largely depends on the relative position of the teeth and their angulation to one another. In 1899, Angle described three basic types of occlusion. Certain subtypes of this system as well as other classifications of occlusion have been devised, sometimes adding to the confusion rather than clarifying the problem. In the Angle system, the

Table 2 Principles of Fracture Repair

| Repair of both skeletal and soft tissue injuries |
| Use of lacerations when possible               |
| Use of mucosal incisions when possible         |
| Exposure of all fractures adequately for fracture healing |
| Reduction of all fractures                     |
| Stabilization of fractures                     |
| Fixation of all fractures adequately to allow bone healing |
Class I occlusion is the ideal form (Figure 2). Usually, these relationships are maintained in the remaining teeth as progression toward the anterior aspect of the dental arches occurs. In Class II and III occlusion, this progression results in aberrations in the relationships of the incisor teeth as reflected in characteristic facial deformities.

In Class II, the mesial or anterior relationship of the maxillary teeth may result in a protrusion of the upper incisors beyond the lower. Not only is there a jutting forward of these upper central teeth, a condition called overjet, but often the lower incisors may bite more deeply toward the palate, a condition called overbite (Figure 5). This condition produces a profile described as “bucktooth” or “weak-chin.” This look is caricatured in the cartoon characters “Andy Gump” and “Sad Sack.” When the condition is due to a lack of mandibular development with a backward positioning of the lower jaw, it is called retrognathism. The setback chin often prevents the upper lip from completely covering the upper incisor teeth. This lack of lip protection, called lip procumbency, can render the incisors more vulnerable to injury. Fractured incisors are often found in this group.

Often in Class III occlusion, an abnormally protrusive mandible causes maxillary incisors to sit behind or distal to the mandibular incisors. This produces a so-called bulldog or Dick Tracy profile. The overbite results in the upper incisors biting into the gingival lingual sulcus below. The malocclusion is often so severe the patient has an extremely difficult time chewing solid food. Often only two or three cuspal pairs are able to occlude. In edentulous patients, it is often exceedingly difficult to fit them with a denture.

The opposite of the closed bite of overbite deformities is the open bite. This may be seen in both class II and class III types of malocclusion. This open bite deformity produces a marked functional disturbance and is extremely unsightly. Even though the molar teeth are in some form of apposition, the anterior teeth never meet.

Class II malocclusions may arise from an underdeveloped mandible or an abnormally protuberant maxilla. Similarly, a Class III malocclusion may arise from a large overdeveloped mandible or a retruded or retroplaced maxilla. Retrognathia is classically used to describe a Class II bite, and prognathism to describe a Class III bite.

In addition to aberrations in the anteroposterior relationship of the dentition are deformities involving malposition in the medial and lateral direction, as well as abnormalities involving a lateral tilt of the occlusal plane. Instead of having their buccal cusps positioned lateral to the buccal face of the opposing mandibular molars, the maxillary molar teeth may be biting end to end or even over the lingual cusps of the mandibular teeth (Figure 6). This is called a lingual crossbite deformity. If both arches are symmetric, the maxillary molars of the opposing side will be put into a more buccal relationship with the opposing mandibular teeth, thereby creating a buccal crossbite.
on this particular side. Because an abnormality in the arch configuration of either or both of the dental arches is often present, it is not uncommon to have a crossbite on one side with a fairly normal occlusal relationship on the other. For instance, a narrow maxillary arch coupled with a fairly normal mandibular arch, as seen in hemimandibular hypoplasia, often produces a buccal crossbite on one side and normal occlusion on the other. In patients with hypoplasia, the plane of the bite is often abnormal as well. These patients normally have a diagonal bite. When they bite down on a tongue blade placed laterally across the teeth, the blade tilts at an angle that is oblique to the horizontal plane (Figure 7). It is not uncommon to see a combination of many of these occlusal abnormalities in any given patient.

**FRACTURES OF THE MANDIBLE**

**Anatomy**

The mandible, a horseshoe-shaped bone, is the largest bone of the face. It is divided into regions well described by Dingman and Natvig. The condyle is the portion extending from the mandibular notch to the condylar head, which articulates in the glenoid fossa. The coronoid process is the anterior-superior extension of the mandibular ramus projecting above the mandibular notch into the infratemporal fossa. Below the mandibular notch is the ramus, which is composed of thin cortical bone. The angle is a non-tooth-bearing portion of the mandible between the ramus and the body. The parasymphyseal region is composed of the anterior arch of the mandible and is bounded by the two mental foramina. The body and the parasymphyseal areas are where the teeth are found. The alveolar ridge or process is composed of thin cortical bone (lamina dura) that encompasses the teeth and atrophies when the teeth are gone. In the edentulous mandible, the tooth-bearing bone resorbs, decreasing mandibular height.

The inferior alveolar nerve enters on the medial (lingual) aspect of the mandibular ramus and passes through its own canal to the mental foramen. While traversing this canal, it gives off sensory innervation to the dentition and gingival. The terminal portion of the inferior alveolar nerve is the mental nerve which exits the body of the mandible on the labial surface just below the second premolar tooth. It is important to remember that the nerve travels about 2 to 3 mm anteriorly beyond the foramen before it doubles back and exits the bone. It provides sensation to the lower lip and ipsilateral chin. After a fracture of the angle and body, the alveolar canal is often fractured. Unless there is a complete transaction or avulsion of the nerve, full sensation often returns within 9 months to 1 year.

The muscles of mastication inserting on the mandible include the temporalis, internal pterygoid, external pterygoid, and masseter. These muscles contribute to the movement of the temporomandibular joint (TMJ), a synovial joint with a fibrocartilaginous disk. The capsule is densely innervated with proprioceptive and sensory fibers, which are extremely sensitive to subtle changes in movement of one or both joints. A slight alteration in occlusion from muscle spasm or a displaced fracture may alter the central perception of joint position. Feedback loops in the central nervous system force the contralateral muscles of mastication to compensate. This series of events may lead to chronic TMJ syndrome in an unrepaired or poorly repaired mandible fracture.

Understanding the various attachments of the aforementioned muscles of mastication, as well as the mylohyoid, geniohyoid, genioglossus, and digastric muscles, is important in understanding the forces of displacement in a mandible fracture. The floor of the mouth and extrinsic tongue muscles tend to displace fractures posteriorly and inferiorly. The medial pterygoid and masseter muscles act as a sling in the posterior part of the body and angle area and tend to elevate a displaced fragment of the angle or posterior part of the body. Condylar fractures are displaced by the pull of the lateral pterygoid muscle, which rotates and dislocates the fracture medially.

**Classification**

Fractures of the mandible may be classified according to specific characteristics and anatomic location. A fracture is considered simple when both the external skin and oral mucosa are intact, or compound (open) when a laceration in the skin or intraoral mucosa is present. If the patient is dentulous and the fracture line passes into the tooth root, the fracture is usually compound because the periodontal pocket of that tooth often extends to the fracture site. If the fracture is incomplete and involves only one cortex, it is termed “greenstick.” The comminuted mandible fracture is one with several fragments of bone. Mandibular fractures are most commonly characterized by anatomic location (Figure 8). The most frequent location of fractures of the mandible is the condylar-subcondylar region. Common sites include the body and the angle. The coronoid process is rarely fractured. An alveolar ridge fracture involves the occlusal surface of a part of the mandible, but does not extend into the inferior cortical surface (Figure 9).

Mandibular fractures can also be classified as dentulous, edentulous, or pediatric. The last category is important because of the vulnerability of unerupted dentition and the conical shape of the teeth, which do not hold a wire ligature well. The accuracy in approximation of the edentulous mandible is not as critical in a jaw without teeth as is the exacting task of establishing the preinjury occlusion of the dentulous mandible. A denture can compensate for minor irregularities in the edentulous jaw.

The final classification may be made according to the stability of the fracture. Vertical instability is lent by virtue of the pull of the temporalis, masseter, and pterygoid muscles. The angle of pull of these muscles will tend to impact a jaw fracture that is obliquely inclined from distal to mesial, (posterior to anterior), rendering it stable. On the other hand, if the inclination is in the opposite direction, then the forces of these muscles will distract the distal segment in a superior and medial direction. An interesting situation presents itself regarding an unfavorably inclined fracture in the distal body, near the angle, just anterior to the third molar tooth. While the tooth is present, the fracture will not dislocate, but, if the tooth is then extracted, the fracture becomes unstable (Figure 10). A fracture becomes horizontally unstable by virtue of its obliquity in the occlusal plane. A fracture with an angulation running...
from the buccal to lingual surface in a posterior to anterior direction is favorably aligned, whereas the opposing obliquity is unstable by virtue of the pull of the mylohoid muscle (Figure 11).

**Diagnosis of Mandibular Fractures**

A good history and physical examination, along with plain radiographic films, fully delineate the large majority of fractures to the mandible. When obtaining the history, determine the nature of the injury, and the force with which it was applied. If the injury is the result of a gunshot wound, then it is necessary to know the weapon’s caliber and the nature of the bullet type. Previous orthodontic work should be noted. Any history of previous mandible or maxillary fractures should also be elicited. Questions should be directed toward establishing the neurologic status of the patient as well as the status of the cervical spine. Frequently, a patient presenting with a mandible fracture has other associated facial fractures. Questions regarding pain, hearing, vision, and occlusal relationships are documented. Soft tissue swelling over the point of contact is often found. Numbness of the lower lip from an avulsed or badly contused inferior alveolar nerve in any part of its course from the ramus to the parasymphyseal area, is commonly encountered.

Physical examination confirms the patient’s complaint of malocclusion. If the fracture is in a tooth-bearing area, loose or missing teeth may be noted. Ecchymosis of the gingiva also indicates the presence of a fracture. Gross displacement of the fragments may be obvious (Figure 12). There may be a foul odor in the patient’s breath from a combination of stagnant food, blood, and frequently alcohol. Bony crepitus and tenderness are also elicited on palpation. A thorough dental examination should be undertaken, including assessment of the presence or absence of teeth and the fractures of dental crowns. Dentures, even if broken, are preserved. The maxillomandibular occlusal relationships are documented. Soft tissue swelling over the point of contact is often found. If there is a missing tooth that is unaccounted for, aspiration is a possibility. In the unconscious patient, evidence of a recently lost unrecovered tooth necessitates a chest X-ray.

Radiographic evaluation can be used to confirm the physical findings and assess the severity of the fracture, including whether it is comminuted and whether there are actually fractured teeth involved. When there is one obvious fracture in the mandibular arch, one must always be aware that there may be an occult fracture in the contralateral ramus or condyle. The panoramic radiograph (Panorex film) is excellent for viewing fractures of the ramus, angle, and body (Figure 13). This type of X-ray is limited, however, in visualizing the symphyseal area as well as telescoping fractures of the condylar area. A modified Townes view usually visualizes significant fractures of the condyles (Figure 14). If a strong suspicion of subcondylar fracture exists, a CT scan will delineate the degree of fragment overlap or displacement into the infratemporal fossa (Figure 15). CT scan reconstructions in three-dimension are often helpful in establishing site of fracture and particularly deformity (Figure 16). If a parasymphyseal or symphyseal fracture is suggested clinically, but not visualized on plain radiographs, then the CT scan will demonstrate it. Dental fractures are best diagnosed with dental occlusal films. If the patient sustains massive trauma as in a motor vehicle accident or other collision, CT scans of other pertinent anatomic areas should be taken, including full facial and cervical spine films. The scan is usually extended superiorly to rule out any intracranial injury.

**Treatment**

After an adequate history and physical examination have been obtained, and a radiographic assessment has confirmed the physical findings, and ruled out any “occult” fracture, treatment is dictated by the following factors: (1) presence...
or absence of other serious trauma, intracranial, intrathoracic, or intra-abdominal and clearance of the cervical spine by a qualified neurosurgeon or orthopedist; (2) adequate surgical consent from the patient; (3) a thorough dental evaluation, including preoperative documentation of occlusion; and (4) availability of bridgework or dentures that accompany the patient to the operating room.

Although many authorities recommended surgical intervention as early as possible to prevent infection, there is no conclusive evidence for this. To decrease the incidence of infection, it is better to administer preoperative antibiotics. Surgery should be done as soon as possible with the previously mentioned factors taken into consideration. It must be emphasized that repairing a mandible fracture is not, in the true sense of the word, an emergency but rather should be done as soon as possible when safe. Some fractures of the mandible do not require surgical intervention. When there is no complaint of malocclusion, most commonly, nondisplaced ramus fractures as well as some subcondylar fractures should be treated with a soft diet. The remainder of mandible fractures, especially when there is malocclusion, should be treated either by closed or open reduction, or in some cases, both.

The cornerstone of facial fracture repair is intermaxillary fixation. This method of repair entails the ligation of the teeth of each arch to those that oppose it. According to Dingman and Natvig, ligation of teeth to each other dates back to the time of Hippocrates. The ancients advised fixing the teeth to one another with gold wire or linen thread. The Greek physician, Soranos of Ephesus, first described the concept of support of the fractured jaw by a barrel-type bandage in the second century AD. These first methods appeared to rely on healing resulting from the wiring of adjacent teeth in the same arch. William of Saliceto, who practiced in Bologna and Verona, first suggested interarch fixation for mandibular fractures in the thirteenth century. He used waxed, twisted silk threads and bound “the injured to the uninjured jaw.” It remained for Gilmer in 1887 to be the first to propose actual rigid interdental and intermaxillary fixation, which he accomplished with iron wire.

Intermaxillary fixation began by separately wiring each individual tooth of the maxillary and mandibular arches and then connecting these wires one by one as the teeth were brought into occlusion. From this method, certain modifications were made and evolved into the method we know today. The most significant contribution was the development of the arch bar. Gruneil Hammond in 1871 may have described the first arch bar, a firm wire that went around the lingual and buccal surfaces of the teeth. Sauer in 1882 used a circumferential gold wire with a spring attachment. These evolved into the Erich and Jelanko arch bars we recognize today. The Erich bar, the one most commonly used, is a malleable metal bar that easily adapts to the buccal surfaces of the teeth and has hooks to which intermaxillary wires or rubber bands can be attached. The Jelanko bar is rigid and difficult to accommodate to the dental arches. Only the application of eyelet wires and the Erich arch bar will be described.

Eyelet Wires. The eyelet wire is best used for subcondylar fractures, greenstick fractures, and favorably aligned noncomminuted mandibular fractures in patients who are cooperative and compliant. The eyelet wire may also be used as temporary fixation until definitive fixation is done. The wire is constructed by taking a half-length of no. 26 gauge wire, bending it in half, and twisting it in a small loop.

The idea of the eyelet wire is to capture two independent teeth on each side of a mandibular fracture and then fix these to two adjacent pairs of maxillary teeth. The ends of the wire are directed from the buccal side through the interdental space below the contact point and close to the gum between the pair of mandibular teeth distal to the fracture. Each wire is brought around the neck of each tooth, and the end of one is passed through the loop and twisted to its mate at a comfortable distance from the loop. The wire ligature now captures the two teeth. Care is taken to be sure the wire is pushed below the embrasure of each tooth and cinched around the tooth neck. The pair of teeth mesial to the fracture line is now ligated in the same way. Similar wires are placed in the same fashion around the maxillary teeth that occlude with the opposing wired mandibular teeth. Pairs of mandibular and maxillary teeth are captured with eyelet wires on the opposite side of the arch for additional stabilization. The patient is placed in his/her premorbid occlusion, and each loop on the mandibular side is individually wired to the loop above. The fracture is now fixed, and the wires are checked on a weekly basis. Occasionally, the interloop wires may loosen or break and may need tightening or replacement. The wire eyelet itself may also come loose and require tightening. Wires are removed at 3 weeks for subcondylar fractures and 6 weeks for others.

Arch Bars. Erich arch bars generally come in a roll. The correct length of bar for each arch is measured by placing one end of the bar on the most distal tooth in the arch on which it is to be fixed. The bar is bent around to the space between the central incisors. This length is now doubled and the bar cut from the roll. Adjustments are made for missing molar teeth. If significant gaps of two or more teeth are present, the gap can be filled in with a pad of cold cure acrylic pressed into the bar.

Once trimmed to length, the bar is carefully contoured to the teeth by hand. Great care is taken to shape the distal ends to fit around the last teeth in the arch, so the bar will not dig into the cheek. Each bar is placed over the buccal surfaces of the teeth and wired into position with the hooks facing away from the occlusal surface (Figure 17).
The best teeth for securing the bar are the molars and premolars. The canine has the longest root but has a shape that is not conducive to retention of a wire. The incisor teeth, because of their peg-like configuration, hold the wire even more poorly. If enough teeth are present in the arch, the four incisor teeth of each arch are left unligated. For purposes of orientation, the application of the arch bar to the maxillary teeth will be described first. A 6 in. piece of prestretched 25-gauge wire is passed through the interdental space below the bar (Figure 18). Care is taken to prevent injury to the interdental papillary; however, in patients with periodontal disease, this may be unavoidable. The wire is placed around the tooth adjacent to the interdental space. The two ends are twisted together with forceps while the wire is held at the level of the neck of the tooth with a periosteal elevator (Figure 19). The wire is twisted until tight. The resulting knot is turned into a tight loop and placed away from the lug on the arch bar. Its end is twisted away from the cheek. The molar and premolar teeth are all ligated to the arch bar using the anterior wire above the bar and the posterior below formulation. All the wires are twisted in a clockwise direction. This convention helps in tightening loose wires during follow-up.

Special attention is spent in securing the canine tooth. Its long root embedded in thick bone makes it the key anchor for the bar. Because of its unfavorable shape, adaptation of the wire ligature enhances its holding ability. The wire is placed above the bar, both anteriorly and posteriorly to the tooth, and then looped around the anterior aspect of the bar (Figure 20).

Once bars have been placed on both upper and lower teeth, they are secured to one another either with wire or elastics. Dental wax may be placed on a protrusive edge that irritates the soft tissues. The patient is also given a stick of wax and instructed how to apply it to irritating wire or lugs. All patients are followed on a weekly basis to check for bar stability and tightness of the interarch wires. Loose wires are tightened and broken wires replaced. Additionally, careful attention is paid to dental hygiene and nutrition. Already curious dentition, a condition not uncommon in patients with facial fractures, is usually the reflection of past neglect. Careful and consistent instructions in proper brushing technique and use of a "water pick" type of device are essential features in the follow-up regimen. Dental caries can lead to the formation of a dental abscess during the healing phase, which in turn, result in osteomyelitis of the jaw.

Nutritional advice is important. The average weight loss in our patient population following intermaxillary fixation is 15 lb. A booklet on dental hygiene and nutrition is supplied to each patient, with instruction on brushing technique and diets that can be employed while in fixation. Of course, only food with the consistency that can be sucked in the free space around the back of the teeth can be used. Balanced high-calorie supplements such as Ensure-plus and Sustacal can be used to augment caloric intake. These products come in both liquid and pudding forms and are quite palatable. When the patient is fixed into occlusion with either Erich arch bars or eyelet wires, it is important to supply the patient with wire cutters so that if he or she vomits, the interocclusal connection can be cut to prevent aspiration.

**Gunning Splints.** In the edentulous patient, the patient’s reduced mandible can be maintained by the use of Gunning splints. In 1861 T.P. Gunning of New York was, according to Dingman and Natvig, the first to describe the use of intermaxillary splints, which he fabricated from vulcanite. To make the splint, a dental impression of the jaws are taken with an impression compound such as alginate and poured in stone. The stone model of the mandible is cut at the fracture line and realigned in the normal anatomical position and fixed with sticky wax. An impression of the realigned model is taken and a hot-cured acrylic stent is made. A stent is also made of the maxilla. A flange and corresponding groove are constructed so that the maxillary splint can fit into the mandibular splint in a lock and key type of articulation. Care is taken so that the normal pre-occlusal relationship is established between the mandible and maxilla. An arch bar is imbedded into the splint before hardening so that the splints can be ligated together.

At the time of surgery, the mandibular fracture is reduced and the splint fixed to the jaw by at least four circummandibular wires. A pair of drop wires suspends the upper splint from the bone of the piriiform apertures and from the zygoma by wires which encircle the arches. Once the flanges on each side of one splint are fitted into the slots of the corresponding splint then the lugs of the maxillary and mandibular arch bars are wired together. Alternatively, the splint may be fixed with screws that pass through the splint and the unfractured alveolar ridge.

A cruder type of splint can be made in the operating room at the time of fracture reduction in the edentulous patient using cold cure acrylic. A lock and key arrangement is constructed and arch bars pressed into lateral surfaces of the acrylic before it cures. This is a less precise splint and less comfortable for the patient. A ny denture, even one that is broken and once mended, will serve well as a Gunning splint. Even a loose fitting denture will provide adequate stabilization of the fracture.

**Fractures of the Parasympyseal Area.** These fractures tend to occur in an oblique line, sometimes even approaching the midline from the mental foramen. The mental foramen is the most commonly involved site of a parasympyseal fracture. A “pure” symphyseal fracture, a fracture through the central incisors, is rare. Either an ipsilateral or contralateral fracture of the angle, ramus, or condyle often accompanies
unilateral parasymphyseal fractures. Parasympyseal fractures may present with a crossbite on the involved side from the posterior pull of the mylohyoid. This is especially true when there is a concomitant ipsilateral fracture of the ascending portion of the mandible. Loose anterior dentition, edentulous spaces, and grossly mobile fractured segments are the hallmarks of these fractures.

The presence of posteriorly displaced bilateral parasympyseal fractures constitutes an airway emergency. An adequate airway should be established promptly by placing the fractured anterior mandibular segment in one’s forefinger and thumb and projecting it anteriorly. Usually the airway can easily be secured by placing a towel clip in the anterior tongue and pulling the tongue and fractured mandible forward. Often an emergency tracheostomy or cricothyrotomy is indicated.

Treatment of a parasympyseal fracture with only intermaxillary fixation is not usually adequate. However, it is often necessary to stabilize these fractures with interosseous wires, plates, or a lingual splint to prevent a permanent crossbite.6,15-17 The approach to open reduction of these fractures can be either intraoral or external but is usually internal. Care must be taken to avoid avulsing the mental nerve by way of either approach.

**Fractures of the Body and Angle of the Mandible.** Patients with fractures of the mandibular body with good dentition have a distinct advantage over the edentulous or partially dentulous patient. Intermaxillary fixation stabilizes many of these fractures sufficiently, alleviating the need for open reduction. The forces generated by the pterygoid-masseteric sling may distract these fractures, requiring open reduction. Once closed reduction is accomplished by means of Erich arch bars, a decision can be made whether the repair is stable. If it is not, an open reduction can be approached by means of a gingivobuccal incision intraorally.6,15 Rarely an extraoral approach will be necessary, and if so a modified Risdon incision is made with care taken to preserve the marginal mandibular branch of the facial nerve. A single fracture may be treated the same way as body fractures. If the oblique line of fracture is in a favorable position, closed reduction is adequate. When there is an “unfavorable” fracture, open reduction is often necessary.19

**Fractures of the Condylar Process and Ramus.** Fractures of the condylar process and condylar neck of the mandible are usually handled by closed reduction. Fractures of the mandibular ramus can be treated in a similar fashion to condylar fractures; even if there is displacement of the fractures and malocclusion results. The closed reduction may be all that is needed. If there is a massive comminution or severe telescoping or just displacement that is not adequately reduced by closed reduction, open reduction should be undertaken to avoid occlusal discrepancies. Severe condylar fractures are defined as (1) telescoping greater than 1.5 cm; (2) a condylar head displaced out of the condylar fossa; or (3) bilateral subcondylar fractures associated with a Le Fort or maxillary fracture.20

The open approach begins with an incision in the preauricular region extending into the temporal hairline, going deep to the temporals fascia superficial.15-17 A flap of superficial temporalis fascia should be raised, and the root of the zygoma should be followed down to the fracture site. The trunk of the facial nerve is avoided by staying on the zygomatic process of the temporal bone, tracking down to the glenoid fossa. W ith a gentle retraction of the superior parotid tissues, the fossa can be exposed and the fracture reduced by means of either a wire or miniplate. Alternatives to repair of a condylar fracture include a Kirschner wire placed by way of the angle of the mandible projected superiorly toward the glenoid fossa.20,21 External pin fixation with a Morris biphasic and plating techniques have also been described.22,23

**Open Reduction.** Before performing open reduction of a mandible fracture, it is always advisable, if possible, to place the patient in closed reduction to establish the occlusal relationship of the teeth. It is folly to attempt open reduction of any sort when the maxillomandibular dental relationships have not yet been established.

**Surgical Approaches.** Intraoral approaches have the advantages of scar camouflage and more direct approach to the fracture reduction and fixation. These approaches require more elaborate instrumentation to allow less direct visualization of fractures. Adequate exposure and accurate reduction through this approach requires an experienced surgeon. Extraoral approaches have the advantage of increased exposure and increased visualization in the region of the posterior part of the body, angle, and ramus. External exposure requires a cervical incision; however, this involves potential risk to the marginal mandibular branch of the facial nerve.

The incision and approach chosen for a given fracture of the mandible depend on several factors. These include the location and type of the fracture, as well as, the available instrumentation and technology and, most important, the surgeon’s comfort with the given approach. The choice for simple fractures of the symphyseal and parasymphyseal region is intraoral. Simple, linear posterior fractures may be approached intraorally, whereas more comminuted fractures or fractures with significant bone loss usually require an extraoral approach. The approach chosen should allow adequate exposure to diagnose, reduce, and immobilize the given fracture.

The symphyseal and parasymphyseal regions of the mandible are easily approached through either an intraoral or an extraoral route. The intraoral incision is made from canine tooth to canine tooth, leaving an adequate mucosal cuff for closure.24 Superiosteal dissection is made, identifying and preserving the mental nerves. The symphyseal and parasymphyseal regions are also easily approached through an external submental incision oriented in RSTL. Reapproximation of the mentalis muscle must be carefully performed to prevent postoperative ptosis of the soft tissues of the chin.

The approach to the mandibular fracture posterior to the mental foramen depends on the surgeon’s experience and the extent and comminution of the fracture.15 Intraoral approaches to the body and angle are best performed by making a gingivobuccal incision immediately adjacent to the fracture. Repair of posterior mandibular fractures requires surgical experience and advanced technology to achieve fracture reduction fixation. Fracture fixation is achieved with a transbuccal system placed through transcortaneous facial stab incisions (Figure 22). The extraoral approach to

---

**Figure 21** Schematic diagram of intraoral approach to symphyseal and parasymphyseal fractures. The dissection is subperiosteal and isolates and preserves the neurovascul ar pedicles from the mental foramina.

**Figure 22** Lateral view of a cadaver showing the use of the transcortaneous-transbuccal system for approach for posterior fractures of the mandible. (A) Stab wound incision has been used to insert the transbuccal system. (B) Intraoral view showing utilization of the transbuccal system to place a plate and screws for fixation of a fracture of the angle of the mandible.
fractures of the mandibular body, angle or ramus is made through a transcervical incision two-finger-breadth below the angle of the mandible. Care is taken to elevate the marginal mandibular branch of the facial nerve to prevent injury. This approach is preferred when the patient has significant comminution of the fracture or bone loss. In each of these cases, a larger reconstruction plate may be required for repair. The external approach allows greater exposure for placement of large reconstruction plates.

As instrumentation and technology have progressed, treatment of mandibular fractures has evolved, but the goals have not changed. These goals include anatomic and functional stability of the mandible. Reduction and stabilization of any mandibular fracture should result in subsequent pain-free function of the mandible without any eventual changes in the TMJ.

The strength of any bony fixation must be adequate to overcome any forces that will act on the repaired bone during function. As previously mentioned, former techniques used fixation with interosseous wiring. This method allows the bone to heal indirectly. Wire fixation is rarely used today. The only theoretic advantage of wire fixation for repair of mandibular fractures is the possibility of increased flexibility in cases with significant bone loss or comminution. In these situations, if rigid fixation is applied without proper restoration of premorbid occlusion, the result can be either poor occlusion or eventual change in the TMJ. If interosseous wiring is used, intermaxillary fixation should also be used for approximately 6 weeks for stable bone repair.

The rationale for the use of rigid internal fixation for repair of mandibular fractures is well documented. With interosseous wire fixation, there is a clinically proven decrease in mouth opening seen 6 months after release of intermaxillary fixation. Additionally, experimental and clinical evidence against wire fixation includes muscle atrophy and histologic changes in the TMJ after prolonged periods of intermaxillary fixation. Although an increased rate of infection has not been conclusively shown with intermaxillary fixation and interosseous wiring, the increased bone movement with nonrigid fixation makes this a theoretic consideration. As knowledge and technology have progressed, rigid internal fixation has become the standard in most centers for treatment of mandibular fractures. This allows the direct form of bone healing. Use of this type of bone repair requires surgical experience, advanced technology, and patient compliance. Direct bone healing can only be achieved with rigid fixation. If properly applied, stable rigid fixation of the mandible obviates the need for intermaxillary fixation.

Rigid fixation of the mandible can be performed by a variety of methods. The fracture is usually first reduced, and the teeth are put into premorbid occlusion by placing the patient in intermaxillary fixation. The fractures are then directly approached (with intermaxillary fixation in place), and anatomic fragment reduction is obtained. Rigid fixation is then performed. This can be accomplished with an inferior mandibular fracture plate (2.4 to 2.7 mm) and a superior monocortical two-hole tension band.

The intraoral incision is retracted with a special intraoral retractor that is fitted to an extraoral device with the tooth roots although such contact is of no consequence in most instances. Care must be taken to avoid overtightening of the screws as this will produce microfractures and destabilize the fixation.

The rationale for the use of rigid internal fixation for repair of mandibular fractures is well documented. With interosseous wire fixation, there is a clinically proven decrease in mouth opening seen 6 months after release of intermaxillary fixation. Additionally, experimental and clinical evidence against wire fixation includes muscle atrophy and histologic changes in the TMJ after prolonged periods of intermaxillary fixation. Although an increased rate of infection has not been conclusively shown with intermaxillary fixation and interosseous wiring, the increased bone movement with nonrigid fixation makes this a theoretic consideration. As knowledge and technology have progressed, rigid internal fixation has become the standard in most centers for treatment of mandibular fractures. This allows the direct form of bone healing. Use of this type of bone repair requires surgical experience, advanced technology, and patient compliance. Direct bone healing can only be achieved with rigid fixation. If properly applied, stable rigid fixation of the mandible obviates the need for intermaxillary fixation.

Rigid fixation of the mandible can be performed by a variety of methods. The fracture is usually first reduced, and the teeth are put into premorbid occlusion by placing the patient in intermaxillary fixation. The fractures are then directly approached (with intermaxillary fixation in place), and anatomic fragment reduction is obtained. Rigid fixation is then performed. This can be accomplished with an inferior mandibular fracture plate (2.4 to 2.7 mm) and a superior monocortical two-hole tension band.

The intraoral incision is retracted with a special intraoral retractor that is fitted to an extraoral device with the tooth roots although such contact is of no consequence in most instances. Care must be taken to avoid overtightening of the screws as this will produce microfractures and destabilize the fixation.
Another means to achieve stable rigid fixation is the placement of lag screw fixation.24 This method employs a basic principle of woodworking and applies compression across the fracture line with minimal direct bone healing. This technique requires adequate exposure and subperiosteal undermining to allow placement of long screws that engage sufficient bone for fixation.

Lag screw fixation requires that there will be sufficient obliquity to the fracture line that allows at least two, preferably three, lag screws be placed at a significant distance from one another that will catch both mandibular cortices thus stabilizing the reduction. The exception to this is the mandibular angle where one screw is sufficient to achieve adequate fixation. This technique is not applicable to all mandibular fractures and takes a degree of understanding of the dynamics of mandibular function and skill in inserting the screws appropriately. Through an intraoral approach the fracture line is exposed, the fracture is reduced, and the reduction is maintained with arch bars or eyelet wires. For anteriorly located fractures in the parasympyseal and mesial part of the body an intraoral approach can be used. For those fractures near the angle, the transbuccal approach is employed. A trocar is introduced through a stab incision in the cheek, and the penetrating point is removed prior to introducing the drill bit (Figure 27). A drill guide is placed that will produce the “glide hole” for the portion of the screw that will pass through the buccal cortex. Once the fracture line is encountered, a second guide is inserted through the hole just made to make the smaller guide hole in the lingual fragment. This screw hole must begin precisely in the center of the glide hole and carried through the lingual cortex. A countersink is made at the start of the glide hole to accommodate the head of the screw. The screw is slid through the glide hole, and the threads engage the thread hole. The fracture is compressed as the screw head enters the countersink.

In those fractures in the parasympyseal area the exposure can be done intraorally. The elevation of the mucoperiosteal flap must be done with an eye to avoid injuring the mental nerves. The gliding hole and the threading hole are placed in the same fashion as those in the area of the angle. The countersink is made and the lag screw placed to ensure stability. Two or three screws are placed (Figure 28). Screws are now available with the screw flutes wider than the diameter of the glide portion of the screw. This then requires that only one screw hole is drilled and the passage of the thread portion of the screw pulls the gliding part through giving tighter grip to the latter while achieving the necessary compression.

If rigid fixation is stable, the patient may be taken out of intermaxillary fixation and allowed to function.30 Of course, this decision is based on the stability of the rigid fixation and on the individual patient’s compliance. If either the fixation stability or patient compliance is in question, the patient may be left in intermaxillary fixation for up to 6 weeks.

Figure 27 Steps in the insertion of a lag screw for mandibular fracture fixation. (A) A large glide hole is made in the lateral fragment using a drill guide. (B) A smaller gripping hole is made in the inner fragment using a drill guide of smaller diameter. (C) After a countersink is made in the lateral fragment, the screw is placed so that it glides through the outer hole, seats in the countersink, and the screw flutes grip the inner fragment. Dental Injury. Injury to the dentition is a common accompaniment to fractures of the mandible and maxilla. A simple chipping of the teeth, which does not extend to the dentin, can be managed by the dentist by simply grinding the occlusal surface smooth. Such injuries are usually uncomplicated by pain. Larger fractures of the tooth substance expose the dentin or pulp and are painful. It is important to dress the tooth immediately with a dental compound that not only protects the tooth, but also alleviates discomfort. A simple mixture of zinc oxide and eugenol done with a metal spatula or a glass plate forms a sticky compound with the consistency of putty that hardens when wet by the saliva. Eugenol helps to soothe the pain. Other proprietary compounds such as Dycal may be used. Later, the dentist can restore the tooth with a crown. In the case of fracturing of a slab of tooth face in a vertical direction, especially from the incisors, the tooth can be repaired by bonding.

A luxion of the crown at the gum line is managed either by the extraction of the root or by application of a dressing until the tooth can later be restored with a crown. If the dentition is neglected and carious, extraction is the best solution.

Dental fractures that occur through the root present a special problem. Root fractures seriously jeopardize the viability of the tooth. If the soft tissue of the pulp is sufficiently traumatized, the tooth will die. Once the pulp undergoes necrosis, the stage is set for the development of a root abscess. This may occur a short time after the injury or may be delayed for years. If such an abscess were to occur during intermaxillary fixation, an osteomyelitis and even a nonunion could occur.

The management of a tooth in the line of fracture is controversial. Some guidelines do exist that may be of help. If the tooth is carious and the root is fractured, the tooth should be removed. If a carious tooth has a fracture through the periodontal ligament, but the root is intact, extraction should be seriously entertained. If the tooth is healthy, the vital consideration is the importance of the tooth in the stability of the fracture. This is especially cogent in the circumstance of the erupted third molar tooth that lies in an unfavorably aligned fracture of the mandibular angle. In such a fracture, the line extends obliquely from anterior to posterior as it proceeds from the occlusal surface to the inferior border of the mandible. If the molar is in the distal fragment, its occlusion is especially cogent. If the molar is in the distal fragment, its occlusion with the maxillary third molar above it will preclude its displacement. If the molar is extracted the pull of the median pterygoid and masseter muscles will displace the distal fragment upward. The wisdom tooth, being the most poorly calcified in the mouth, is the most susceptible of all to caries. One should probably remove a carious or impacted third molar in such a circumstance and achieve fixation by an open technique.

Any dental trauma can cause pulp necrosis, even without a root fracture. It is important to follow-up patients after facial fractures with vitality testing of the teeth. Once viability is lost, a root canal procedure should be performed to prevent abscess and tooth loss.

The final consideration is that of avulsed teeth. Such teeth should be immediately replaced in the avulsion socket and fixed with wires to the adjacent teeth for splinting. Many such teeth later become nonvital and require a root canal procedure. Most are retained, however, and their
preservation helps greatly in the maintenance of dental arch integrity. A avulsed tooth that remains out of its socket for longer than 1 or 2 hours will likely not survive if reimplanted. It is important to stabilize the tooth in the arch after reimplantation. Some type of bonding material is applied to the face of adjacent teeth and the fixation achieved by a form of banding.

Postoperative Care. Drains are usually placed in open reduction wounds of the body, angle, and ramus. These drains are usually removed on the first postoperative day. Local wound care to the suture line is best done with peroxide cleaning and antibiotic ointment to avoid infection. Introral care should begin as soon as possible and consist of a water pick to the dentition but not the suture line and gargle of a solution of mouthwash and peroxide. The lingual aspect of the denition is inaccessible in the patient with closed reduction in intermaxillary fixation. The effervescence of the peroxide will help to debride the areas of the gingiva and teeth of the lingual surface.18 Patients often complain of pain, especially in the first two postoperative weeks because of the spasm of the pterygoid and masseter muscles while the patient is in intermaxillary fixation. Codeine and acetaminophen with codeine syrup are useful analgesics during this immediate postoperative phase. Persistence of pain beyond 2 weeks requires nonsurgical examination of the operative site as well as a radiographic study to determine whether there has been a shift in the fracture site.

The increased metabolic demands of healing and the difficulty of eating while in intermaxillary fixation make adequate nutrition a common problem. Liquid diets must be supplemented with a protein powder as well as whole milk. It is not uncommon for patients to sustain severe weight loss during the ensuing 6 weeks of intermaxillary fixation. Dietary counseling is often helpful. If the patient remains in intermaxillary fixation, weekly checkups to tighten the intermaxillary wires are absolutely necessary. If the wire ligatures are used for intermaxillary fixation, the wire stretches loosening the fixation. If there is no close contact with the maxillary and mandibular teeth, a lingual version may develop. This results in a severe malunion if not corrected before fibrous union occurs. Tightening of the wires every week prevents this from happening. Dental checkups, when possible, are also necessary in the case of impending dental abscess.

Intermaxillary fixation may be removed 5 to 6 weeks postoperatively, providing that there is no evidence of a nonunion. Nonunion can best be assessed by palpation at the fracture site. If there is pain in the mandible and not the teeth at the operative site, a nonunion or fibrous union should be strongly suspected, especially when accompanied by mobility. A nonunion is the "torque test," which involves placing a standard wooden tongue blade on the side of the fracture and having the patient bite down and break the tongue blade.21 If there is no bone pain with this procedure, a good union has been achieved and the arch bars may be removed. The patient is still cautioned to remain on a soft diet for two to three additional weeks.

When arch bars are removed, a dental consultation is needed to inspect the teeth for occlusal discrepancy. Orthodontia may provide the necessary correction. Major malunions may require ostotomy of the involved segment and repositioning with further intermaxillary fixation. With an accurate initial assessment, careful surgical technique and good postoperative care, the need for further adjustments of occlusion should be infrequent.

Special Considerations: The Edentulous Mandible. The fractured edentulous mandible presents specific management problems for the surgeon. With the absence of teeth, the alveolar cortical bone undergoes total resorption. The superior portion of the mandible is greatly attenuated. The overall height of the mandible, therefore, is much less than that of a tooth-bearing mandible. Maintaining correct mandibular height, however, especially in the case of angle, ramus, and condyle fractures, is essential to avoid possible TMJ problems.

Ideally, in a completely edentulous patient with mandible fractures, the dentures can simply be wired into place. In the maxilla, screws used in plating techniques or Kirschner wires are excellent means of fixing the upper denture to the palate. The lower denture is affixed using circummandibular wires. The patient should be kept in some form of intermaxillary fixation for at least 6 weeks.

A new form of fixation, although less acceptable, is a cap splint. This can be especially helpful in a fracture involving the body or symphyseal area. The cap splint is formed, by placing acrylic over the ridge of the mandible with the fracture, and affixing it to the mandible, using circummandibular wires. Wires are not available for the fracture is in an area that cannot be splinted but intermaxillary fixation is necessary, dental impressions can be made as a template for Gunning splints. Gunning splints can be affixed to the edentulous upper and lower jaw by means of the same techniques used to affix dentures.

Open reduction is necessary in edentulous mandibles with unfavorable "fracture lines" and in severely comminuted fractures. Interosseous wiring can be accomplished in the same fashion as with tooth-bearing mandibles. Intermaxillary fixation, however, must be used in this situation. Compression plating is also convenient in these cases, by way of either the external or intraoral approach. The advantage of using a compression plate is the achievement of rigid fixation, which does not require intermaxillary fixation. In elderly patients, however, especially those with osteoporosis of the mandible, placement of a secure plate may be difficult and may be loosen with time. Compression plating, once the state of the art in mandibular fracture repair, has largely gone out of fashion and has been replaced by the titanium plating systems.

Pediatric Mandibular Fractures. A mandibular fracture in a patient younger than 15 years, requires a knowledge of the state of both permanent and deciduous dentition. The tooth buds of the permanent teeth are located below the roots of the deciduous teeth. Surgical trauma to the tooth buds may retard or completely negate the buds’ ability to erupt later. Primary teeth are fully erupted usually by the second or third year of life. The central incisors are the first teeth to appear, followed by the lateral incisors, the first molars, canines, and second molars. The shedding of these teeth occurs in the same order and is usually complete by 12 years of age. Therefore, in the first 12 years of life, there are tooth buds of permanent teeth or partially erupted permanent teeth that may be endangered by surgery. The presence of these tooth buds also makes the tooth-bearing areas of the mandible in a child more prone to fracture than in an adult. They, in effect, create a more porous bony surface with less structural support.

In the tooth-bearing areas of a mandibular fracture in a pediatric patient, an overlapping cap splint provides adequate, stable reduction to promote anatomic bone healing. Because of the ability of children to heal rapidly, the splint is required only for approximately 4 weeks. In the angle area, if the fracture is in an unfavorable line, open reduction may be attempted. Radiographic documentation of the proximity of the erupting of the third molar bud and second molar tooth bud should always be confirmed. If the fracture line is close to a tooth bud, closed reduction may be necessary. Arch bars can be used in a pediatric patient with wire ligatures; however, they may cause premature shedding of the deciduous teeth. Generally, intermaxillary fixation is not necessary in a child for safe healing of a fracture of the symphysis or body. Condylar fractures in the pediatric population have been seen to remodel completely without surgical intervention; therefore, no treatment is recommended.

Complications in Pediatric Fractures. The tooth buds of an infant or young child are especially susceptible to damage that may cause deformities of the erupted mature tooth later.31 A long-term follow-up study of 28 children with mandibular fractures was done by McGirt and Salisbury.32 The mean length of follow-up was 10.5 years. The children were divided into condylar only, noncondylar fractures, and condylar fractures with other facial fractures. Forty-six percent of the patients had Tmj compromise. Five patients were concerned about their external facial asymmetry, although a medical/dental team reviewed abnormalities in 47% of the patients radiographically. Sixteen percent of the overall group was thought to be both clinically and radiographically abnormal enough to require intervention therapy. Therefore, one can expect nearly one out of five children with a mandible fracture to have some sort of difficulty that may require later intervention. It is recommended that these patients be followed closely postoperatively by a dentist and/or orthodontist, and the use of braces...
and elastics may be necessary to promote growth and development of the fracture area.\textsuperscript{33} The remodeling of untreated subcondylar fractures is well documented.\textsuperscript{33, 34}

**Severe Mandibular Fractures.** If the trauma is from an explosion or a gunshot wound or if the blunt trauma is excessively severe, there can be multiple missing pieces of mandible.\textsuperscript{35, 36} In these cases, open reduction and exploration are mandatory if the patient’s condition permits. The bony fragments that do not have periosteal attachments should be removed, and the area should be debrided and cleaned aggressively. Often in these fractures, there are portions of mandible that are pedicled on small pieces of periosteum. If less than 25% of the bone surface area is attached to periosteum, most surgeons would agree that debridement is necessary to prevent this from becoming a sequestrum.

Gunshot wounds require soft tissue debridement, especially high-velocity wounds in which there may be a large temporary cavity. High-velocity weapons cause extensive soft tissue damage from both the impact of the missile and the secondary-missile effect of fractured bone fragments through soft tissues. The utilization of external pin fixation and the application of the biphase appliance to the mandibular segments alleviates the possibility of infection that would otherwise be incurred by placement of a foreign body such as a plate in a potentially grossly infected wound.

If the wound can be cleaned adequately and soft tissue coverage achieved, a long mandibular plate can be used to approximate the (usually) multiple segments. Once healing has taken place and infection is cleared, in 6 months to 1 year this area can be reconstructed using autogenous bone from a variety of sources or a free flap\textsuperscript{34} (Figure 29).

**ZYGOMATIC FRACTURES**

The zygoma is the third most frequently fractured facial bone, with 85% of fractures occurring in men. Blunt trauma, caused by motor vehicle accidents or sports, make up the great majority of fractures. Fractures of this region are often called trimalar fractures, meaning fractures of the zygomaticotemporal, frontozygomatic, zygomatico-maxillary suture lines\textsuperscript{37} (Figure 30). Indeed, the fracture of the zygomatic sphenoid suture makes these fractures quadramalar.\textsuperscript{7} The zygoma can withstand severe force, but owing to the most lateral extension of the facial skeleton, it is prone to injury in both the anterior–posterior direction and the lateral and transverse directions. The attachments of the temporalis superiorly and the masseter muscle inferiorly tend to neutralize the action of each other. However, the movement of the jaw with the masseter muscle does tend to distract the segments downward and medially.

The arch of the zygoma, which has contributions from both the zygomatic bone and the temporal bone, lies over the coronoid process. A depressed fracture of the arch pushing into the temporal fossa often results in restriction in movement of the jaw because of impingement of the arch on the coronoid process. The fractures of the zygoma tend to occur at the articulations with the aforementioned bones. Although the body of the zygoma, which makes up the inferolateral orbital wall, is often the point of impact from trauma, is rarely fractured because it is the thickest part of the bone. Comminuted fractures of the zygomatic body are a difficult problem in surgical management.

**Surgical Anatomy**

The zygoma has four suture lines connecting it with the temporal, frontal, maxillary, and sphenoid bones. In addition to the temporals and masseter muscles, the lesser and greater zygomatic muscles are also inserted on its surface. The orbital process of the zygoma makes up the anterolateral portion of the infraorbital foramen in the floor of the orbit. It is not uncommon, with a severe zygoma fracture, for there to be a prolapse of orbital contents through the orbital floor due to fracture of the maxillary zygomatic suture line.

![Figure 29](A) Three-dimensional computed tomographic scan of patient with a large defect secondary to self-inflicted high power rifle wound to the face. (B) Preoperatively, the patient can be seen to have loss of mandible and soft tissue of chin and neck. (C) Reconstruction with a fibular free flap.

![Figure 30](Tripod fracture of the zygoma. (Reproduced with permission from reference 38.)}
The infraorbital nerve exits from the infraorbital foramen at the articulation of the zygoma and maxilla. Damage to this nerve causes hypesthesia of the cheek on the affected side as well as the lateral aspect of the nose. From the body of the zygoma exit two sensory nerves, the zygomatic frontal and zygomatic temporal, which generally are clinically insignificant. When discussing a fracture of the zygoma, one must realize the importance of the intimate association to the lateral canthal tendon and the suspensory ligaments of the globe. There is some downward displacement in many fractures of the zygoma because of the previously mentioned traction of the masseter, and therefore the globe position can change. The entire globe can be pulled down because of downward displacement of the suspensory ligament of Lockwood, which attaches to the Whitnall tubercle, located on the lateral aspect of the orbital process of the zygoma. Also associated with the floor of the orbit are the inferior oblique and inferior rectus muscles, which are most often the cause of entrapment when the floor of the orbit is badly fractured (blowout fracture). Impalement of the muscles on a fracture fragment puts the muscle into spasm, which limits upward gaze. True entrapment of these muscles, which is rare, must be corrected surgically.

**Diagnosis**

History and physical examination are of primary importance in evaluating a zygomatic fracture. The patient gives a history of having received a blow from a fist, a ball, or other blunt object or has been involved in a motor vehicle or motorcycle accident. He or she complains of localized pain and often has numbness over the ipsilateral cheek. If there is significant herniation of fat into the maxillary sinus, diplopia ensues from simple herniation of the inferior rectus and inferior oblique muscle. With herniation of orbital fat or entrapment of the inferior rectus and inferior oblique muscle, there is some downward displacement of the suspensory ligament in many fractures of the zygoma because of the previously mentioned traction of the masseter, and therefore, the ligament of Lockwood, causing the same problem of diplopia.

Trismus can result from impingement of the zygomatic arch on the coronoid process of the mandible. Often there is substantial masseter and temporalis spasm from contusion to that area, which may produce trismus even if the arch is intact.

The patient with a zygomatic fracture may also have epistaxis from bleeding into the maxillary sinus; the blood exiting by way of the ostium of the maxillary sinus and nose. On inspection, the patient has severe periorbital ecchymosis and swelling as well as a lateral subconjunctival hemorrhage secondary to tearing of vessels of the canthi. Blood in the anterior chamber (hyphema) indicates severe damage to the globe, and an emergency ophthalmologic consultation is mandatory. Hemorrhage restricted to the subconjunctiva does not imply serious damage to the globe per se. Enophthalmos is common secondary to fat and muscle herniation into the maxillary sinus. Because concomitant intraocular injury is so common, an ophthalmologic consultation should be obtained in all cases.

There is palpable facial skeletal asymmetry over the malar eminence and zygomatic arch if the swelling is not too severe. One may place a gloved finger into the oral cavity to feel the zygomatic buttress and appreciate crepitus and swelling. This movement is exquisite to a patient with a fracture. There is trismus as well as difficult and painful opening of the jaws. The inability to open the mouth more than a 3 cm strongly suggests a fracture involving the zygomatic arch. In the absence of severe swelling, a fracture of the orbit and the infraorbital rim can be palpated. The patient may be unable to raise the affected eye from the equator and experiences diplopia (Figure 31). A forced duction test should be done on all patients with diplopia. A positive test indicates entrapment of the inferior rectus or inferior oblique muscle. Table 3 provides a listing of symptoms and signs of zygomatic fractures.

Zygomatic fractures can be classified according to their severity. An isolated fracture of the zygomatic arch may occur with no orbital involvement. However, most fractures involve the four suture lines previously mentioned. Fracture of the zygomaticomaxillary suture line and orbital floor without involvement of the frontozygomatic or zygomaticotemporal suture line constitutes an impure blowout fracture. A pure blowout fracture refers to a dehiscence of the orbital floor with an intact orbital rim. A severely comminuted body fracture requires extensive exposure and is managed differently than a tripod fracture. The treatment of these various fractures differs, and diagnosis should be confirmed with X-rays.

Standard facial films, including Waters, Caldwell, Townes, and submental vertex views are usually obtained. This battery of films helps rule out associated facial fractures. The Waters and submental vertex views are of greatest help in diagnosis. The Waters view can reveal an orbital floor dehiscence by the teardrop sign indicating herniation of orbital contents into the maxillary sinus. There is often blood in the maxillary sinus, however, which may obscure this finding. Also, the orbital rim frontozygomatic suture line and the body of the zygoma are well visualized with the Waters view. The submental vertex view is excellent for evaluating the zygomatic arch. Although, most zygoma fractures are readily diagnosed on plain radiographs, the CAT scan affords a more accurate rendition of the fracture details. It is especially good at depicting the degree and severity of orbital floor and in detecting fractures of the orbital apex. Subtle unilateral associated fractures of the palate will be detected as well. Three-dimensional CT scanning provides a dramatic view of the fracture.

**Treatment**

The decision to repair a zygomatic fracture should be based on the goals one hopes to attain by such surgical intervention. The only strict indications for surgery are relief of trismus and correction of diplopia from an inferior displacement and entrapment of the inferior rectus and inferior oblique muscles. Most often, the patient desires repair for cosmetic reasons. If there is ipsilateral numbness after a fracture, this improves, in the large majority of cases, with no surgical intervention. Therefore, numbness of the cheek should not be the indication for surgery. When obtaining the patient’s consent for surgery, one must be careful to counsel about the proximity of the globe to the surgical site and alert the patient to the real risk of retrobulbar hematoma and retinal tear from retraction of the globe. These complications are extremely rare with careful surgical technique. Also important in preoperative counseling, if an infraorbital rim approach is needed, is the need to inform the patient of the possibilities of prolonged lower lid edema and ectropion. The onset of visual field changes, diplopia, or a change in the patient’s visual acuity required an ophthalmologic consultation.

One of the possible occult injuries of a zygomatico-orbital fracture is a retinal tear. Traction of the globe during surgery to repair a zygoma may extend a small, insignificant retinal tear, creating a large visual field defect. This can be avoided by limiting retraction of the globe to short periods of time and using extreme caution.

Serious intraocular injury mandates delay of repair until the globe has stabilized. Otherwise, the timing of the repair of a zygomatic fracture depends on the degree of soft tissue swelling. If swelling is severe, waiting for 5 to 10 days is acceptable and reducing the zygoma will not be
a significant problem during that time. After 10 to 14 days, the zygoma may form a fibrous union, making mobilization of the fracture difficult. A good rule of thumb is to reduce the fracture as soon as the swelling has subsided enough to compare both zygomas intraoperatively.

**Surgical Technique.** Multiple techniques have been used to repair a zygomatic fracture. The four fracture lines imply that there should be 4 points of fixation to stabilize the fracture, both laterally and inferiorly. The technique of placing a plate or wire in the frontozygomatic fracture line and the zygomaticomaxillary suture line at the infraorbital rim provides adequate stabilization for a large majority of fractures. Some fractures treated in this manner are not adequately stabilized and require antral packing or an intraoral approach to reduce the inferior aspect of the fracture. One-point fixation techniques have been described using, either a Kirschner wire or more recently, a rigid miniplate.

Fractures of the zygomatic arch (Figure 32) with a significant cosmetic defect or trismus can be elevated by means of a Gillies incision in the temporal hairline and reduced directly. The temporal branch of the facial nerve is avoided by placing the elevator deep to the superficial fascia of the temporalis muscle. The Boies elevator is placed under the arch, and the fragments are lifted into position. A plate is rarely required for fixation because of the splinting action of the underlying temporalis muscle. It is vitally important not to lever the arch into position. The point of the fulcrum becomes the lateral wall of the skull which can be fractured when a lot of force is required for arch reduction.

For the repair of the more commonly occurring trimalar fracture, two principal open approaches are used: the transfacial and the bicoronal scalp approach. These approaches provide good visualization of the rim and orbital floor while, at the same time, decreasing the chance of trauma to the infraorbital nerve (Figure 36A). If there is a significant dehiscence of the orbital floor (>1.5 cm) or entrapment of the inferior rectus or inferior oblique muscle, a graft of malar bone, nasal septum, gel film, or suitable alloplast should be used to repair the defect. We recommend homografts to reconstruct the floor and feel the danger of migration or extrusion with silastic sheeting prohibits its use.

Titanium rigidly placed mesh has been added to the armamentarium of alloplasts to reconstruct the orbital floor. Initial results are encouraging, but the implant will need to stand the test of time.

When performing the more commonly used open approaches, the transfacial approach begins with a supraorbital brow incision made within the brow line or as an extended upper blepharoplasty incision (Figure 33), and the frontozygomatic suture line is exposed. The approach to the infraorbital incision varies depending on the surgeon’s discretion. Choices include a transconjunctival approach (Figure 34) or an approach through the skin of the lower lid at various distances from the grey line of the lower lid. The placement of the subciliary incision should be along the crease and should be at least 3 to 4 mm below the ciliary line to avoid ectropion and prevent lid edema. The author advocates the stair-step technique (Figure 35), in which a skin flap is elevated, leaving the orbicularis oculi muscle intact to prevent fat herniation from obstructing visualization of the fracture. Once the step incision of approximately 4 mm in length is made, an inferior skin flap is elevated over the orbicularis oculi muscle until the maxilla inferior to the infraorbital rim can be palpated. Using a pair of Steven scissors, the muscle is split in the direction of its fibers and carried down to the maxilla below the infraorbital rim. The periosteum is entered below the infraorbital rim to avoid interruption of the orbital septum that may cause later scarring and ectropion. The orbicularis oculi muscle and orbital septum are retracted superiorly.

These approaches provide good visualization of the rim and orbital floor while, at the same time, decreasing the chance of trauma to the infraorbital nerve (Figure 36A). If there is a significant dehiscence of the orbital floor (>1.5 cm) or entrapment of the inferior rectus or inferior oblique muscle, a graft of malar bone, nasal septum, gel film, or suitable alloplast should be used to repair the defect. We recommend homografts to reconstruct the floor and feel the danger of migration or extrusion with silastic sheeting prohibits its use.

Titanium rigidly placed mesh has been added to the armamentarium of alloplasts to reconstruct the orbital floor. Initial results are encouraging, but the implant will need to stand the test of time.

A Boies elevator is placed into the infratemporal fossa from the brow incision, beneath the orbital floor. Initial results are encouraging, either a Kirschner wire or more recently, a rigid miniplate. When performing the more commonly used open approaches, the transfacial approach begins with a supraorbital brow incision made within the brow line or as an extended upper blepharoplasty incision (Figure 33), and the frontozygomatic suture line is exposed. The approach to the infraorbital incision varies depending on the surgeon’s discretion. Choices include a transconjunctival approach (Figure 34) or an approach through the skin of the lower lid at various distances from the grey line of the lower lid. The placement of the subciliary incision should be along the crease and should be at least 3 to 4 mm below the ciliary line to avoid ectropion and prevent lid edema. The author advocates the stair-step technique (Figure 35), in which a skin flap is elevated, leaving the orbicularis oculi muscle intact to prevent fat herniation from obstructing visualization of the fracture. Once the step incision of approximately 4 mm in length is made, an inferior skin flap is elevated over the orbicularis oculi muscle until the maxilla inferior to the infraorbital rim can be palpated. Using a pair of Steven scissors, the muscle is split in the direction of its fibers and carried down to the maxilla below the infraorbital rim. The periosteum is entered below the infraorbital rim to avoid interruption of the orbital septum that may cause later scarring and ectropion. The orbicularis oculi muscle and orbital septum are retracted superiorly.

These approaches provide good visualization of the rim and orbital floor while, at the same time, decreasing the chance of trauma to the infraorbital nerve (Figure 36A). If there is a significant dehiscence of the orbital floor (>1.5 cm) or entrapment of the inferior rectus or inferior oblique muscle, a graft of malar bone, nasal septum, gel film, or suitable alloplast should be used to repair the defect. We recommend homografts to reconstruct the floor and feel the danger of migration or extrusion with silastic sheeting prohibits its use.

Titanium rigidly placed mesh has been added to the armamentarium of alloplasts to reconstruct the orbital floor. Initial results are encouraging, but the implant will need to stand the test of time.

bony union with the coronoid pro-

t process. An unreduced fracture of the zygomatic arch

or one that is incompletely elevated into position

may form a bony union with the coronoid arch from collapsing with some pressure, but it will remind the patient not to roll on that side of the face while sleeping. This protective device is best retained for at least 2 weeks but can be removed when the patient is not sleeping. The zygoma guard is necessary in patients who have had interosseous wiring of a trimalar fracture, a reduced but not rigidly fixed arch fracture or an unstable fracture with multiple comminution. Most fractures fixed with a rigid plating system will not need the guard.

Routine wound care is administered in the postoperative period and the sutures should be removed within 3 to 5 days. Diplopia from the operation surgery may not be resolved for up to 2 months. If there is postoperative diplopia and a thorough exploration of the orbital floor revealed

the infraorbital incision superiorly and the upper brow incision laterally. Either a rigid miniplate or a multiple interosseous wires can be used to fix multiple comminuted body fractures. When interosseous wiring is used for the compound body fracture, it is sometimes necessary to maintain elevation of the zygoma as it tends to prolapse. This can be done with an external pin fixation device such as a Morris biphasic appliance.

Figure 35

their approximation may need to be done with fine wire or suture material. Some surgeons add an additional plate at the inferior aspect of the zygomatic buttress. This will require an additional incision in the gingival buccal sulcus like an extended Caldwell-Luc incision. A subperiosteal elevation will expose the under side of the zygomatic buttress. In most trimalar fractures, this step is entirely unnecessary.

Compound comminuted fractures of the body (Figure 37) require a direct approach to the way of either a coronal scalp incision or extending

the infraorbital incision superiorly.

no significant blowout fracture, the patient may be managed expectantly with a good prognosis. Unrepaired zygoma fractures often lead to cosmetic deformity. Because of the pull of the mas-

ster, the zygoma is distracted in a downward and medial direction. This type of deformity causes lack of cheekbone prominence and an increase in orbital volume.

Enophthalmos is the result of failure to reduce an orbital floor fracture properly, with subsequent atrophy of herniated orbital fat. The actual orbital volume is increased if the zygoma heals in a rotated position. If orbital volume is increased appreciably, the remaining orbital contents are insufficient to maintain normal anterior protrusion of the globe, resulting in the "sunken eye" appearance of enophthalmos. In rare instances, postero-medial displacement creates a smaller orbital compartment and a concomitant exophthalmos.

In the nonseeing eye, the problems of enophthalmos can be corrected with minimal risk. All grafts or autogenous material may be placed in the orbit to increase orbital volume. Bony deformities are treated with onlay grafts or osteotomies of the zygoma with interposed calvarial bone grafts. Enophthalmos in a person with vision can safely be corrected with calvarial bone grafts to the orbital floor. The use of other material such as titanium mesh or mesh covered in hydroxyapatite bone cement has also been advocated. Danger to the optic nerve and of extrusion or migration of alloplastic material makes this procedure potentially hazardous.

An unreduced fracture of the zygomatic arch or one that is incompletely elevated into position may form a bony union with the coronoid process of the mandible. This is a rare complication but will produce severe trismus that can only be eliminated by an open osteotomy and rigid fixation of the arch. Removal of the bony connection between the arch and the coronoid is essential, and placement of a silastic sheet between the two bony structures may be necessary to prevent a relapse. The silastic may have to be removed at a future time; but, if it is not problematic, it may remain indefinitely.

Anatomy

The maxillae are the large paired bones of the midface that are approximately box shaped and almost fully pneumatized by their own sinuses. The lateral wall is a part of the infratemporal fossa and articulates with the zygoma superiorly and the temporal bone posteriorly. The anterior wall has a medial articulation with the nasal bones by way of the frontal process of the maxilla, which extends along the pyriform aperture up toward the bony orbit to form the anterior crest of the lacrimal fossa. The medial wall is intimately associated with the ethmoid complex superiorly as well as the inferior turbinate. The posterior wall is relatively more substantial than the anterior wall “protecting” the pterygomaxillary fossa and its nerves and vessels. Posteriorly, the maxilla also communicates with the sphenoid bone, both superiorly with the inferior aspect of the greater wing of the sphenoid and posterolaterally with the pterygoid plates. The vomer, ethmoid complex, palatine bones, zygoma, and nasal bones should also be considered part of the midface. One or all of these bones are often fractured in Le Fort fractures, although they may not all need direct treatment.

Le Fort Fracture Classification. Le Fort classification refers to the lines of the three most common types of midface fractures (lineae minores resistentiae) (Figure 39). The Le Fort I fracture is a lower palatal fracture also called the Guérin fracture. Le Fort II fractures are also referred to as pyramidal fractures. Le Fort III fractures are also known as craniofacial disjunctions.

The Le Fort I fracture involves the floor of the nose, lower third of the maxilla, palate, and pterygoid plates, usually in one segment. The Le Fort II fracture occurs across the nasal bony superstructure and the frontal process of the maxilla, down across the face of the anterior wall of the maxilla, and orbital floor, including the infraorbital foramen. The fracture line goes through the lateral wall of the maxilla extending to the pterygoid plates, usually higher than the Le Fort I. Le Fort III fractures extend laterally across the orbital floor into the lateral orbit through the zygoma. They can include the frontal zygomatic suture line. If the zygoma moves during palpation of the palate with movement, a Le Fort II fracture is present.

Le Fort fractures are commonly found in combinations. A Le Fort I fracture may have an associated Le Fort II or III on the side of impact. A Le Fort II fracture may be a Le Fort III fracture on the side of the impact. The exact classification of the fractures on each side is important because of the differences of treatment associated with the various types. One should refer to the fractures based on the type of fracture on each side, for instance, left Le Fort III or right Le Fort I.

The Structural Pillars of the Midface. Le Fort’s classification was surprisingly complete in its description of the midfacial fractures, although there are certain limitations to his original description. The classification of Le Fort fractures is based on the most superior fracture line involved in the fractures and does not take into account the facts that many of the fractures of the midface are comminuted and that within the confines of the midfacial skeleton these multiple fractures may take on many configurations. The concept of the structural pillars of the midface (Figure 40) helps to elucidate the key areas of fracture and, therefore, the subsequent stabilization of the midface as it relates to both potential cosmetic deformities and functional problems. An understanding of these structural pillars not only aids in assessment of the severity of the fracture but also provides an excellent strategic framework for surgical intervention.

There are three main buttresses of the midface-cranial complex. Going from anterior to posterior, the anteriormost buttress is the

MAXILLARY (LE FORT) FRACTURES

Causes

Fractures of the midface, commonly referred to as Le Fort fractures, occur with much less frequency than fractures of the mandible, zygoma, or nose. Most often, they are the result of blunt trauma from accidents in automobiles, motorcycles, snowmobiles, or boats. The force required to fracture the maxilla and pterygoid plates of the sphenoid, which are the two fractured bones common to all Le Fort fractures, is considerable. Because of the alignment of the buttresses of the midface, which protect this area from vertical displacement, most of these fractures are caused by horizontal forces from the lateral, oblique, or anterior direction. The cranium and the orbit are intimately associated with these injuries and should be addressed with a high index of suspicion in all patients with midface injuries.

In the early 1900s, Rene Le Fort described the common lines of fractures associated with severe blunt trauma to cadaver heads. Although his descriptions are not characteristic of many compound midfacial fractures, they do serve to stage the degree of severity of the fractures and also alert the physician to concomitant antecedent injuries that are peculiar to the three types of fractures. It is much more accurate to describe an injury in such terms as a compound palatal zygomaticomaxillary or maxillonasal fractures. Because of the number of bones in the face that can be associated with large compound midfacial injuries and because many of them are not surgically accessible by any means other than that associated with those injuries, the classic descriptions of Le Fort become useful indices for patient management and as the tools for communication between physicians of different specialties.
The orbital process of the palatine bone and pterygoid plates extending inferiorly and anteriorly toward the maxilla. The horizontal system of buttresses divides the oral, nasal and orbital regions of the face.

If one considered these pillars in midfacial fractures, therapy should be directed toward the stabilization of as many of these buttresses as possible. Probably the two most important areas of stabilization are the nasomaxillary buttress and the zygomaticomaxillary buttress. The more posterior vertical pterygomaxillary buttress is more inaccessible surgically, although the most inferior portion of it can be stabilized if necessary. In severely comminuted Le Fort fractures, the surgeon must appreciate the advantage of open reduction and internal fixation of multiple fragments in their anatomic positions, especially those relating to this buttress complex. Without proper reduction of the midface fractures or proper stabilization of concomitant subcondylar mandible fractures, there is always the possibility of midfacial telescoping, which results in a shortened midface.51-53

Diagnosis
Eliciting an accurate history on a patient with severe midfacial injury is often difficult or impossible because of associated intercranial, abdominal, or intrathoracic injuries. The motor vehicle accident victim may also be inebriated. If the patient is conscious, however, and does not have any life-threatening injuries requiring emergency surgical intervention, a thorough history is helpful in ascertaining the extent and severity of facial injury.

Because the maxilla forms the anterior floor of the orbit, there may be herniation of the orbital soft tissues into the maxillary sinus, similar to that seen in a blowout fracture. Diplopia is a complaint in Le Fort II or Le Fort III fractures. Complaints of blurred vision or a change in visual acuity mandate an ophthalmologic evaluation. Epiphora may also be a component of compound fractures involving the lacrimal duct and/or the inferior medial orbital area. Difficulty in breathing is a common problem from congestion associated with edema from the fractures as well as physical derangement of the nasal bones and septal structures. The commonest cause of upper airway obstruction in these patients is the posterior inferior displacement of the maxillary segments by the pull of the medial pterygoid muscles, which pull the maxilla via the pterygoid plates toward their insertions at the lingual surface of the mandible. Bleeding from the maxillary or ethmoid ostia or from lacerations within the nasal cavity may cause severe nasal obstruction. Patient complaints of a salty taste in the mouth should alert the physician of the possibility of a cerebrospinal fluid leak. Most commonly these are found in the cribiform plate or the roof of the ethmoid sinuses.6,7 Displacement of the maxilla causes the patient to complain of malocclusion. Although there may be either buccal or lingual version, the most common occlusal abnormality is an open-bite deformity. The open-bite deformity is caused by the powerful forces of the pterygoid muscle distracting the posterior part of the maxilla inferorly.7 A blow from the front causes displacement of the maxilla posteriorly, resulting in a so-called “dish face” deformity and resulting in a Class III malocclusion. A more detailed discussion is of occlusal abnormalities is in the section on mandible fractures.

Airway compromise is often the presenting problem and must be immediately addressed by the establishment of an emergency airway, either a tracheostomy or if feasible a tracheostomy. Intubation is dangerous especially by the nasal route because of accidental passage of the tube intracranially. In the author’s opinion, most patients with Le Fort fractures require a temporary tracheostomy.

On physical examination, the patient may have periorbital ecchymosis, massive tissue swelling, or subconjunctival hemorrhage if the infraorbital rim is involved. Dental examination confirms the previously mentioned findings relating to open bite, lingual/buccal version, and Class III malocclusion. Bony crepitus of the midface, especially in severely comminuted injuries, is common. Also, extensive fractures in the presence of a large communication with the anterior part of the antrum and the nose cause subcutaneous emphysema.

Nasal or pharyngeal hemorrhage may be massive. This is important because most patients are evaluated in the supine position. Nasal and pharyngeal bleeding drain toward the posterior part of the pharynx and may go unnoticed. Palpation reveals a mobile palate. If the palate does not move even though there appear to be gross occlusal differences and/or obvious fractures, it is because the midface has impacted into an immobile position.54 To move the palate in these cases may require excessive force. Pain in the areas of the fractures are exacerbated by attempting to bite down. The patient may notice the mobility of his midface on moving his jaws. The complaint of amaurosis suggests either intraocular injury or damage to the optic nerve. Progressive blindness in the presence of a fracture of the optic canal constitutes the major indication for orbital decompression among those individuals who are proponents of this procedure. Despite years of controversy and discussion over the value of orbital decompression, definitive evidence as to its efficacy is still wanting. However, I think that in a patient with failing vision with an optic canal fracture not responding or worsening with a short course of large doses of corticosteroids, surgical decompression is indicated.

Imaging
Radiologic diagnosis of Le Fort fractures is an important adjunct to their treatment. Many midfacial fractures can be assessed with routine sinus X-rays, but the precision of the CT scan is a huge advantage in delineating the extent and severity of midfacial fractures. Central injuries can be
ruled out by extending the scan through the head, any nasal-frontal or frontal sinus components can be delineated and fractures of the sphenoid and orbital apex are excellently portrayed. Scans in both the axial and coronal planes are necessary for the most complete analysis. MRI is of little added assistance except in the case of cerebral trauma or compromise of the optic nerves. Three-dimensional reconstruction, although spectacular to look at, offers little additional information that will guide therapy.

**Treatment**

As in all patients involved in trauma, the fundamental precepts of trauma care apply. The airway is of great importance in these patients. A displaced Le Fort fracture can compromise the airway, especially if it is associated with concomitant massive swelling of the tongue and oropharynx.6,7 A cricothyrotomy may be required urgently. Endotracheal intubation should be avoided because of the problems of poor visualization, the possibility of aggravating a cervical spine injury, and possibly causing injury to the central nervous system from the endotracheal tube. Nasotracheal intubation is even worse because of the danger of intracranial intubation through a fracture line in the skull base. Tracheostomy preferably should not be done in the emergency room but performed electively in the operating room. All other injuries should be ruled out, including intra-abdominal, intrathoracic, and intracranial injuries. The cervical spine should undergo radiographic evaluation.

If the patient is to undergo immediate general anesthesia for a related injury and is hemodynamically stable, immediate repair can be undertaken if good radiographic documentation of the injury has been obtained. Often, if a patient is rushed to the operating room because of a life-threatening injury, proper radiographs may not have been obtained and, if a Le Fort fracture is suspected, the patient should be placed temporarily into intermaxillary fixation and undergo tracheostomy. In this emergency situation, the patient can be more fully evaluated radiographically at a later time to ascertain the extent of the midfacial fractures.

Definitive repair of all fractures may be delayed for up to 10 days before bony union may make reduction difficult. Thorough preoperative planning to repair these fractures includes ophthalmologic examination, dental evaluation, and clearance by neurosurgeons if there are concomitant intracranial injuries. Repair should also be delayed until the status of the cervical spine is determined.

**Surgical Approaches.** Incisions used to approach midfacial fractures vary according to the specific location of the fracture. Isolated Le Fort I fractures are usually approached by an extended sublabial incision (Figures 41 and 42). This incision allows exposure of the zygomaticomaxillary buttresses and pyriform apertures bilaterally. If the fracture involves the infraorbital rim (Le Fort II), a transconjunctival-lateral canthotomy or subciliary incision is usually used to expose these fracture sites. If a Le Fort II fracture is more extensive and greater exposure to the nasoethmoid complex is required, an external Lynch incision or extended coronal incision may be used. The frontozygomatic suture line may be approached with a coronal, brow, or extended upper blepharoplasty (supratarsal) incision. The coronal incision has the advantage of providing exposure to the zygomatic arch and the nasoethmoid region. This incision obviates the need for a Lynch incision for nasoethmoid exposure.
The incisions used depend on the location and extent of the fractures. Most Le Fort fractures do not manifest as the original description, but these are combinations of complex fractures of the midface and require knowledge of multiple surgical approaches.

In patients with dentition, arch bars and intermaxillary fixation are initially applied to reestablish pretrauma occlusion. In edentulous patients, a splint or denture containing an arch bar is fixed to the mandible or maxilla to reestablish appropriate skeletal relationships. This is performed with circummandibular wires or drop wires from the pyriform rim or zygoma. The maxillary (palatal) splint may also be fixed to the palate with two transpalatal screws. In any case, splints or dentures are placed to reestablish the occlusal and skeletal relationship.

In patients whose midfacial fractures are displaced, disimpaction of fractures may be required before placement of intermaxillary fixation. Disimpaction is best achieved by use of the Rowe-Killey disimpaction forceps (Figure 43). The straight blade is placed in the nasal cavity along the nasal floor and the curved blade over the alveolar ridge and along the palate. Grasping the handles firmly a downward and anterior pull will disimpact the maxilla and restore it into its normal relationship with the mandible and skull base. After the occlusal relationship is reestablished, all fracture sites are fully exposed. The facial skeleton should then be reconstituted in three dimensions: height, width, and depth. Careful attention should be paid to reestablishing all important facial buttresses. In particular, the vertical zygomaticomaxillary and nasomaxillary buttresses should be carefully reduced and fixed to reestablish vertical facial height. All rigid fixation should be applied with sufficient stability to counteract any forces that could disrupt bone repair during healing.

For a Le Fort I fracture, a two-point stabilization at the nasomaxillary and zygomaticomaxillary buttresses is established on each side. Titanium low profile miniplates in an “L,” “X” or square configuration are placed on the anterior buttresses and usually an “L” shaped plate on the under-curve of each zygoma onto the maxilla bilaterally (Figure 44). More recently, in some cases, low-profile absorbable plates of polymers comprising polyglycolic or polylactic acid or a combination have been employed in place of titanium plates. These plates are reputed to retain sufficient strength to maintain fixation over the critical period of healing and then are absorbed. This especially is an advantage in children in whom the metal plates may impede bony facial growth at suture lines. In adults, the principal advantages of absorbable plates are in preventing pain that occasionally occurs with the metal plates and eliminating the palpable plate at the lateral and infraorbital rims once they have been absorbed. The durability and utility of absorbable plating systems have yet to stand the test of time. Le Fort II fractures require fixation at the infraorbital rim and the zygomaticomaxillary buttress. If the nasal bones are comminuted, microplates...
entrapment, a patent nasal airway bilaterally and functional elements must be restored, such as the fixation proceeds. First, the supporting buttresses Fort III fracture must be clearly borne in mind as tion. The goals of reduction and fixation of the Le fractures is vital to ensure this relationship. Displaced subcondylar fractures must be fixed in a correct position to establish the occlusal point and the mandible the inferior. All forms. The cranium provides the superior stabili- zation point and the mandible the inferior. All displaced fractures of the cranial vault must be rigidly fixed in a correct position to establish the occusal template for the maxillary dentition to approximate accurately. Rigid fixation of all mandibular fractures is vital to ensure this relationship. Displaced subcondylar fractures must be fixed to provide the stable platform even when only unilateral. Undisplaced subcondylar fractures are usually sufficiently stable to avoid rigid fixation. The goals of reduction and fixation of the Le Fort III fracture must be clearly borne in mind as fixation proceeds. First, the supporting buttresses of the face must be reestablished. Second, the functional elements must be restored, such as the correct orbital volume, including an adequately restored orbital floor with orbital contents free of entrapment, a patent nasal airway bilaterally and maxillary sinuses that will adequately drain. Third, all-important aesthetic landmarks must be restored, such as the orbital rims, nasal dorsum, and malar eminencies. It is not necessary and in some instances, is indeed impossible to approxi- mate every small maxillary fragment. The lateral orbital rims and the buttresses are fixed with miniplates and the nasal dorsum and infraorbital rims with microplates (Figure 45). Occasionally small fragments in key positions may require fix- ation with fine wire or even suture material. The use of titanium wire will prevent interference in subsequent scans.

If rigid fixation is considered stable and if the patient is compliant, intermaxillary fixation may be removed at the conclusion of the operation or within the first 1 to 2 weeks after the operation. If the stability is in question, that is, with bone comminution or bone loss, intermaxillary fixa- tion should be left in place for up to 6 to 8 weeks. This will help maintain the occlusion while bone healing occurs.

**NASOFRONTAL-ETHMOIDAL FRACTURES AND TRAUMATIC TELECANTHUS**

A central blow to the face created by a small diameter object, such as the head of a hammer, may not produce a Le Fort type maxillary fracture, but if of sufficient force, may cause a severe comminuted nasal fracture that shatters the medial orbital walls and telescopes into the ethmoid block lodging the fractured bones under the nasal process of the frontal bone (Figure 46). Not uncommonly this nasofrontal-ethmoidal fracture will be accom- panied by telecanthus that result from either the shearing away of the medial canthal tendons or a displacement of the lacrimal and maxillary bone onto which the tendon or tendons insert. The nasal dorsum is essentially displaced into the fractured anterior ethmoid sinuses (Figure 47). This injury produces a typical clinical picture of a patient with a “pig nose” deformity consisting of a flattened nasal dorsum with an exaggerated excessively superiorly rotated tip (Figure 48).

The telecanthus may be unilateral or bilateral. The natural contraction of the orbicularis oculi, whose tendinous extension comprises the bulk of the medial canthal tendon, pulls the medial canthus away from the midline. This produces a blunting of the medial canthus, with a widening of the medial canthal angle, a shortening of the width of the palpebral fissure, a slight ectropion and an inferior inclination of the medial canthus (Figure 49). The width of each palpebral fissure should normally be the width between both eyes, approximately 25.5 to 37.5 mm in adult women and 26.5 to 37.8 mm in men. With this injury, there is usually the absence of the “bowstring” sign. If tension is created in the medial canthal tendon of the normal eye by pulling laterally on the lateral canthus of the eye, a taught bowstring-like sensa- tion is felt by the palpat ing finger. If instead there is a soft, loose boggy feeling at the inner canthus, the presence of a ruptured tendon is highly likely. In addition, there may be injury to the lacrimal system with fracturing of the bony nasolacrimal duct. This will produce epiphora. Epiphora may also result from the loss of the effectiveness of the “lacrimal pump” mechanism. This is formed by the splitting of the medial canthal tendon into two slips of tendon which then insert onto the lacri- mal bone both anteriorly and posteriorly to the lacrimal sac. With slackening of the tendon by displacement of the medial canthal tendon, the pump is unable to function effectively.

At times the nasal skeleton is so badly com- mitted that the small fragments cannot even hold the small 0.8 mm screws required for microplate fixation. A solution to this is the use of suspension wires and lead plates. The wires are driven from one side of the nose to the other with the nasal skel- eton in the reduced position. The wires penetrate skin, the nasal bone, and ethmoid sinuses on one side then pass through the septum and the same structures of the other side (Figures 50 and 51). It
must be remembered that the plates act simply as anchoring sites for the wires and not as a means of narrowing the nose. Over-tightening of the wires can lead to underlying skin necrosis. The wires are removed after 3 weeks.

Obtaining an excellent cosmetic result in the reduction of dislocated medial canthal tendons is one of the most demanding tasks in the surgery of facial trauma. The repair is best done as soon as possible after the accident. Late repairs are notoriously noted for their less than optimal results. Often the tendon comes away with a fragment of attached lacrimal bone. In those instances, two small holes are placed in the bone that will serve as anchor points for the wire used in fixation. If no anchoring bone exists, some kind of stabilization must be created to prevent the wire from pulling through. The Kazanjian button may be created by twisting the two wires passed through the tendon into the configuration of a rosette.57 Another method is the use of a Dacron bolster (Figure 52) that is usually used to stabilize hemostatic sutures placed in the aorta.58 In a unilateral canthal repair, the wire can be secured to the bone of the medial wall of the opposite orbit. If enough bone of adequate strength is present on the ipsilateral side, that would be preferable. A bone graft on the opposite side of the nose can be used or even two holes in a microplate that has been used to stabilize the nasal bones. It is vital to place the tendon high and posterior with some small overcorrection as some degree of relapse is almost inevitable.

The worse injury is the bilateral lateral canthal tendon avulsion. The Converse-Hogan open sky technique is probably the most effective59 (Figure 53). This method wires one canthal tendon to that of the opposite side and supports the skin of the nasal area with lead plates.

**Bone Grafting**

In some patients with midfacial fractures, bone comminution or bone loss prevents proper reestablishment of facial buttresses. Loss of vertical height with midfacial shortening can result. When this condition is recognized, immediate bone grafting is indicated.53 Grafting is usually performed by harvest of split calvarial bone grafts. These grafts have a good viability and stabilize fixation in cases with significant bone loss.

**Figure 53** Bilateral medial canthal tendon avulsion repaired using the Converse-Hogan “open sky” technique. (A) Incisions opened. (B) Fractures are reduced. (C) Two pairs of wires inserted—one through the medial canthal tendons (above), the second through the adjacent nasal bones (below). (D) Wires are tightened, bringing canthal tendons into position. The wires are twisted together over each avulsed tendon, pulling the tendons together. Tendons are supported, and soft tissue is splinted by Tefla pad-Silastic-lead plate assembly (see Figure 51).

**Figure 54** Incisions used for access for frontal sinus fracture repair. (A) Butterfly incision. (B) Coronal scalp incision.

**Figure 55** Through-and-through frontal sinus fracture. (Reproduced with permission from reference 55.)
In these patients, intermaxillary fixation usually should remain in place for at least 6 weeks. In patients with severely comminuted nasal bones, in whom an aesthetically acceptable nose cannot be created, an onlay graft cantilevered from the forehead using a microplate can restore a more normal nasal dorsum. Small areas of avulsed or missing bone can also be replaced with hydroxyapatite bone cement.60

FRONTAL SINUS FRACTURES

Despite the use of the shoulder harness in automobiles, frontal sinus fractures still occur with regularity. The old-fashioned lap belt that restrained the passenger in the seat during the impact of a car crash unfortunately allowed the face to move forward, striking the dashboard with the frontal calvaria often fracturing the frontal sinus. A considerable amount of force is required to fracture the anterior wall of the frontal sinus because of its arch configuration and thickness. In Nahum’s study, it was apparent that it took more foot-pounds of force to break the frontal sinus anterior wall than any other facial bone including the symphyseal area of the mandible and the zygomatic body.61

The problems of the frontal sinus center around the issues concerning the cavity, the duct and the mucosa. The cavity on each side has a thick anterior wall but thin posterior and inferior walls. It has only one point of egress; a funnel shaped structure at the anteromedial part of the frontal sinus floor that empties into the middle meatus of the nose. According to Lang, 77.3% of individuals have a frontonasal duct and 22.7% have a foramen.62 A fractured or even damaged duct has a marked propensity to undergo stenosis. The mucosa of the sinus cavity acts in a uniquely pathologic manner when traumatized. It has a tendency not to reconstitute itself with normal-appearing and normal-behaving mucosa as the other paranasal sinuses do when they are injured. In the frontal sinus, damaged mucosa has a propensity for subepithelial fibrosis, especially in the area of the frontonasal ducts. Furthermore, it has a tendency to form cysts, some of which will enlarge and erode bone; the resulting mucocele may become infected and form a mucopyocele. Both have the notable characteristic of eroding bone.63,64

For the sake of treatment considerations frontal sinus fractures can be classified as: anterior wall, posterior wall, nasofrontal duct, and “through and through.” They can further be classified as: linear, displaced, compound, and compound with “missing bone.” A treatment algorithm has been designed that specifically addresses each site and each type of fracture, bearing in mind that seldom do single fractures occur in isolation. However, with each site and each type, different therapeutic solutions should be invoked. Therefore, in any given patient, some combination of procedures should be employed to repair the fracture adequately and safely.

Linear fractures of the anterior frontal sinus wall require no operative intervention. Depressed fractures must be opened, the fragments elevated, and all mucosa entrapped between the fragments excised. The fragments are restored to their normal anatomic position and fixed with miniplates. Exposure is through a coronal scalp flap or the so-called “butterfly incision” (Figure 54). If the patient has a compound fracture the exposure can be gained by extending the laceration into a natural crease line in the forehead.65

Displaced posterior wall fractures are notoriously difficult to diagnose even with fine-cut CT scanning. In the author’s opinion, all posterior wall frontal sinus fractures should be opened. Even when a small amount of displacement occurs, mucosa can be entrapped and grow into the anterior cranial fossa or form a mucocele. Because the victims of trauma are often hard to follow clinically, the first subsequent presentation of a patient that has been followed rather than operated upon may be in the emergency department with meningeitis or a brain abscess. The treatment of choice is the osteoplastic flap and fat obliteration procedure.

The area of the frontal sinus that is the most difficult to visualize radiographically is the region of the frontonasal duct. The most important radiographic sign is the presence fluid in the sinus as demonstrated by sinus opacification. If this persists over a 3-week period, the index of suspicion regarding the possibility of a duct fracture should be high. If the patient has sustained an anterior wall fracture and early intervention for its repair is undertaken, at the same time, a sinus endoscopy can be placed through the site of the fracture and the duct visualized directly. If, however, there is a suspicion of an isolated duct fracture, a trephine hole in the orbital roof will provide access to wash the sinus out with saline, instill some cocaine and place a radiopaque dye within the sinus cavity. A subsequent radiograph will show presence of the dye in the nose if the duct is patent and absence of the contrast material if the duct is fractured. Surgical treatment of the fractured duct is somewhat controversial. The author prefers to do the osteoplastic flap and fat obliteration operation to eliminate the duct. Others prefer the Lynch procedure combined with a nasal septal or medially based lateral nasal wall flap; the so-called Sewall-B oyden flap.66 Removal of the intersinus septum will allow egress of mucus from the fractured to the non-fractured side. More lately, the interest in functional endoscopic sinus surgery has prompted some to do a conservative removal of the duct through the nose. They have yet to stand the test of time.

The most serious of all the frontal sinus injuries is the “through-and-through fracture.”67 In this dramatic injury, the frontal skin is lacerated, both anterior and posterior walls of the sinus are fractured, often with extensive comminution, the dura is torn and the brain contused (Figure 55). The frontal sinus is often merely an inferior extension of a larger compound cranial fracture. Approximately 50% of these patients affected by a through-and-through injury die at the scene of the accident. Often the first encounter with the patient by the otolaryngologist is during the craniotomy being done by the neurosurgeon to remedy the patient’s intracranial injuries. Usually

![Figure 56](image-url)

**Figure 56** Repair of through-and-through fracture of the frontal sinus. (A) Anterior craniotomy completed. (B) Anterior wall fragments are cleansed and stored. Fracture of both sinus walls, dural rent, and damaged brain exposed. (B) Brain debrided, dura patched, and posterior wall remnants removed with double-actioned rongeur. (C) Removal of remaining posterior wall of frontal sinus producing craniolization. (D) The mucosa of the sinus is removed from the sinus lumen, the nasofrontal duct mucosa is inverted on itself and the frontonasal ducts are plugged with temporalis muscle. a large anterior craniotomy has been done. Once the neurosurgeon has controlled the central hemorrhage, removed the devitalized brain and repaired the dura, the otolaryngologist should manage the severely damaged frontal sinus. This is best done by the cranialization procedure (Figure 56). The anterior wall fragments are removed, divested of mucosa, thoroughly irrigated, and debrided to ensure the removal of all the contaminants acquired at the trauma scene. The bone fragments are stored in Betadine until the end of the procedure. The posterior wall of the frontal sinus is completely removed with a rongeur and a cutting bur. The anterior cranial fossa is now entirely in continuity with the cavity of the frontal sinus. The cutting bur is used to remove thoroughly all vestiges of sinus mucosa including the small projections into the vascular pits in the frontal sinus anterior wall and floor. This is the most important step in the procedure. Any remaining mucosa provides the potential for its regrowth and subsequent infection. The mucosa of the nasofrontal duct is inverted on itself toward the anterior ethmoid sinuses. The duct is plugged with a block of temporalis muscle or bone dust. The anterior walls of the sinuses are restored, and the dural graft will expand with time and fill the new space created in the anterior cranial fossa.

CONCLUSIONS

In summary, treatment of facial fractures requires a multisystem approach. All bony and soft tissue injuries should be diagnosed, and reconstitution of all tissue layers should be performed, if possible. The advancement of technology has enabled rigid fixation to become the standard care for the fixation of most facial fractures. More precise stability and fixation of fractures have become possible, and intermaxillary fixation is used less frequently. Well-planned incisions minimize scarring. A dequate exposition, precise reduction, and stable fixation remain the hallmarks of treatment of facial fractures.

REFERENCES

Wound healing is an essential part of any discussion of plastic and reconstructive surgery, and a general understanding of it is beneficial to aid in promoting the most favorable environment for minimal scar formation. Despite this, unwanted scars and poor healing may occur. It is helpful to have an understanding of the possible causes of poor wound healing as well as basic flap physiology to minimize iatrogenic causes for failure.

ANATOMY

The epidermis and dermis are the major components in a discussion of cutaneous wound healing (Figure 1). The outer layer, the epidermis, is the most apparent and also the most prone to scar formation that is readily visible. It is highly durable, waterproof, and serves to protect underlying tissue from dehydration and bacterial invasion.

The epidermis consists of four distinct cell types including keratinocytes, melanocytes, Langerhans cells, and Merkel cells. Merkel cells are of an unknown function and origin. The most numerous is the keratinocyte, and it comprises 80% of the cell composition. Keratinocytes form the major layers of squamous cell epithelium originating with the basal germinal layer (stratum germinativum), which is highly mitotic. As cells mature they migrate toward the surface and take on a more granular appearance (stratum granulosum) and then begin to dehydrate as they migrate away from the blood supply located nearest to the basal layer in the dermis. The next layer (stratum spinosum) retains cell-to-cell junctions but the cell decreases in size causing it to have angle sides or “spines.” There is a translucent layer (stratum lucidum) comprised of flattened picnotic cells followed by a layer of cell bodies (stratum corneum), which is relatively inert and serves as a protective shield. Langerhans cells are one of the most efficient antigen-presenting cells and essential in the immune response within the epidermis. Although they are found mostly in the epidermis, they are a bone marrow derived cell. Melanocytes are neural crest cells that produce melanin, a pigment that shields the nuclei of the squamous cell epithelium from ultraviolet radiation. Although the number of melanocytes does not vary with race, the activity of the pigment production does, causing the difference in skin color.

Injuries to the epidermis are relatively superficial and heal without scarring, as there is no collagen deposition. Rapid turnover and cell replication pushes new cells into the wound replacing lost tissue. This occurs in only a few hours. In addition, the basal cell layer migrates rapidly to replace and cover exposed dermis and regenerate lost skin. This is one of the reasons why skin resurfacing and skin grafts are successful. In exchange for rapid growth potential and quick response time, wound strength is minimal. Although there is no scarring with superficial wounds, melanocytes are located in this layer and may cause discoloration.

The dermis is deep to the epidermis and is tightly adherent to it as a result of its irregular border. There are two primary anatomical components to the dermis, the papillary and reticular layers. The papillary layer consists of outpouchings extending up into the epidermis and is vascular, supplying the metabolic needs of the basal layer. The dermis has great intrinsic strength secondary to its abundant collagen producing fibroblasts. As might be expected, repair and healing in this layer are not as rapid as in the epidermis, but the dermal layer provides tensile strength to the wound. In addition, the dermis contains epithelial lined skin appendages such as sweat glands, hair follicles, and sebaceous glands. Sebaceous glands are of particular importance as they are a reservoir for germinal cells for epidermal regeneration.

STEPS IN WOUND HEALING

After an injury, wound healing has been described as progressing in three major phases: (1) inflammatory, (2) proliferative, and (3) maturation or remodeling (Figure 2). The entire process can take up to a year to complete and, thus, many plastic surgeons will wait until the scar has matured prior to revision.

Inflammatory Phase

The inflammatory phase begins at the initial insult and is characterized by local vasconstriction, which lasts for up to 10 minutes. If endothelial injury has occurred, the coagulation cascade is activated. Platelet adhesion and clot formation...
result from numerous cytokines released from the endothelium and activated platelets. Vasooactivators such as serotonin, histamine, proteases, and thromboxane α as well as platelet-derived growth factor (PDGF), insulin-like growth factor-1 (IGF-1), transforming growth factor-beta (TGF-β), epidermal growth factor (EGF), and fibroblast growth factor (FGF) are secreted to aid in cell recruitment and fibronectin forms a network for cell-mediated responses increase. Fibronectin-mediated migration of circulating cells, such as neutrophils, monocytes, fibroblasts and locally derived endothelial cells, forms granulation tissue. This conglomerate along with the clot and fibrin forms a network for fibroblasts and migratory endothelial cells to proliferate (Figures 3 and 4).

The primary action of the neutrophils and monocytes is phagocytosis of bacteria and wound debris. These cells are usually short lived unless the wound is contaminated, then they persist and continue to migrate until the wound is sufficiently clean. Prolongation of the inflammatory phase secondary to wound contamination is a significant contributor to increased scar formation. In a noncontaminated wound, collagen deposition begins, provided the macrophages, fibroblasts, and endothelial cells are functioning normally.

Macrophages are extremely important for wound debridement but also have a significant role in days three to four of wound healing as they facilitate granulation tissue formation and collagen deposition through release of chemokines and growth factors essential in cell signaling. Macrophages release PDGF, TGF-α, EGF, TGF-β, and FGF, among many other cytokines, which activate endothelial cells to migrate into the wound and fibroblasts to produce collagen. The important function of macrophages is readily apparent when they are dysfunctional and wound healing is hindered.

Initial wound strength relies on the fibrin clot and rapid re-epithelialization of the wound and is relatively weak. Collagen deposition does not begin until the inflammatory phase has subsided. Although this model of wound healing would suggest three distinct phases, the process is much more fluid and overlapping.

**Proliferative Phase**

The next recognized phase is the proliferative phase and is characterized by regeneration of the epithelium, collagen deposition, neovascularization, and wound contraction.

tion, and wound contracture. This phase typically is thought to begin during the initial 24 hours and lasts for up to 3 weeks.

The initial part of this phase is characterized by epithelial migration into the wound and is activated by EGF and TGF-α. These polypeptides induce the germinial basal membrane to undergo rapid mitosis and subsequent migration cells into the wound both from the edges and from deep structures, for example, hair follicles and sebaceous glands, within the dermis. Cell-to-cell contact results in further cell messaging, increased mitotic activity, and stratification of the basal cell layer resulting in recreation of the stratified squamous cell epithelium. This critical phase occurs relatively quickly and peaks in 48 to 72 hours thus laying down a protective layer to insulate underlying tissue from bacteria and foreign material.

This phase is much quicker in primary closed wounds taking as little as 24 hours to re-epithelialize. In large or full thickness injuries that are allowed to close by secondary intention, this process can be up to five times as long.

This knowledge of the basic cellular level of wound healing provides an apparent reason for keeping wounds clean and moist during early healing. Packing wet to dry dressings and meticulous cleansing of wounds to remove crusting and scabs allows for more rapid epithelial migration. Large scabs formed by early clots that become dehydrated may protect the wound initially, but adhere to the dermis and form a barrier to impede migrating basal cells thus prolonging the wound closure and increasing the size of the final scar.

Maturation or Remodeling Phase

The final stage in wound healing is marked by decrease in scar size and inflammation and is secondary to remodeling of the wound. This phase begins sometime between the second and third week and continues for up to a full year. It is characterized by dehydration of the surrounding area, change in collagen type, and parallel arrangement of previous randomly arranged collagen fibers. Vascularity is also decreased as scars are usually avascular.

**Figure 3** A cutaneous wound 3 days after injury. Growth factors thought to be necessary for cell movement into the wound are shown. TGF-β1, TGF-β2, and TGF-β3 denote transforming growth factor-beta1, -beta2, and -beta3, respectively; TGF-α, transforming growth factor alpha; FGF, fibroblast growth factor; VEGF vascular endothelial growth factor; PDGF, PDGF AB, and PDGF BB, platelet-derived growth factor, platelet-derived growth factor AB, and platelet-derived growth factor BB, respectively; IGF, insulin-like growth factor; and KGF keratinocyte growth factor. FACTORS AFFECTING WOUND HEALING

Factors such as metabolic deficiencies, local environment, cellular deficiencies, and delayed wound closure can all have an affect on the timing and strength of wound healing. Many of these factors can be influenced by the physician and the educated patient.

Closure technique is one factor at the forefront of the surgeon’s mind. Some of the more common mistakes include injury to wound edges while suturing, excessive cauterization, and ischemia induced by suture material or constriction. These factors play a part in increasing the length of the inflammatory phase by causing necrosis, inflammation, and increase the risk of infection thus prolonging healing.

As mentioned, tissue ischemia may prolong wound healing as well. Tying sutures too tightly may induce local tissue ischemia as well as local collections of blood and serum to cause hematoma or seroma formation. Good surgical technique, drain placement as necessary, and appropriate suture material and technique are recommendations to prevent the above-mentioned complications.

Systemic disease such as anemia and inadequate debridement of the wound are also contributing factors to poor tissue oxygen tension. Although a low PaO2 will induce neovascularization and epithelial migration, it will also hinder fibroblast activity and collagen formation. For this reason, hyperbaric oxygen therapy has been thought to speed the healing process. Studies suggest it may increase the rate of epithelialization and improve long-term healing results.

Wound healing is further retarded by desiccation. Large clots dehydrate and create a barrier to migrating epithelial cells. These cells require more energy as their course is deviated to migrate around a scab that penetrates into the dermis. In a closed system without a ready blood supply, this can prolong healing and use up necessary nutrients. Many dressings have also been studied to help prevent crusting and maintain a properly humidified environment to improve wound healing efficiency. As the literature suggests that little atmospheric oxygen is absorbed through a wound, either occlusive or semiocclusive dressings are beneficial. An occlusive dressing has the added benefit of fluid collecting under the impermeable membrane which can be rich in chemotactic factors and further promotes recruitment and decreases healing time.

In addition to dressings, one study demonstrated a 28% increase in healing rate with the use of antibiotic ointment. Conversely, corticosteroid ointment and petroleum jelly were shown to be ineffective in promoting wound healing and decreased healing rates by 34 and 8%, respectively. Topical bacteriostatic agents, such as Silvadene, may promote healing, but caution is advised because others, such as Provodine iodine, may actually inhibit healing.

Despite excellent surgical technique, wound healing can be hindered by systemic diseases as well. Most common on this list is diabetes and hypertrophic scar formation. Although rare, pseudoxanthoma elasticum, osteogenesis imperfecta, progeria, dermatomalalus, and Ehlers-Danlos syndrome are also considered wound healing. Any congenital or acquired deficiency in the wound healing process or collagen formation has potential to slow the healing process.

Diabetes deserves focused attention in discussing the biological pathways disrupted by this congenital and acquired disease. One well-known way is microangiopathy causing decreased oxygen delivery to the wound site. A nothing is insulin deficiency causing leukocyte dysfunction. Many of these effects have been linked to glycosylation of membrane proteins. For this reason, and probably several others, patients with diabetes are at increased risk for infections in addition to the slower wound healing. Collagen synthesis has also been found to be adversely affected by low or ineffective insulin levels. Studies suggest that insulin therapy and supplemental vitamin A (25,000 U/d) benefit diabetics in the healing process.

Although one would expect nutritional status to be a significant liability in wound closure and healing, it has only been observed in severe cases. Physicians should be cautious in patients with a malignancy or alcoholism. Building protein in the form of amino acids may be necessary to correct any deficiency and promote normal wound healing.

Vitamins A, C, K, and E have been observed to be important cofactors in the healing process as well. Vitamin A deficiency manifests as poor epithelialization and wound closure. Deficiency causes decreased collagen cross-linking and formation. Deficiency of vitamin C causes scurvy. The body cannot synthesize this essential vitamin and can only store about 4 to 5 months worth. It is an important cofactor in the hydroxylation of lysine and proline in collagen synthesis. Vitamin C is also a reducing agent in neutrophil superoxide formation necessary for bacterial extermination. Vitamin K is also a cofactor in the clotting cascade and is specifically implicated in the formation of factors II, VII, IX, and X. As a result, longer bleeding times and large hematomas inhibit collagen matrix formation and increase ischemia to the wound site. Vitamin E is well known as necessary for collagen formation and tensile strength, but its clinical importance has not been demonstrated. Trace elements such as iron and zinc are also included in the healing pathway. Zinc is involved in collagenase activity and enzymes used to synthesize RNA and DNA. Other medical conditions that may cause...
nutritional deficiencies or immune dysfunction should also be considered. Although this list is extensive, several are worth mentioning here. Congestive heart failure, atherosclerosis, venous stasis, and lymphedema cause poor tissue delivery of oxygen and nutrients. Chronic renal failure, Cushing syndrome, and hyperthyroidism are other systemic diseases known to inhibit wound healing. Chronic liver disease, human immunodeficiency virus (HIV) or other immune deficiency states (chemotherapy, leukemia), thrombocytopenia, and previous radiation therapy have also been implicated as decreasing healing. A ging is associated with slower healing and decreased strength of scars. Medications such as chemotherapeutic agents and corticosteroids can have a clinically significant effect on wound healing by decreasing inflammatory agents and prolonging the inflammatory phase. Although the oral administration of vitamin A has been shown to reverse the effects of corticosteroids, the routine use of other vitamins does not seem to promote overall wound healing.

Abnormal Scar Formation

Hypertrophic scarring is a problem for surgeons. Keloids are an example of extreme hypertrophy of a scar and represent excessive collagen deposition without the normal degradation to shrink the scar. The difference between keloid scars and hypertrophic scarring is one of severity. Hypertrophic scars are along the wound line and may regress with time whereas keloid scars tend to invade surrounding tissue. Treatment for both is aimed at decreasing collagen formation by use of intralesional corticosteroids. Severe keloids may also require postoperative excision with direct pressure dressings, silicone gel sheeting, interferon-alpha 2b, or radiation to inhibit excessive collagen deposition. Recurrence is frequent, but one study showed promising results with only 8% recurrence of keloid scars with surgical excision combined with radiation or intralesional corticosteroids and interferon-alpha 2b. Although no marketable therapy is currently available, TGF-β1 has been shown to inhibit keloid growth. Further research into the science of cell-mediated cytokines and wound healing may lead to new and better treatments in the future for those prone to excessive scarring.

FLAP PHYSIOLOGY

In discussing the physiology of flaps, a basic understanding of the surgical anatomy of the skin and superficial tissues is necessary. The dermis (and epidermis) is supplied by two major vascular plexus (Figure 6). The deep vascular plexus, or subdermal plexus, exists at the junction of the reticular dermis and subcutaneous fat (hypodermis). Arterioles from the deep vascular plexus supply sweat glands and pilosebaceous units consisting of hair follicles and sebaceous glands. The superficial vascular plexus exists at the superior border of the reticular dermis and consists of capillary loops within the dermal papilla. The superficial plexus provides the major blood supply to the epidermis through diffusion as it does not extend up into the epidermis. In the head and neck, especially the face, there may also be a large network of deep subcutaneous perforating vessels named according to the anatomical location, for example, transverse facial and submental. This network provides a rich source of blood supply to the skin.

The arterial blood supply to the skin consists of two major categories, the musculocutaneous and cutaneous. Musculocutaneous vessels arise from segmental arteries, which are named branches of the aorta, and run deep to muscle groups. These musculocutaneous arteries permeate through underlying muscles before reaching the skin and supply blood to both muscle and skin. Musculocutaneous arteries run perpendicular to skin for much of their course and thus typically supply only a small area superficially.

Direct cutaneous, also called septocutaneous or fasciocutaneous, arteries traverse within the fascial septa of the muscular bundles and course directly to the dermis. These vessels supply blood only to the skin and not to the adjacent muscle tissue. As opposed to musculocutaneous arteries, direct cutaneous arteries run parallel to skin and supply a large area of skin.

Blood flow through the skin is one of the most variable in the body its thermoregulatory responses. Even at its baseline flow rate, the skin receives 10 times the rate that is required for nutritional support. It is because of this abundant blood flow that random flaps are able to survive. An extensive network of capillaries supplies the skin with its blood volume and flow and is controlled by precapillary sphincters. These sphincters are induced to relax by local hypoxemia and an increased level of metabolic products. In addition, arteriovenous (AV) shunts further regulate flow through the capillary network. The AV shunts also have regulatory sphincters that control both thermoregulation and systemic blood pressure. An increase in core body temperature causes a decrease in norepinephrine release, which results in contracture of the AV shunt sphincters and increased blood flow to the skin. Increase in metabolic products may cause a similar reaction. This control mechanism is of utmost importance in flap survivability.

The skin is innervated by both the sensory and sympathetic nervous systems. Sensory nerves are distributed in a predictable segmental fashion along the skin. The sympathetic nerves control the AV shunt sphincters by release of norepinephrine. Incisions at the flap edges interrupt the parallel superficial and deep cutaneous plexus causing decreased perfusion pressure to the skin. In addition, when sympathetic nerves are severed, norepinephrine is released from the nerve terminal and catecholamine reuptake is eliminated. This surgical sympathectomy contributes to decreased blood flow to the flap.
Flap Designs

The four basic types of flap designs are based on the vascular supply. The most common flaps used in the head and neck are random and axial. Fasciocutaneous and musculocutaneous flaps discussed in Chapter 97, "Neoplasms of the Oral Cavity" and Chapter 98, "Neoplasms of the Oropharynx and Hypopharynx." 

Random Flaps. Random flaps represent the majority of local facial flaps. As the vascular supply to these flaps arises from the subdermal plexus through the base, which is supplied by musculocutaneous arteries, the appropriate plane of dissection for elevation of the flap is along the subcutaneous (hypodermal) adipose. Multiples length-to-width ratios have been recommended in the literature to increase flap survivability, but, practically speaking, survivability may be more related to the perfusion pressure of the feeding blood vessels.

Axial Flaps. Axial flaps derive their blood supply from the named direct cutaneous arteries. As a result, axial flaps are capable of a greater length-to-width ratio than are random flaps. The plane of dissection is, therefore, deeper and includes the fascia containing the relevant named artery. Some additional length is obtainable with axial flaps if more tissue at the distal tip is included with its corresponding blood supply derived from the random subdermal plexus. Examples of axial flaps and their corresponding direct cutaneous artery are the paramedian forehead (supratrochlear artery) and the nasolabial flap (angular artery). Axial flaps are discussed in Chapter 54, "Nasal Reconstruction."

Fasciocutaneous and Musculocutaneous Flaps. Fasciocutaneous flaps contain associated skin, subcutaneous fascia, and deep fascia. One such example is the radial forearm flap. Musculocutaneous flaps include all the elements of the fasciocutaneous flap with the added underlying muscle. An example would be the latissimus dorsi flap.

Cellular Physiology of Flaps

Following transposition and insetting of a flap, the first 48 hours represent the most critical period with respect to determining flap survival. A surge in the level of catecholamines occurs locally with tissue damage and flap placement, resulting in vasoinnconstriction secondary to catecholamine release. The catecholamines released from traumatized nerves are exhausted after 48 hours. In addition, the inflammatory cascade releases increased levels of thromboxane A2 (also a powerful vasoconstrictor) and free radicals, with resulting edema. The combination of these factors can cause both ischemia and direct injury to the flap. During the inflammatory phase, a fibrin layer forms at the recipient site. Neovascularization is delayed until 3 to 7 days in the proliferative phase and thus the flap is dependent on nutrient absorption from the surrounding tissues and blood supply from the pedicle during this critical time. Revascularization has been described as being adequate for division of the flap pedicle at 7 days.22

This revascularization occurs through two processes, direct in growth (neovascularization) and angiogenesis. Angiogenic stimuli such as ischemia cause the vessel at the edge of the flap to become dilated, and a thinning of the basement membrane facilitates endothelial cell migration. Endothelial cells move from the adjacent vascular lumen toward the vascular stimulus. Replication of endothelial cells is stimulated in the bordering vessel lumen and forms a capillary sprout which elongates toward the angiogenic source. Neighboring capillary sprouts anastomose to form capillary loops and then new blood vessels. Inosculating is direct ingrowth of surrounding capillaries into preexisting vessels in the flap.

Flap Biomechanics

In discussing flap physiology, four biomechanical principles are emphasized: stress, strain, creep, and stress relaxation. The first concept, stress, refers to the force applied per cross-sectional area of the skin. Strain, the second principle, refers to the change in length divided by the original length of the given tissue to which a force is applied. Creep is the increase in strain applied to skin when it is under constant stress. Creep can occur over a brief amount of time (minutes) and is due to the extrusion of fluid from the dermis and breakdown of the dermal framework. The final principle, stress relaxation, is the decrease in stress on skin when it is held in tension at a constant strain for a given period of time. Stress relaxation occurs days to weeks after flap placement and is due to the increase in skin cellularity and permanent stretching of skin components with wound healing and contracture. The concept of serial excision is based upon the principles that skin closed under tension will display stress relaxation and creep over time.

In forming a flap, the distal segment from the proximal end with the blood supply is referred to as the tip and is usually the most tenuous area with reference to survivability. The probability of tip necrosis has been directly related to both the length of the flap and distance from proximal vessels and the tension under which it is closed. In essence, longer flaps display a higher probability of tip necrosis when placed under the same closing tension as shorter flaps.

Undermining is the usual surgical technique for relieving tension in a flap but may not always represent the best means of correcting for excessive tension. Undermining has been shown to be of little benefit on tension beyond four centimeters. Other studies performed on animals demonstrated that excessive undermining actually increases flap necrosis probably by decreasing the vascular supply from both the superficial and deep vascular plexus.23,24

Many physiologic factors have been indicated to affect flap survival. The common denominator involves two basic factors. The first is the blood supply to the flap through its base, and the second is the formation of neovascularization between the flap and the recipient bed. It has been thought that the survivability of a flap depends entirely on the width of the base. However, the surviving length of random pattern flaps is determined by perfusion pressure within the arterioles and intravascular resistance. Widening the base of a flap does not affect either perfusion pressure nor intravascular resistance. Widening the base of a flap is necessary to a certain critical ratio, but more is not necessarily better when it comes to flaps; and there is no benefit to widening the base beyond that ratio. The literature suggests that a length to width ratio of 3:1 to 4:1 will result in a viable random pattern flap for the face or scalp.1

Historically, delaying of flaps was the generally accepted answer to tip necrosis and flap failure secondary to ischemia. In random flaps, this was performed by incising the long axis of the flap and undermining without dividing the ends of the flap. Axial flaps are incised around the margins excluding the base, or vascular pedicle, of the flap without undermining. In this way, the flaps are initially incised and then left in place at the donor site to be transposed and inset into the recipient bed after 1 to 2 weeks. Of note, any benefits gained from a delayed flap are lost if delayed beyond 3 weeks. There are several proposed reasons why delayed flaps seem to perform better. It is thought that delaying the flap improves blood flow after setting by reorienting vascular channels and inducing the formation of new vascular collaterals. In addition, the flap itself is conditioned to withstand ischemia, and delaying causes diversion of blood from the A V shunts thus ensuring adequate flow to the tissue.

Management of Complications

The same complications to wound healing apply to skin and tissue flaps as well. The most common causes of complications are poor flap design and increased tension from closure. These concerns must be addressed prior to forming the flap and while in the operating room. Potential postoperative complications of local skin flaps also include infection, hematoma, ischemia, flap necrosis (distal flap or tip necrosis), dehiscence, and an undesirable cosmetic result.

Tension on a flap increases the risk of tissue necrosis. Some flaps, such as a transposition flap, tend to have decreased tension on the distal extension of the flap. Often times, a flap that is thicker will perform better than a flap with a wider base in the prevention of tip necrosis. Adequate perfusion is assured if, at the conclusion of the inset, the flap is pink with brisk capillary refill. The progression of ischemia to necrosis may be in a stepwise fashion with blanching and increasingly prolonged capillary refill until capillary refill is no longer evident with direct pressure. The natural consequence of poor perfusion without intervention follows a stepwise fashion as well. Tissue ischemia causes cell death, which
is initially superficial, but may progress to full thickness. With tissue necrosis, eschar formation follows. Eschar formation leads to widening of the scar secondary to poor migration of epithelial cells and goes on to separation of the eschar with an exposed defect and healing by secondary intention.23

Cyanosis of flaps in the immediate postoperative period is most often attributed to insufficient venous drainage. Clinical symptoms include an edema, purplish or bluish hue to the flap with dark colored blood on pinprick. Initial management should include removal of tense sutures that are potentially compromising venous drainage. It may be necessary to explore the vascular pedicle to remove any kinking or compression caused by hematoma formation. In addition, multiple punctures may be made with a 22-gauge needle to relieve venous hypertension. Application of heparin-soaked gauze and even medicinal leeches have been used. Should medicinal leeches be utilized, antibiotic prophylaxis is recommended to prevent Aeromonas infection. Although medicinal leeches are raised in a sterile environment, their digestive tracts are colonized with this microorganism and it is transferred in the saliva.25

Clinical symptoms of ischemia secondary to arterial insufficiency include pallor, delayed capillary refill, decreased temperature, and decreased or absent bleeding with pinprick. A retinal insufficiency may be due to the same causes of venous congestion. Mechanical pressure from a wound dressing applied too tightly, hematoma, or a kinked pedicle is the most common cause that can be remedied initially. It is recommended that adequate perfusion be assured prior to leaving the operating room. Otherwise, the option of further delay of flap placement is lost, nevertheless, the outcome may be a necrotic flap in its original position with a remaining tissue deficiency. It is important to note that although a flap can survive arterial insufficiency for up to 13 hours, venous congestion will cause flap failure within 3 hours.13

In combating flap ischemia, hyperbaric oxygen (HBO) therapy should be considered although it is not a mainstay of therapy. Positive results have been demonstrated in studies involving animals and humans. Therapy is initiated through multiple “dives” in which 100% oxygen is administered at two to three times atmospheric pressure. This results in an increased amount of dissolved oxygen in plasma, which increases the oxygen level in the peripheral tissue by a reported 10- to 20-fold. HBO therapy is dependent on an efficient cardiopulmonary system to deliver the oxygen and may not be useful in individuals who are compromised such as those with congestive heart failure or emphysema. To determine if a patient is a good candidate for HBO therapy, transcutaneous oxygen measurements are made with the patient breathing room air and compared to the patient breathing 100% oxygen. An increase in the oxygen saturation while breathing 100% oxygen suggests that the patient has sufficient cardiopulmonary function to benefit from HBO therapy.25

HBO therapy has been discussed as benefiting tissue flaps for a number of reasons. First of all, it encourages capillary neovascularization within the flap thus increasing blood supply and oxygen delivery to the ischemic tissue. Secondly, HBO therapy is thought to decreases tissue reperfusion injury, a major cause of tissue damage after an ischemic event such as a tissue flap transfer. Thirdly, HBO therapy induces vasoconstriction in healthy tissue, but not ischemic tissue, which decreases edema and allows more blood to be diverted to tissue that needs it. Lastly, HBO therapy decreases hypoxia and helps prevent cellular death for the first 72 hours, which is the most critical time for ischemia and until revascularization has begun. HBO therapy has demonstrated a 90% salvage rate in ischemic flaps when performed one to two times per day for 3 to 5 days.22,26

HBO therapy is not without potential risks. Complications may be various and usually result from either barotraumas or oxygen toxicity. These complications can include pneumothorax, barotrauma to the middle ear with tympanic membrane perforation, seizure, pulmonary toxicity, myopia, and an increased rate of cataract formation, particularly in patients with preexisting cataracts. Myopia usually resolves within 6 months following treatment, but the other complications can be serious and long-term. Oxygen-induced seizures have been reported in one in 10,000 patients.25

Some authors have argued that aggressive debridement is contraindicated until the wound has marginalized and the eschar has begun to separate. However, a wound may benefit from some debridement as it increases migration of epithelial cells. This is counterintuitive; as previously discussed, scabbing causes widening of the scar. Fortunately, the eschar acts as a biological dressing in protecting the defect. Local wound care is recommended even with partial distal tip necrosis. Although debridement is rarely necessary, failure of a flap may necessitate another reconstruction if more conservative measures fail to provide adequate coverage of the tissue defect.

Infection, another dreaded complication in surgery, is surprisingly uncommon in head and neck local flaps, although higher than in traditional facial surgery. The reasoning is multifactorial. Plausible reasons include delayed flaps becoming contaminated, higher colonization rates in the head and neck regions, for example, nose and oral cavity, and lastly, because those undergoing surgery for head and neck flaps usually have increased risk factors for infection including malignancy, diabetes, and malnutrition.27

Regardless of the cause, the results can be devastating. Infection may be as problematic as dehiscence with widening or thickening of scar or as devastating as flap necrosis or sepsis. For these reasons, prevention of infection is critical because of the potential for catastrophic consequences. Simple measures, such as observance of sterile technique, handling tissues gently, avoidance of aggressive hemostasis, closing and suturing with as little tension as possible, and postoperative irrigation with hydrogen peroxide to remove dried blood which increases local bacterial load, are recommended to prevent untoward events. Antibiotic prophylaxis has been proven effective for clean-contaminated operations such as with delayed wound closure, but not necessarily for clean wounds. As expected, Staphylococcus aureus as a skin contaminant is the most common pathogen isolated from infected wounds. An infection typically begins manifest between postoperative days 3 to 6. Management usually includes opening up a small area of the incision to facilitate drainage of pus and decrease bacterial load as well as pressure on the flap. Any purulent fluid should be sent for culture and sensitivities for isolation of the microorganism, and the patient should be started on broad-spectrum antibiotics until a more specific antibiotic is indicated by the sensitivities. The wound may be packed open, or a wick placed to drain purulent fluid. When the drainage stops and the infection has resolved, the wound is allowed to close. Failure to pack the wound can result in further dehiscence and persistent infection with abscess formation.23,28

Another contributor to flap failure is hematoma formation. Hematomas cause flap failure by increasing tension on the wound closure thus increasing the likelihood of ischemia and dehiscence. Hematoma formation also increases both the risk of infection and the inflammatory response that directly interferes with flap circulation. Two of the most common causes of bleeding that result in hematoma formation are preventable. Meticulous hemostasis at the time of the operation is essential to prevent a hematoma. Caution is advised as one cannot be too aggressive if electrocautery is used since it contributes to poor wound healing and can also contribute to flap ischemia and failure. The second major cause of hematoma formation is drug-induced coagulopathy. The most common medications associated with increased bleeding leading to hematoma formation are over-the-counter therapeutic agents including aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), vitamin E, and herbal remedies and garlic. Prior to the operation, the patient’s medications should be reviewed for other medications, such as coumadin, low molecular weight heparins, and Plavix, which also cause increased bleeding. Typically, it is recommended that patients who are undergoing an operation with flap placement be instructed to stop these medications for 2 weeks prior and 1 week after the operation if medically feasible. Patients who are high risk for pulmonary embolism or other hypercoagulable states may require special consideration.22,28

Although prevention is the preferred course, several options are available for intraoperative control of bleeding. Specific and selective electrocautery is most often the first step. Other options include reverse Trendelenberg positioning of the patient, application of epinephrine soaked cotton
pledges, and direct pressure. Continued oozing of the tissue despite adequate efforts to control bleeding is often removed via a sterile rubber band drain or suction drain placed under the flap or adjacent to the oozing tissue overnight (or until output is decreased) to prevent hematoma formation. In such cases, the patient should be held for observation in case a return trip to the operating room is necessary.29

In the event a hematoma should form despite the best efforts at prevention, evacuation is easiest within the first 2 days. Persistent bleeding necessitates re-exploration of the wound. If the hematoma persists beyond 2 days, the clot organizes into a solid mass, and removal may require mechanical debridement. Although resorption of the hematoma begins after 10 to 14 days, this is long after the critical first few days.30

A serious complication, dehiscence, usually is caused by hematoma formation, infection, tip necrosis, or from dynamic facial movement. Because the wound is weakest during the first week prior to collagen deposition, bolstering the wound after suture removal with sterile strips can be beneficial to support the flap edges. A simple dehiscence can be repaired if recognized early (within 24 hours). After 24 hours or with a more complex breakdown, it may be better to allow the wound to heal by secondary intention.

Despite good wound care, an undesirable scar or poor cosmetic result will occur. Dermabrasion should be considered for smoothing height differences between the flap and surrounding skin and in areas with thick, sebaceous skin such as the nasal tip. Dermabrasion produces the best results at 6 to 9 weeks postoperatively when fibroblast activity is greatest. Operative scar revision should be delayed for at least 6 months, and more often 1 year, when the scar has matured. Widened scars that parallel relaxed skin tension lines can be simply excised. This is also a good option if the scar is within an aesthetic unit. However, longer linear scars may need to be excised and revised with either a W-plasty or geometric broken line contracture. Contracted scars may require a Z-plasty to lengthen and change the direction of the scar if unfavorable.21 Scar revision and skin resurfacing are discussed in Chapter 57, “Scar Revision and Skin Resurfacing.”

CONCLUSIONS

A basic knowledge of wound healing and flap physiology is beneficial to the surgeon in preventing untoward events. Many of the causes of poor healing are preventable with the use of proper surgical technique, knowledge of patient risk factors, adequate patient education, and appropriate wound care. When complications arise, proper awareness of the practical treatment is essential in salvaging flaps and preventing undue scar formation. This may include drainage of a hematoma postoperatively, early infection control measures, and watchful waiting for demarcation of fl ap necrosis prior to debridement.

SCAR REVISION

Unlike the wizard’s scar, most scars serve no useful purpose. Facial scars, in particular, can be emotionally devastating and may affect self-esteem in some patients. Facial plastic surgeons may be called upon to aid in correction of these defects. While not all facial scars require surgical intervention, scars are unacceptable when they are excessively long, not oriented along the relaxed skin tension lines (RSTLs) or when wound edges are of uneven heights.

Ideally, a scar should be parallel to the RSTLs, or hidden in the junction between facial subunits. Scar revision may be indicated when scars lie between facial subunits. Scar revision may be performed when scars are contracted and lie across the RSTLs.1 The technique of Z-plasty both lengthens a contracted scar and changes the orientation of the scar. The Z-plasty technique consists of two triangular flaps of equal size which are transposed and sutured into place (Figure 1).

The design of the Z-plasty is critical. The limbs of the Z-plasty should be the same length as the excised scar. There are usually two ways to draw the flaps, mirror images of each other (Figure 2). The surgeon can draw both options, then choose the design which best places the limbs of the Z in the RSTLs. Scar lengthening is dictated by the angle that the limbs extend from the scar. If the limbs are drawn at 30° angles, the scar will be lengthened 25%, 45° angles will lengthen the scar by 50%, and 60° angles will lengthen the wound by 75% (Figure 3).

Dissection should be carried out in the subdermal plane for ease in flap transposition. Wide undermining is necessary to achieve a tension-free closure. The wound may be closed in one or two layers.

Common areas on the face where Z-plasty scar revision is used include: medial canthal webs, postauricular webs after facelift or parotidectomy surgery (Figure 4), contracted scars of the neck and the Philosopher’s Stone

Simple Excision and Serial Excision

Simple fusiform excision of facial scars is performed on wide or hypertrophic scars, when the suture line can be oriented parallel to the RSTLs. The scar is excised sharply, undermined in the subdermal plane, and closed meticulously in a layered fashion. Occasionally, scar tissue is left in the deeper planes to prevent a concavity in the skin from soft tissue loss.

Serial excision may be performed for lesions which are extremely wide. A portion of the scar is removed in fusiform fashion, and the resultant scar is placed either in a RSTL or at a junction between facial subunits. After 6 to 8 weeks, the tissue has regained enough strength and elasticity to undergo another excision. These excisions are performed every 6 to 8 weeks until the scar is completely removed. The result of serial excisions is to produce one narrow scar which is cosmetically acceptable. Techniques to lessen tension on the closure, such as subcutaneous sutures or taping, can decrease the chance for postoperative widening of the new scar.

Z-Plasty

Scar excision with Z-plasty reconstruction is performed when scars are contracted and lie across the RSTLs.1 The technique of Z-plasty both lengthens a contracted scar and changes the orientation of the scar. The Z-plasty technique consists of two triangular flaps of equal size which are transposed and sutured into place (Figure 1).

The design of the Z-plasty is critical. The limbs of the Z-plasty should be the same length as the excised scar. There are usually two ways to draw the flaps, mirror images of each other (Figure 2). The surgeon can draw both options, then choose the design which best places the limbs of the Z in the RSTLs. Scar lengthening is dictated by the angle that the limbs extend from the scar. If the limbs are drawn at 30° angles, the scar will be lengthened 25%, 45° angles will lengthen the scar by 50%, and 60° angles will lengthen the wound by 75% (Figure 3).

Dissection should be carried out in the subdermal plane for ease in flap transposition. Wide undermining is necessary to achieve a tension-free closure. The wound may be closed in one or two layers.

Common areas on the face where Z-plasty scar revision is used include: medial canthal webs, postauricular webs after facelift or parotidectomy surgery (Figure 4), contracted scars of the neck and the Philosopher’s Stone

Figure 2 Two Z-plasty patterns are possible for every wound. The design selected is the one which best places the limbs of the Z-plasty in the relaxed skin tension lines (RSTLs).

Figure 1 Z-plasty technique. Triangular flaps A and B are transposed to reorient and lengthen the scar.

Figure 5, scars which are oriented perpendicular to the nasolabial fold, misaligned vermilion-cutaneous junctions, and occasionally for the repair of torn earlobes (Figure 6).

Z-plasty excisions may be single or multiple. When a multiple Z-plasty technique is performed, the final scar is lengthened, the scar is irregularized for maximal camouflage, and wound tension is more evenly distributed in the final scar. Multiple Z-plasty excisions can be used to improve pincushioned or trap-door deformities.

W-Plasty

Scar irregularization is a common technique for scar camouflage. Scars which cross the RSTLs at angles of 35° or more can be camouflaged by breaking up the scar into smaller, irregular segments. This irregularization of the scar makes it more difficult for an observer’s eye to follow. The two most common techniques of scar irregularization are W-plasty and geometric broken line closure (GBLC).2 Unlike Z-plasty, these techniques require removal of surrounding normal tissue and do not result in significant scar lengthening.

The W-plasty technique, or “running W-plasty” is a bilateral advancement flap that is relatively easy to diagram and to perform. The scar is excised by using a series of triangularly shaped segments (Figure 7). The limbs of these segments should be oriented along the RSTLs. Each limb of the triangle should be approximately 3 to 5 mm in length and the base of the triangle should be approximately 5 mm in width. The apex of the triangle is approximately 60°. The triangles become slightly smaller at the ends...
of the wound to allow closure without standing cone or “dog ear” formation. The scar itself can be excised with the W-plasty design or can be excised before the flaps are designed. Once the W-plasty flap is diagrammed on the skin, a No. 11 scalpel blade assists in the exact excision of the segments. The wound edges are undermined and closed in a layered fashion to minimize wound tension. The resultant scar is usually slightly longer than the original scar which aids in the prevention of standing cones.

Running W-plasty techniques have been used to camouflage coronal browlift incisions, especially in the frontal hairline. They are also used to improve the appearance of long linear facial scars, forehead vertical scars, and along concave facial areas which have formed a webbed scar.

**Geometric Broken Line Closure**

The GBLC technique is similar to the running W-plasty technique; however, in addition to triangularly shaped limbs, rectangles, semicircles and squares are used (Figure 8). The limbs are placed parallel to the RSTLs for maximal camouflage. Unlike W-plasty, this technique is more difficult to draw preoperatively. It is used primarily for long scars that are oriented 45º or more from the RSTLs. Each limb should be 3 to 7 mm in length because longer limbs become difficult to camouflage and shorter limbs produce flaps which are difficult to close.

The scar is incorporated in the GBLC design. A straightforward technique to design the flaps is to outline the scar, then draw lines parallel to the RSTLs (Figure 9). Next the geometric shapes are drawn in each segment, along with its mirror image on the opposite side. The scar is excised with a No. 11 blade, the wound edges undermined and closed in a layered fashion.

**Dermabrasion**

Dermabrasion is a resurfacing technique which can be used to aid in camouflage of surgical or traumatic scars or scars with uneven contours (Figure 10). Dermabrasion may be performed on mature scars, such as acne scars or scars with elevated and uneven wound edges. It may also be used within the first 2 to 3 months postoperatively to improve scar camouflage (Figure 11).

The technique involves using a low speed powered sanding burr (either wire brush or diamond fraise) to plane down the scar. The endpoint of sanding is usually when pinpoint bleeding is noted from the capillary plexus of the dermal papillae. Scarring may be worsened if dermabrasion is carried out too deeply into the reticular dermis.

**Postoperative Wound Care**

Poor postoperative wound care can contribute to a poor surgical result. Wound care may include local care with hydrogen peroxide and antibiotic ointment. The hydrogen peroxide is frequently
diluted 50:50 with saline to prevent burning the skin. Adhesive strips (Steri-strips) may be placed to minimize wound tension in the early postoperative period.

The patient is generally seen at 1 week, when the nonabsorbable skin sutures are removed. Although surgeons vary in their postoperative instructions for wound care, all agree that sun exposure should be minimized for 6 months to 1 year after scar revision surgery. If sunburned, scars may become hypertrophic, widened, or hyperpigmented. When the patient is outdoors, the wound should be covered with a bandage or a sunscreen lotion (SPF [sun protective factor] 30 or more) generously applied over the scar.

**Complications**

There are few complications for scar revision procedures when they have been well planned preoperatively, performed meticulously, and cared for appropriately in the postoperative period. Wounds closed under tension can widen or necrose, so adequate undermining is necessary to prevent a closure under tension. Tension can also be reduced by the use of taping either at the time of the operation or after suture removal. Hypertrophic scars can be treated with silicone gel sheeting.

**Nonsurgical Treatments for Scars**

Depressed scars may be improved by the use of filler agents like collagen and hyaluronic acid. The use of filler agents in these scars removes the shadowing effect from the depressed scar and improves cosmesis. The surgeon can pull the skin taught and if the scar elevates, it likely will be improved by filling the dermis and subcutaneous tissues. Some scars do not elevate due to deep dermal adhesions. In this case, release of the dermal attachments by subcision techniques, that is, separating the skin tissue in the affected area from the deeper scar tissue, before the filler is placed, will aid in scar elevation.

Keloids and hypertrophic scars result from abnormal deposition of collagen and glycoprotein during wound healing. Keloids grow beyond the original wound boundaries, whereas hypertrophic scars do not (Figure 12). Interestingly, there is no animal model to study keloids because they only occur in humans after tissue injury. Hypertrophic scars and keloids often respond to intralesional corticosteroid injections such as triamcinolone acetonide (Kenalog) and triamcinolone diacetate (Aristocort). Corticosteroids reduce blood vessel formation and decrease fibroblast proliferation and fibrosis in healing wounds. M ature hypertrophic scars and small keloid scars may respond to a series of corticosteroid injections given 4 to 6 weeks apart. Larger keloids should be excised, and corticosteroids injected either intraoperatively, or in the early postoperative period, as well as every 4 to 6 weeks. Low dose external beam radiation has also been used for the treatment of recurrent keloids. Mechanical compression may be used to flatten some hypertrophic scars and keloids. The mechanism by which compression improves scars currently is not known, but it is possible that the wounds exposed to silicone sheeting have less scar contraction, possibly by downregulating fibroblasts and decreasing fibrogenic cytokines such as transforming growth factor-beta 2 (TGF- \( \beta \)).

Hyperpigmented scars can occasionally occur in darker skinned patients. It is crucial these patients avoid sun exposure to the healing

wound. Hyperpigmented scars can be treated with skin bleaching agents such as hydroquinone 4%; however, they occasionally improve with no treatment.

The flashlamp pulsed dye (FLPD) laser can be used to treat hypertrophic scars, especially those with erythema. Components of living tissue that absorb particular wavelengths of laser light are called chromophores. The FLPD laser is a “vascular” laser with a wavelength of 585 nm. At this wavelength, the laser energy is best absorbed by the chromophore hemoglobin. This principle of selective photothermolysis allows for treatment of vascular lesions without harming the surrounding tissues. Hypertrophic scars become more pliable and smaller when treated with the FLPD laser. The mechanism of action is not clearly understood, but it is believed that the laser energy breaks the disulfide bonds in collagen. The collagen fibers are then able to reorient, and the scar flattens. Treatment with the FLPD laser is relatively painless; the patients often describe the discomfort like a “rubber band snapping against the skin.” Topical anesthetics are usually not used because the vasoconstrictive properties diminish the erythema, a necessary component for the laser. The patients may experience bruising after treatment, which may last 7 to 10 days and may be covered with camouflage makeup. Subsequent treatments also may be necessary. Occasionally hyperpigmentation can occur after FLPD laser treatment (Figure 13). This minor complication usually resolves without treatment.

**Scarless Healing**

Small fetal wounds induced early in gestation can heal with normal dermis and skin appendages, essentially without producing a scar. This observation had yielded vigorous research in the mechanism of “scarless healing.” Initially it was believed that the intrauterine environment, bathed in amniotic fluid rich in growth factors and hyaluronic acid, was necessary for scarless healing to occur. However, studies have shown that fetuses which heal outside a uterus, for example, marsupials, are also capable of scarless fetal healing. In humans, scarless repair is dependent on both the gestational age of the fetus and the size of the injury. Scarless repair can occur when small wounds are induced in human fetuses before 24 weeks of gestation.

The normal wound healing process consists of four phases: hemostasis, inflammation, proliferation, and remodeling. Immediately after injury, the initial response is coagulation, mediated by platelets and fibrin. The inflammatory phase then occurs over the next 3 days, as neutrophils and macrophages phagocytize foreign material and bacteria. The macrophages also secrete growth factors: transforming growth factor alpha, TGF-β, epidermal growth factor, fibroblast growth factor, and platelet derived growth factor. Proliferation occurs from 3 to 12 days after injury, as fibroblasts synthesize collagen and neovascularization occurs. In the final phase, which occurs for several months after injury, remodeling takes place as the wound is re-epithelialized and collagen is remodeled. Myofibroblast activity is responsible for wound contraction. The final result is a mature scar, which histologically is noted to have disorganized dermal collagen and the absence of dermal appendages.

Quite different reactions occur after injury in scarless healing. Fetal wounds have no inflammatory infiltrate, partly due to the characteristics of fetal platelets. Unlike adult platelets, which aggregate when exposed to collagen, fetal platelets degranulate less and aggregate poorly. In addition, few neutrophils and macrophages are present in fetal wounds. This lack of inflammatory response is critical in fetal scarless healing. Manipulations which induce inflammation in fetal wounds result in scarring. Myofibroblasts, which appear in adult wounds at 1 to 3 weeks postinjury and contribute to wound contracture, appear only briefly in fetal wounds.

Lorenz and colleagues have shown that the critical factor in scarless healing is the fetal fibroblast which is the major source of collagen in wound repair. Fetal fibroblasts have more receptors for hyaluronic acid (HA) and synthesize more Type III and IV collagen than adult fibroblasts. In scarless wounds, the collagen is laid down in a fine, organized, reticular pattern, which is identical to uninjured skin. Scars, however, are characterized by disorganized bundles of thick collagen fibers. In addition, scarless fetal wounds manifest a more rapid and higher content of HA than do adult wounds. HA stimulates fetal fibroblast migration and may result in scarless healing. TGF-β1 inhibits fibroblast migration and is associated with scar formation.

Many of the differences in adult and fetal responses to injury originate at the gene expression level. Recently, homeobox genes, a group of genes which influence the expression of other genes early in physical development, have been implicated in fetal wound healing. As our knowledge of wound healing improves, we may one day be able to prevent the formation of scars.

**Tissue Engineering**

Another exciting area of genetic research involves the use of undifferentiated cells.
Embryonic stem cells can be propagated in vitro and maintain their pluripotent potential. In the murine model, embryonic stem cells have been cultured to produce a multilayered epidermis with underlying dermis which was similar to native skin. This bioengineered skin is a powerful tool for studying skin development and has the potential in humans for production of bioengineered skin grafts.

In 1975, Rheinward and Green developed a cell culture technique by which keratinocytes could be cultured on a “feeder layer” of lethally irradiated mouse fibroblasts. By using this technique, a small skin biopsy could, in just 3 to 4 weeks, produce enough sheets of epithelial cells to cover the entire body. This had dramatic potential for the treatment of burn victims. Subsequent developments in tissue engineering allowed the grafts to be grown serum free and without a feeder layer of fibroblasts.

However, controversies developed over the use of bioengineered grafts. The main disadvantage is the high cost, which has precluded widespread use. The cultured sheet grafts are usually three to five cell layers of epithelial cells and are delicate to handle and are easily injured. Even after graft “take” the grafts are susceptible to blistering as a response to sheering forces. Wound infection is also problematic because the tissue is more susceptible to bacterial infection from wound contamination. In addition, the uncertain “take” rates of grafts may be due to the lack of anchoring fibrils present in normal skin dermis. For these reasons, human allografts may be used early in burn wound coverage to produce a well-vascularized and clean wound bed. The use of temporary allograft placement can increase the chance for success of a subsequently placed epidermal sheet graft.

Cell suspensions are known to attach better to wound beds than skin grafts. Cultured keratinocytes can be suspended with fibrin sealant and placed on a wound bed then covered with an allograft. As it heals, the allograft initially becomes revascularized, like an autologous graft, then after approximately 2 weeks, the epithelial components slough and the wound becomes stable as it is covered by epithelium produced from the cultured keratinocytes. Suspended keratinocytes with fibrin sealant can also be either sprayed onto the surface of the wound or placed as a gel. These methods result in more reliable cell delivery.

The combination of gene therapy and keratinocyte culture techniques has potential to both improve the performance of cultured skin substitutes as well as address healing and scar formation. The goals of future research will be to improve both cosmesis and function of healing tissues and one day to develop the ability for wounds to heal without scars.
SKIN RESURFACING

Techniques of facial skin resurfacing have been known for thousands of years; the ancient Egyptians described treating the skin with ground rocks and chemicals. Hungarian gypsies were known to place chemicals on the face for skin rejuvenation, and these techniques were brought to the United States in the 1900s by European dermatologists. The classic methods of facial resurfacing have been chemical peels; however, newer laser technologies have been able to produce similar results.

Chemical Peel

Chemical peeling involves the application of chemicals which injure the epidermis and dermis to produce the stimulation of new growth of the epidermis and tightening of the dermis (Figure 14). The peels can be superficial, injuring only the epidermis, medium-depth, injuring the papillary dermis, and deep causing a reaction in the deep reticular dermis and induction of collagen and ground substance.

Superficial chemical peels, such as 10 to 20% TCA, Jessner solution (combination of resorcinol, salicylic acid, lactic acid, and ethanol), and 40 to 70% glycolic acid remove the stratum corneum and damaged upper epidermis. These peels are performed without anesthesia, and patients can return to normal activities immediately after the procedure. Erythema and desquamation may persist for several days.

Medium-depth chemical peels injure tissue down to the papillary dermis. Classically 50% TCA has been used for these peels; but, because of increased risks of scarring at that concentration, 35% TCA is combined with either Jessner solution or 70% glycolic acid. The procedure is moderately uncomfortable, and patients are usually given a mild oral sedative preoperatively.

Deep chemical peels injure tissue into the deep reticular dermis. The Baker–Gordon chemical peel has been the standard method for skin resurfacing for nearly one half century. It consists of 88% phenol, water, Septisol, and croton oil. The soap acts as a surfactant which allows an even penetration of the solution. The croton oil is an epidermolytic agent that enhances phenol absorption. Phenol is cardiotoxic, so cardiac monitoring is crucial during its application. Intravenous fluids should be given because phenol is also hepatotoxic and nephrotoxic. Because of these toxicities, the chemical peel solution is placed on single cosmetic units of the face at 15-minute intervals.

The chemical peel solution is usually applied with a cotton-tipped applicator after the face has been vigorously cleansed and degreased. As the chemical is applied, frosting of the skin occurs, which indicates keratocoagulation. It is important to assure even peeling by producing an even frost. If the frosting is not even, the nontreated areas may be retreated. Care must be taken not to over treat areas because deeper penetration of the chemical increases the chance of scarring.

Immediately after placing the chemical, the peeled skin can be either occluded or left unoccluded. When occluded with a biosynthetic dressing (Vigilon or Flexan), the peel is absorbed deeper into the tissues into the mid-reticular dermis. As the peel penetrates deeper, the risk of post treatment scarring also increases. Re-epithelialization generally occurs from days 3 to 10; however, erythema can last for several months.

Complications can be minimized by adequate training in chemical peeling procedures as well as meticulous attention to details. The solutions must be mixed correctly and applied to the face appropriately. The novice surgeon should, after adequate training, proceed slowly with chemical peeling until a level of comfort is reached with the solutions and their effects.

The complications of chemical peels include hypopigmentation, hyperpigmentation, infection, and scarring. Pre- and postprocedure skin care and wound care are of the utmost importance. The skin should be kept moist with ointments during the healing phase. Sun exposure is contraindicated. Acetic acid soaks may be performed...
postoperatively to prevent infection. A history of herpes simplex also should be ascertained, because perioral resurfacing can stimulate the eruption of herpetic lesions or “fever blisters” that can spread to the resurfaced areas and may result in scarring. Because of the severe risk of disfigurement from herpetic infection, all resurfacing patients, no matter their history, are placed on antiviral medication perioperatively. If scars develop from resurfacing, they may be treated with topical or injected corticosteroids.

### Laser Resurfacing

Initially used for scar revision and tattoo removal, laser skin resurfacing has found its niche in wrinkle reduction and skin rejuvenation. Equipment companies today are producing a myriad of lasers and pulsed light devices which are being used for cosmetic enhancement of the skin. When laser skin resurfacing was first introduced, many complications emerged due to physician inexperience with the new technology. Companies currently are striving to develop a device which produces the best cosmetic results with the least risk of complications.

#### Carbon Dioxide Laser

Many surgeons believe the carbon dioxide (CO2) laser has become the gold standard for skin resurfacing and skin rejuvenation. CO2 laser resurfacing can produce results analogous to deep chemical peels. It has been used to treat actinic keratoses, uneven scars, dyschromias, and rhytides (Figure 15). The laser removes the epidermis and part of the papillary dermis without damaging the dermis. Keeping the dermis intact is crucial because hair follicles are the source of skin epithelial regeneration after laser treatment.

The mechanism for skin tightening and wrinkle reduction is not fully understood. Laser treated tissue does show increased levels of Type I collagen and elastic tissue. Most lasers destroy tissue by the process of photothermolysis, the destruction of tissue by the conversion of laser energy into heat. Laser energy can be absorbed by three cutaneous chromophores: hemoglobin, water, and melanin. At a wavelength of 10,600 nm, the CO2 laser energy is absorbed by water and heats the tissue by vaporization. The heat energy is then released by the tissue. The period of time it takes for half of the energy generated to be released by the target tissue is called the thermal relaxation time. The thermal relaxation time for the skin is less than one millisecond. Not to cause heat damage to the skin, pulses of laser light are randomly placed in a pattern. By randomly pulsing the light, the pulse duration is decreased to less than the target tissue thermal relaxation time. Most CO2 resurfacing lasers are equipped with an computerized pattern generator (CPG) hand piece that allows for the random placement of laser spots in a variety of geometric shapes. The amount of spot overlap, or density, can be varied.

Appropriate patient selection and the setting of realistic expectations are of paramount importance when performing laser resurfacing. The ideal candidates have facial wrinkles but not significantly lax skin. Because the laser cannot be used on neck skin, patients with significantly lax neck skin are counseled that they would be better treated by facelift or neck lift procedures.

A commonly used description of skin types is known as the Fitzpatrick skin type classification (Table 1). This classification denotes six different skin types, skin color, and reaction to sun exposure. Patients with Fitzpatrick skin types I and II generally are the most ideal candidates for laser resurfacing. Patients with Fitzpatrick skin types III and IV can be candidates, but may develop postoperative dyschromias. Patients with acne scarring are also ideal patients, and usually can be treated with laser resurfacing.
expect approximately a 50% improvement in their skin quality postoperatively. It is important to document the prior use of isotretinoin (Accutane), which affects epidermal differentiation, especially at the follicular infundibulum. It is recommended that patients wait at least a year after Accutane use before undergoing laser resurfacing, so as to allow recovery of the dermal sebaceous elements necessary for skin regrowth.

Preoperative skin care is an important adjunct to surgery and usually is initiated at least 4 to 6 weeks preoperatively. Hydroquinones are used to decrease melanin production and lessen the chance for postoperative dyschromias, but do have some controversies associated with their use. Although hydroquinones are called “bleaching” agents, they actually function to decrease the formation of melanosomes in the melanocytes and, therefore, stop the production of melanin. This works well with the concomitant use of tretinoins, which stimulate keratinocyte maturation and turnover.

The use of tretinoins or retinoids (Retin-A) is important preoperatively in skin resurfacing, although it can be controversial. Retin-A has been shown to increase dermal collagen synthesis, decrease the thickness of the stratum corneum, reduce epidermal dysplasia and atypia, increase angiogenesis, and reconstitute the papillary dermis. Benefits to its use include reduced postoperative milia formation, reduced hyperpigmentation, and accelerated epidermal regeneration with faster healing. Disadvantages include increased angiogenesis, which may contribute to prolonged postlaser erythema. Retin-A can be irritating to the skin, especially in the first few weeks of use, and can increase photosensitivity.

Alpha-hydroxy acids (AHAs), such as glycolic acid, are used as superficial peeling agents to both reduce keratinization and increase thickness of the epidermis and papillary dermis. The AHAs are less irritating than the retinoids and can be used in addition to retinoids in a prelaser skin treatment regimen. Facial laser resurfacing is usually performed in the operating suite with the patient under intravenous sedation or general anesthesia. Laser safety precautions are performed at all times, both protecting the eyes of the patient and operating room staff, as well as taking precautions for fire prevention. If the patient is intubated, a laser-safe endotracheal tube must be utilized. Oxygen is not delivered to the patient at the time of laser firing when the procedure is performed under sedation. The patient’s face is prepared with a nonflammable solution, and the face is draped with saline-soaked towels. If desired, the treatment areas of the face can be outlined with a surgical marker. The laser is then applied to resurface the face in the designated areas. Care is taken to place each pattern of the CPG directly adjacent to the previous one to prevent skip-areas and not to overlap the treated areas. Once the area is treated, the char is wiped away with a moist gauze. This is crucial so that the char does not absorb the laser heat and cause increased thermal injury to the tissue. Once the char is removed, a second pass can be performed. Collagen tightening demonstrated by tissue tightening and shrinkage can be observed during the second pass. Resistant areas of the face, such as the perioral lip lines, can be treated with three to six passes, if necessary. The endpoint of laser resurfacing is when a chamois color is noted; indicating the level of the papillary dermis has been reached. The patient is placed on antibiotics and antiviral medications postoperatively.

After the resurfacing has been completed, an occlusive or nonocclusive dressing may be applied to the face. Some surgeons prefer petrolatum ointments (Vaseline) or soybean emollient (Crisco) application due to the low incidence of sensitivity to these products, however, the use of petrolatum ointments is associated with milia formation postoperatively. Semi-occlusive dressings, such as polyurethane foam adhesive dressing (Flexzan), can be applied and left in place for several days. Occlusive dressings are associated with faster healing times but increased chance of wound infections.

Postoperative complications can include prolonged erythema that can last from 4 to 8 weeks and can be camouflaged with makeup, or treated with topical or systemic corticosteroids. Hyperpigmentation can be treated with hydroquinone postoperatively. Hypopigmentation is more difficult to treat and may resolve over time. Telangiectasias can be worsened after laser resurfacing and can be treated with the FLPD laser.

More serious complications include scarring and infection. Bacterial infection generally resolves with wound care and appropriate antibiotics (cultures usually show Staphylococcus aureus or Pseudomonas aeruginosa). Herpetic outbreaks must be treated aggressively to prevent scarring. Scarring itself can be a devastating complication of laser resurfacing. Areas of hypertrophic scarring can be treated with topical fluorinated corticosteroids, silicone gel sheeting, corticosteroid injections, and the FLPD laser.

**Erbium:YAG Laser Resurfacing.** The erbium: YAG (yttrium–aluminum–garnet) laser also uses water as its chromophore, but the absorption of erbium light by water is ten times that of the CO2 laser. The laser wavelength of 2.940 nm corresponds to the optimal absorption peak of collagen and causes much less thermal damage than the CO2 laser. The erbium:YAG laser thus produces a more superficial injury by vaporization. Both the CO2 and erbium-YAG lasers are considered ablative lasers because they remove the epidermis and part of the papillary dermis.

The erbium laser is much less painful than the CO2 laser and can be performed under topical or local anesthesia. Unlike the CO2 laser, the pulses are placed with 10 to 12% overlap. Debris is minimal, and wiping is often not necessary between passes. The endpoint of treatment is when pinpoint capillary bleeding is observed. Unlike the CO2 laser treatment, collagen tightening is not observed during erbium laser treatment. Ointment is applied postoperatively, erythema is minimal, and makeup may be applied in approximately 4 days. Erythema is generally gone by 2 weeks postoperatively. Dyschromias rarely occur postoperatively.

When the results with the erbium-YAG laser are compared to those of the CO2 laser, they are not as dramatic. The erbium-YAG laser does not produce the same amount of collagen remodeling and is not as good for deeper rhytides. However, because of its low chance for complications and quick recovery, it does have a role in skin resurfacing of superficial rhytides and scars.

**Newer Technologies.** Fractional photothermolysis (Fraxel, Reliant Technologies, San Diego, CA) was introduced in 2004 as a nonablative laser, which selectively damages the dermis and spares the epidermis by cooling the skin during treatment. Like the CO2 and erbium-YAG lasers, the Fraxel laser uses water as a chromophore. The Fraxel technology is a 1,550 nm diode-pumped erbium fiber laser which produces “microthermal treatment zones”: thousands of small columns of thermal energy that penetrate the epidermis and dermis. This fractional energy does not injure the surrounding tissue, which allows for more rapid healing. Only about 20% of the surface area is affected, therefore, about four to five treatments are needed for complete effect. Fraxel laser treatments can be used on all skin types and can be used to treat the neck, chest, and hands.

Fraxel treatments are performed under topical anesthesia. A blue tint is applied to the face, to guide the laser, and is removed after the procedure. The patients may look pink and swollen for up to 4 days.

**Newer lasers** are combining both CO2 and Fraxel technologies for the ultimate in flexibility for resurfacing. In addition, companies are continuing to produce skin resurfacing laser technology aimed at improving results and minimizing risk.

Skin resurfacing techniques should only be performed by surgeons with the proper training and experience. Complications of these procedures can be devastating when not performed properly. The novice surgeon is admonished to proceed with caution when employing these procedures.

Local Flaps in Facial Reconstruction

Peter A. Hilger, MD
Kofi O. Boahene, MD

The face is the central focus for one’s identity, and any disfigurement of it draws undesirable attention. Even minor soft tissue defects can disrupt the delicate highlights and shadows of the face. To look normal minor, and major soft tissue defects of the face should be repaired with a carefully selected plan based on proper principles of cutaneous flaps and appreciation for the esthetic aspects of the face.

Soft tissue defects of the face most commonly result from resection of cutaneous malignancies or trauma. Unfortunately, the incidence of skin cancers of the face is on the rise with a particularly notable increase in younger patients. Esthetics standards for younger people are often high and during their lifetime they have the possibility of developing additional cancers and associated defects. This fact requires judicious use of available flaps as one anticipates numerous reconstructive interventions over many years. Basal cell carcinoma, squamous cell carcinoma and melanoma are the most common cutaneous malignancies. Surgical excision with confirmation of margins must be ensured before embarking on any reconstruction. Mohs excision should be considered in the surgical plan as it has the highest rate of cancer clearance. Facial avulsion injuries from vehicular accidents, human or animal bites, and burns also present complex and irregular defects that may require the use of local flaps. Dog bite injuries with tissue loss are often encountered in children, and their repair can be both emotionally and technically challenging.

While some facial soft tissue defects can be closed primarily by advancing adjacent tissue, others require skin grafting or healing by secondary intention. The disadvantages of these methods are the limitation in scar placement, contour irregularities, color and texture mismatch, wound contracture, and distortion of mobile facial structures. Local flaps recruit tissue from adjacent local or regional facial subunits and can provide skin, fat, cartilage, or hair with appropriate color, contour, and texture matching. When properly executed, local flaps can be used to repair most small and intermediate sized defects with excellent esthetic results.

ANATOMY AND PHYSIOLOGY OF LOCAL FLAPS

Local flaps can be designed to recruit skin, fat, other subcutaneous tissue, cartilage, hair follicles, and accompanying adnexal tissue. The survival of all these recruited tissues depends primarily upon the adequacy of the blood supply. A thorough appreciation of vascular anatomy of the facial skin is, therefore, central to the successful execution of local flaps.

The face has an extensive vascular supply arising from branches of both the internal and external carotid systems with rich collateralization and defined vascular territories. Knowledge of these vascular territories and the extensive collateralization of these vessels allow the successful design of a variety of local flaps. The vascular territories of the face and scalp have been thoroughly investigated by dye injection techniques. Eleven vascular territories each supplied by a distinct vessel have been described: the transverse facial, submental, zygomatico-orbital, anterior auricular, posterior auricular, occipital, supratrochlear, frontal and parietal branches of the superficial temporal, and superior and inferior labial arteries (Figure 1). Terminal perforators arise from these vessels to form the subdermal plexus. The subdermal plexus resides at the junction of the deep dermis and the subcutaneous tissue. From the subdermal plexus, ascending vessels arise to form a more superficial subepidermal plexus between the papillary and reticular dermis. Angiographic studies of the head and neck have shown that the subdermal plexus exists in defined territories that tend to vary in size, pattern, and orientation among regions of the face. Adjacent territories of subdermal plexuses are interconnected by reduced caliber vessels known as choke vessels. Choke vessels may dilate under certain physiologic circumstances such as when a flap is delayed allowing the inclusion of adjacent vascular territory in local flap design.

CLASSIFICATION OF LOCAL FLAPS

Local flaps of the face are commonly classified based on their vascular supply (axial vs random) or method of movement (sliding or lifting).

Classification of Flaps by their Vascular Supply

The blood supply of random flaps is primarily based on the subdermal plexus derived from fasciocutaneous, musculocutaneous, or direct cutaneous perforators. The distribution of these perforators and their associated vascular territories are well defined on the face (see Figure 1). Knowledge of these territories allows the safe design of random flaps. Examples of common random flaps are the rhomboid flap used in cheek reconstruction and the bilobe flap used in nasal reconstruction. It was long thought that the surviving length of a flap was entirely dependent upon the width of its base. Generally, a 3 to 1 ratio was felt to be optimal. This is now known to be inaccurate, but the length to width ratio should still serve as a rough guide. More important than the width of a flap is the perfusion pressure through the supplying vessels. When the perfusion pressure along the length of a flap drops below the critical closing pressure of the arterioles in the subdermal plexus, perfusion of the flap ceases. A wider random flap will only include additional subdermal arterioles that have the same perfusion pressure since they are all based on the same feeding vessel. Adding additional vessels at the...
same perfusion pressure, that is, widening the base of the flap, does allow for some increased collateral circulation which can be beneficial but does not affect the perfusion pressure at the distal portions of the flap. It is now recognized that the length to width ratio is only a rough guideline and varies with different flaps.

In contrast to random flaps, axial flaps receive their blood supply from named vessels which extend along the linear axis of the flap giving off perforators to form the subdermal plexus. The distal portion of axial flaps can be random. The forehead flap based on the supratrochlear vessels is an example of an axial pattern flap.

**Classification of Flaps by Method of Movement**

When characterized by their method of transfer, two basic local flap movements can be described: sliding or lifting. Advancement and rotation flaps slide adjacent tissue into a defect, whereas transposition and staged interpolation flaps move tissue into defects by lifting.

**Flaps that Move Tissue by Sliding**

**Advancement Flaps.** Advancement flaps are designed directly adjacent to a defect and slide in a linear vector into the primary defect. In advancement flaps, one border of the defect becomes the leading edge of the flap. Examples of advancement flaps are the V-Y advancement flaps (Figure 2A) and pedicle advancement flaps (Figure 2B).

**V–Y Advancement Flaps.** V–Y advancement flaps are versatile flaps based on an island subcutaneous pedicle. Movement of the V–Y flap depends on the mobility of the subcutaneous tissue. It is most suitable in regions of the face such as the cheek and melolabial (formerly known as the nasolabial) area where there is abundant subcutaneous tissue and rich vascularity (Figure 3). When designing a V–Y flap, one of the limbs of the V is placed along an anatomic boundary when possible. The incisions made through the subdermal plane are beveled outward and the surrounding skin is undermined in this plane. Deeper dissection of the subcutaneous tissue is carried out only at the distal end of the flap adjacent to the defect. Blunt dissection can be carried out lateral to the flap until the island of skin advances into the defect without tension. Variations to the classic V–Y island flap have been described in which a complementary transposition flap is added to one end of the flap to increase its length and versatility.²

**Pedicle Advancement Flap.** A single pedicled advancement flap is raised as a square or rectangle with one edge bordering the defect and two parallel incisions along the sides of the defect (see Figure 2B). The plane of flap elevation is deep to the subdermal plexus in the subcutaneous tissue. The tissue surrounding the defect is undermined to allow for secondary movement in a direction opposite to that of the stretched advancement flap. The pedicled advancement flap depends on the elasticity of the skin to stretch into the defect. A secondary defect primarily consisting of a wound of unequal length results. The closure of this secondary defect is facilitated by excising Burow triangles. A small Z-plasty may also be incorporated at the base of the flap to achieve greater advancement. Pedicled advancement

**Figure 2** A advancement flaps move tissue by a sliding movement. (A) V–Y advancement flap. (B) Advancement flap with excision of Burow triangles.

**Figure 3** Repair of alar base defect with a V–Y advancement flap.
flaps are useful for reconstruction of defects of the forehead where the incisions can be placed parallel to the horizontal forehead rhytides. Two pedicled advancement flaps can be designed on opposite ends of a defect and each advanced over a shorter distance to close a defect such as helical defects on the ear (Figure 4).

**Bipedicled Advancement Flaps.** Advancement flaps pedicled on both ends are also useful in repairing longitudinal defects. They are designed by making two incisions that parallel the defect margin keeping the base and midsection of the flap wide. The flap is then elevated in the subcutaneous plane leaving the two ends attached (Figure 5). It can then be advanced sideways into the defect. Examples of bipedicled advancement flaps are the tubed postauricular flap for helical reconstruction and the bipedicled advancement scalp flap for hairline reconstruction.

**Rotation Flaps.** Rotation flaps move tissue by sliding a semicircular flap into a defect along an arc of rotation and a pivot point. They are usually random flaps and are commonly used for closing triangle defects. When the primary defect is circular, it is first converted into a triangular shape by excising a Burow triangle (Figure 6). A semicircular flap is then raised starting from the edge of the defect. The resulting secondary defect is mainly a wound of two unequal lengths. The greatest tension is along a line between the pivotal point and the most peripheral point of the flap. Closure is accomplished by distributing the extra length and tension along the arc or by including a Burow triangle or a Z-plasty adjacent to the pivot point. Rotation flaps are commonly used in closing scalp defects where tissue stretch necessary for advancement flaps is minimal. A cervicofacial rotation flap is also another common rotation flap useful for closing large cheek defects. A rotation flap may also be designed as a double flap (referred to as an O to Z flap) to recruit tissue from both sides of the defect (Figure 7). These flaps are useful in locations where the arc of rotation may be less noticeable as in the lateral side of the face and scalp. Limitations of rotation flaps are tissue resistance to rotation and the noticeable dog ear that is created at the rotation pivot. The cheek and the scalp tend to rotate well while the tip of the nose, the nasal alar region and the auricle rotate poorly. In addition, any back-cut at the base of the flap to achieve lengthening or correct dog ears, compromises the blood supply to the flap. To circumvent this problem, dog ears may be left in place and allowed to settle over time. Alternatively, cuts placed at the base of the flap to improve rotation or to remove dog ears should be directed away from the pedicle and designed as a Z-plasty or Burow triangle, thus maintaining a wide pedicle base.

**Flaps that Move Tissue by Lifting**

**Transposition Flaps.** A transposition flap is usually a random flap that is incised on three sides and lifted laterally into an adjacent defect. It has a pivot point located at the base of the defect. Transposition flaps are versatile in that they can be designed with borders that are removed from the defect thus allowing flexibility in placing incisions. Examples of transposition flaps commonly used in head and neck reconstruction include the Limberg or rhomboid flap, note flap, bilobe flap, interpolation flap, and hinge flap.

**Limberg (Rhomboid) Flap.** The Limberg flap is an extremely versatile example of a transposition flap used in closing rhomboid-shaped defects. The flap is designed by extrapolating the short axis of the rhomboid defect onto the adjacent skin.
Four options for placing the third limb of the flap can be selected and drawn parallel to the edge of the defect. Thus for a given rhomboid defect, four Limberg flaps can potentially be raised depending on where the third limb is placed. The third limb is selected to recruit the most mobile skin that allows for the best camouflage without distortion of surrounding structures. All limbs of the flap should be of equal length. The rhomboid-shaped flap is then incised and lifted into the primary defect. The resulting secondary defect is then closed primarily by undermining and advancing the surrounding tissue. The classic Limberg flap has 60° and 120° angles. For larger defects two or more Limberg flaps can be used.

One modification of the classic Limberg flap is the Dufourmentel flap (Figure 9). Like the Limberg flap, the Dufourmentel flap is also a transposition flap designed to close rhomboid defects. It differs from the Limberg flap by having angles that are not necessarily 60° and 120°. The flap is designed by extending one line from the short axis to a length equivalent to the side lengths, similar to a classic rhomboid flap, and another line is drawn by extending the side adjacent to the lower angle to a similar length. However, the incision is made along a line that bisects these two extended lines. A second incision is made along a line that is dropped from the end of the bisected line parallel to the long axis of the rhomboid defect to complete the flap. With this modification, the pedicle is wider and the leading angle more obtuse. This results in less vertical pull. Therefore, the Dufourmentel flap is useful in areas where lateral tension is acceptable but vertical pull is not.

One disadvantage of the rhomboid transposition flap is that more than half of the resulting scar does not fall within or parallel to the natural skin lines. It is therefore best suited for repair of defects of the lateral facial subunits: lateral cheek, mandible, and temple regions.

Z-Plasty. The classic Z-plasty is essentially two adjacent random triangular flaps that interchange position by being lifted into each other's defect thereby lengthening and reorienting their common central limb. Z-plasties are used to lengthen tight, contracted scars or reorient tissue or scars into a more desirable location. In the classic Z-plasty, the adjacent triangles are equilateral triangles with 60° angles. Varying this angle alters the theoretical gain in scar lengthening. A 30°, 45°, and 60° Z-plasty can theoretically lengthen a scar by 25%, 50%, and 75% respectively. The actual gain in length is dependent on the elasticity of the surrounding tissues. Occasionally the best flap design requires that the two flap angles be of different sizes or angles. Other variants of the classic Z-plasty are the double opposing Z-plasty used in cleft palate and epicanthal fold repair, and the multiple running Z-plasty used in scar revisions.

Note Flap. Another common transposition flap is the "note flap," so called because the design is reminiscent of a musical eighth note. A note flap is useful for repairing small circular defects. To design the flap, a tangent is drawn from the edge of the circular defect parallel to a relaxed skin tension line for a distance of 1.5 diameters. A second line equal in length to the first is drawn at 50° to 60° to the first to create a triangular flap. The flap is then elevated with wide undermining of the tissue surrounding the defect. The note flap is then transposed into the defect. The secondary defect is closed primarily (Figure 10).
Bilobe Flap. Bilobe flaps are double transposition flaps that share a single base. They move tissue by lifting the first lobe into the primary defect. The resulting secondary defect is closed by transposing the second lobe. A tertiary defect results which is closed primarily. Invariably a standing cone deformity develops, the size of which is dependent upon the arc of rotation. In its original description, the two lobes of the bilobe flap were at 90° angles so that the final transposition was over an 180° arc. An increased arc of rotation leads to a more prominent standing cone deformity. Final arcs of transposition of 90° to 110° are more optimal with less resulting deformity. The bilobe flap is primarily used in closing defects of the lower third of the nose but can be used in other regions of the face such as the infraorbital region. It has the distinct advantage of recruiting tissue farther away from the primary defect and therefore reducing the final tension of closure. A disadvantage of the flap is that the resulting scar is unable to follow skin tension lines in many cases. It is also more prone to pincushioning because the curvilinear scars and the wide bed of scar that contracts deep to the flap.

A simple way of designing a bilobe flap is to first pick out a pivot point one diameter away from the center of the defect (Figure 11). A needle is inserted at this pivot point and a suture is wrapped around a marking pen. Using this as a guide, the path of rotation is drawn out starting from the edge of the defect. The first lobe of the flap equaling the size of the defect can then be drawn adjacent to the defect. The second lobe is usually designed as a triangular flap to facilitate closure and can be made smaller than the secondary defect. The distal portion of the flap can be tailored to fill the depth of the primary defect, but the rest of the flap should be kept thick to optimize its vascularity. A Buvor triangle centered on the pivot point is then excised at the base of the primary defect to facilitate transposition of the lobes.

Interpolation Flaps. The interpolation flap is a random or axial flap designed and lifted into a nearby defect over or under an intervening bridge of normal skin. Common examples include the melolabial flap, the paramedian forehead flap, and Monk eyelid flap. When the flap passes over an intervening tissue, a second stage procedure is required for pedicle division. When the pedicle passes under a bridge of normal skin, a portion of the pedicle can be de-epithelialized to allow a one-stage procedure. The paramedian forehead flap is the flap of choice for reconstructing extensive nasal defects. It can also be used for reconstructing complex periorbital and medial cheek defects. A detailed discussion of the paramedian forehead flap is provided in Chapter 54, "Nasal Reconstruction."

The melolabial flap is another example of an interpolation flap that lifts tissues from the cheek and is often used in reconstructing defects of the lower part of the nose. It is often raised as a superiorly based axial pattern flap supplied by direct cutaneous perforators exiting from the angular branch of the facial artery. It is best suited foralar, nasal tip, or columellar defects. To facilitate flap mobilization, the flap can be designed as an elliptical island flap with a wide based subcutaneous pedicle. The melolabial crease is drawn on both sides to establish symmetry. Using a template of the defect, the necessary width of the flap is determined (Figure 12). The distal portion of the flap is raised in the subcutaneous plane but the base of the pedicle should be kept as a wide subcutaneous pedicle by blunt mobilization of the surrounding tissue. Closure of the secondary defect before flap insertion further improves the rotation of the flap. The melolabial incision should be closed in such a manner so as to mimic the contralateral melolabial fold, thus minimizing cheek asymmetry. Pedicle division can be performed in 3 to 4 weeks depending on individual patient factors.

Hinge Flap. The hinge or turn-in flap is a random flap that moves tissue by lifting tissue pivoted along the edge of a defect to fill the deep aspect of the defect. It is commonly used to provide closure of the inner layer of a full-thickness nasal or cheek defect. It is also useful in repairing full-thickness central auricular defects. It is used in conjunction with a second flap that provides the external coverage (Figure 13).

PLANNING THE REPAIR OF A FACIAL DEFECT

Optimal repair of facial defects with local flaps requires thoughtful planning. The defect should be analyzed in the context of facial esthetics, function, and adjacent tissue characteristics. A systematic, rather than a “cookbook” approach fosters creativity and a consistently superior outcome. First, it is important to draw theesthetic units and define the defect size, depth, and location. The following questions and considerations should be contemplated in the planning process:

How much of a facial subunit is involved and does it cross subunit boundaries? Next, consider potential donor sites by looking within the involved subunit as well as surrounding subunits. Where is tissue redundant? A saes tissue movement by sliding or pinching the adjacent tissue. Consider the secondary consequences of tissue movement from each of these potential donor sites. Where will the maximum tension vector be distributed and will it cause any distortion of free margins? Can incisions be placed along anatomic boundaries and in the direction of relaxed skin tension lines? Consider the vascularity of the surrounding tissue. Are there previous scars that may compromise blood supply to the flap? Are there any patient factors such as smoking, diabetes, previous radiation, or small vessel disease...
The hinge or turn-in flap provides lining for a full-thickness nasal tip defect.

Figure 13

that may influence the vascularity of a chosen flap? Finally, consider patient factors such as esthetic expectations, ability to tolerate multi-staged procedures, natural history of the underlying problem that resulted in the defect and impact on the patient’s quality of life.

Pretransfer Flap Manipulation

With further understanding of flap physiology, various techniques have been used to manipulate local flaps prior to their transfer to improve their survival, extent, or structure. These techniques include flap delay, tissue expansion, and flap prelaminating.

Flap Delay. Surgical delay of flaps before transfer has long been known to improve the vascularity and survival of cutaneous flaps. The phenomenon of delay first involves full-thickness incisions around portions of the flap to raise a bipedicled flap and later converting it to a single pedicled flap after a "delay" period before transfer. The delay process improves the flap microcirculation and maximizes flap survival. Dhar and Taylor performed various animal studies with angiographic techniques and identified a consistent pattern of arterial vasodilatation after delay. The delay effects of lasers are the inflammatory changes induced by laser injury as well as the partial vessel blockage that targets hemoglobin. Potential applications of laser flap delay include pretreatment of planned skin flaps in high-risk patients before surgery, for example, pretreatment of the preauricular skin with the pulse dye laser 1 or 2 weeks before large cervico-facial rotational flaps in smokers. Other potential uses include paramedian forehead flaps and Juri flaps in high-risk patients. Potentially, pretreatment with these lasers can be done in the office setting with minimal discomfort, bleeding, and cost. The clinical benefit of lasers as a delay tool awaits confirmation in clinical studies.

Tissue Expansion. The technique of tissue expansion has found a wide range of application in head and neck reconstruction. It provides local tissue of appropriate thickness, texture, color, and sensibility at a nominal donor-site cost. Expansion is achieved by inserting a silicone expander and gradually filling it with saline over time, often waiting 3 to 5 days between injections. The base of the expander selected should be at least 2 to 2.5 times the size of the defect. The incision made to insert the tissue expander should be placed with thoughtful consideration of the final flap design. When used in the neck, scalp, or forehead, massive amounts of expanded skin can be made available for reconstructing large defects.

Tissue expanders are most effective when there is a solid bony support. Hence the scalp and forehead are ideal sites for tissue expansion. In children, expansion of neck and cheek skin may allow single staged resurfacing of burn injuries and extensive hairy nevi. Stretching skin prior to transfer has some of the physiologic benefits of flap delay as there is increased flap vascularity. In expanded skin, angiogenesis is stimulated, and epidermal proliferation results in a thicker epidermis. Dermal thickness initially decreases and epidermal proliferation results in a thicker epidermis. Potential applications of laser flap delay include pretreatment of planned skin flaps in high-risk patients before surgery, for example, pretreatment of the preauricular skin with the pulse dye laser 1 or 2 weeks before large cervico-facial rotational flaps in smokers. Other potential uses include paramedian forehead flaps and Juri flaps in high-risk patients. Potentially, pretreatment with these lasers can be done in the office setting with minimal discomfort, bleeding, and cost. The clinical benefit of lasers as a delay tool awaits confirmation in clinical studies.

CASE ILLUSTRATIONS: LOCAL FLAP RECONSTRUCTION BY FACIAL REGIONS

Defects of the Forehead-Brow-Temple

The forehead–brow–temple area is a particularly challenging area for reconstruction. The forehead skin is thick and lies in a broad convex plane that extends from the hairline superiorly to the brows inferiorly. It extends laterally to the temples and has skin of varying thickness. The eyebrow, scalp hairline, and lateral canthus comprise the aesthetic boundaries of the forehead and limit the available tissue for repair of defects. The goal of forehead reconstruction is to recreate the esthetic boundaries of the forehead and to regain symmetry with the contralateral side. Several cases are presented for illustration of local flaps used in this area.

Case 1. A 54-year-old male presented with two separate defects following Mohs excision of a basal cell carcinoma (Figure 14). The defects extended into the subcutaneous tissue. The superior defect is close to the hairline while the inferior defect involves the eyebrow. The patient preoperatively had a baseline asymmetric brow with the right side lower than the left. While various options exist for closing the defects, a simple linear closure in the direction of the forehead rhytides was chosen. The forehead skin was widely undermined. The defects were converted into an ellipse and closed primarily. Primary closure within relaxed skin tension lines by advancing surrounding skin often gives the best result and should always be considered before more complex local flaps. In this case, the expected temporary asymmetry of the eyebrow was discussed with the patient. Botulinum toxin was also injected for chemomobilization to improve the final scar result.

Case 2. A middle-aged female presented with a forehead defect following Mohs excision of a basal cell carcinoma (Figure 2B). The defect
extends down to the frontalis muscle. She has dynamic forehead rhytides and a moderate degree of skin laxity. The defect was reconstructed with two pedicled advancement flaps. Small Burow triangles were included at the base of the flaps to facilitate tissue advancement. Incisions parallel to the relaxed skin tension lines were used to minimize visible scars.

**Case 3.** A 56-year-old male presented with a large defect of the temple following wide local excision of a fibrosarcoma (Figure 15). The defect extended down to the underlying temporalis muscle with partial excision of the muscle. The temporal branch of the facial nerve was excised. Multiple subunits were involved, including the cheek, temple, forehead, and lateral brow. The facial subunits were drawn. A template was taken from the uninvolved side and transposed to the involved side to help define the hairline as well as the extent of the various subunits involved. Reconstruction of the defect was accomplished with a combination of a large medially based cervicofacial rotational flap, rhomboid flap, and full thickness skin graft. In the future, the skin graft portion can be secondarily removed by serial excision or following scalp expansion.

**Cheek Defects**

The cheek unit of the face is defined laterally by the preauricular sulcus, superiorly by the lower lid-cheek boundary extending laterally across the zygomatic arch, medially by the nasofacial and melolabial groove, and inferiorly by the jaw line. The lateral cheek contour is relatively flat while the medial cheek is soft and rounded. In primary gaze, the medial cheek is more visible hence distortions in this region are more apparent than in the lateral cheek. The reconstructive goals for cheek defects are uniform color and texture matching, preservation or restoration of the temporal hair tuft, and prevention of lower lid retraction. Unlike defects of the central part of the face, the rule of resurfacing an entire subunit takes on a lesser importance.

Cheek defects may be divided into lateral and medial defects. The site of defect influences the choice of flap, pedicle base, and direction of tissue movement. Small to medium defects located in the medial or lateral cheek may be closed in the direction of relaxed skin tension lines by wide undermining and bidirectional advancement of surrounding tissue. When possible, deep tension sutures should be placed around stable structures such as the nasal spine, nasal periosteum, or periorbital periosteum to minimize distortion of the alar or eyelid margins. Standing cone deformities are excised with incisions placed in natural rhytides.

Larger medial cheek defects may be closed with laterally based cervicofacial rotation advancement flaps that recruit skin from the inferior face, jowl, and neck. Incisions for this flap extend from the defect along the nasofacial groove, the alar crease, and the melolabial groove. This incision can be extended as needed across the mandible in which case the addition of a Z-plasty is helpful. If the medial cheek defect extends onto the nose or eyelid, these latter subunits should be reconstructed with a separate flap or graft. This flap is vascularized by branches from the superficial temporal artery and branches of the occipital artery in the neck. Flap elevation may include platysma or superficial musculoaponeurotic system to improve vascularity, especially in high-risk patients.

Larger lateral cheek defects may be closed with medially based cervicofacial rotation-advancement flaps. The flap is vascularized by branches of the facial and submental arteries. The incision extends from the edge of the defect, around or through the temporal hair tuft, inferiorly along the preauricular sulcus and then around the earlobe. In the temporal region, the incision is placed along the temporal hair tuft to prevent movement of the hair tuft. Beyond the earlobe, the extension and design of the incision depends on the amount of skin needed.

**Figure 14** Primary closure reconstruction of two separate forehead defects following Mohs excision of basal cell carcinoma.

**Figure 15** Large temple defect following wide local excision of a fibrosarcoma. Closure was accomplished with the combination of a cervicofacial rotation flap, rhomboid flap and full thickness skin graft.
Case 4. A 47-year-old female presented with a lateral cheek defect following Mohs excision of basal cell carcinoma (Figure 16). The cheek defect was repaired with a classic rhomboid transposition flap. One disadvantage of the rhomboid flap is that the incisions do not follow relaxed skin tension lines. This drawback is better tolerated in the lateral facial subunits such as the lateral cheek and temple.

Case 5. A 49-year-old female presented with an intermediate size cheek defect following Mohs excision of a basal cell carcinoma (Figure 17). The defect is mainly confined to the lateral cheek subunit but extends slightly into the temple. The defect was reconstructed with a medially based cervicofacial rotation flap. In females incisions are placed in the preauricular skin crease and extended into the infralobular crease. In males, a similar incision may distort the preauricular hair tuft. Modifications should, therefore, be made in males to preserve the nonhair bearing skin in the pretragal region.

Scalp Reconstruction

Reconstruction of small and intermediate size defects of the scalp can be more challenging than similar size defects in other parts of the head and neck. This is mainly due to the inelasticity of the scalp. The primary goal of scalp reconstruction following tumor ablation is to provide soft tissue coverage of the skull in time to start radiation therapy when indicated. Some small and intermediate size defects are amenable to primary closure facilitated by external expansion or rapid intraoperative expansion. In the presence of periosteum, skin grafts can be placed. When the periosteum is absent, one can rotate a pericranial flap to provide bone coverage and then place a skin graft. Alternatively, the outer cortex of the exposed calvaria can be drilled down to bleeding bone which can adequately support split thickness skin grafts. Meticulous wound care can also allow healing by secondary intention. The application of vacuum assisted wound healing devices has been useful in speeding up the process of generating granulation tissue. When designing local flaps for scalp defects, the base and arc of rotation should be kept wide relative to the defect because of the inelasticity of the scalp. The scalp is an ideal region to consider tissue expansion. A principal advantage of tissue expansion of the scalp is the movement of hair-bearing skin into the defect. The primary disadvantage is the prolonged period involved in the expansion process. Animal studies have shown that the expansion process can be accelerated by the topical application of papaverine cream, but its clinical utility is yet to be proven.13

Case 6. A large scalp defect is reconstructed with a double rotation (O to Z) flap (see Figure 7). The defect was initially minimized with deep tension sutures, skin grafting, and tissue expansion. Tissue expansion preceded this double rotation flap closure (Figure 7).

Complex Defects Involving Multiple Subunits

Reconstruction of complex defects involving multiple facial subunits can be challenging. These may require an integrated technique that...
wounds resulted in significantly better cosmetic appearance of the wounds when compared to controls. The beneficial role of botulinum toxin in wound healing has been confirmed in clinical studies and may be considered as an adjuvant treatment in local flap closure especially of the forehead.

**SUMMARY**

Local flaps remain an effective method of reconstructing simple, intermediate, and complex defects of the head and neck. A fundamental understanding of the vascular territories of the face and the dynamics of soft tissue movement is necessary for the optimal selection and design of local flaps. Complex defects can be fragmented into smaller defects and reconstructed based on the principle of facial subunits. Flap prefabrication, tissue expansion and flap delay are important techniques that may be employed to expand the composition, vascularity, and survival of local flaps.

Regional Flaps and Free Tissue Transfer

Mark K. Wax, MD
Shri Nadig, MD

The majority of neoplasms involving the head and neck are easily treated by local resection and reconstruction. Cosmetic and functional outcomes have proven to be excellent whether this reconstruction involves letting the tissues granulate or the transfer of local regional flaps utilizing skin from the surrounding face or neck. Regional flaps and free tissue transfer are most often used in reconstruction of defects following ablation for neoplasms of the upper aerodigestive tract. They are occasionally used for congenital and traumatic defects. This chapter reviews the commonly used flaps in head and neck reconstruction with an emphasis on their indications in particular circumstances. Local and regional flaps for nasal reconstruction are discussed in Chapter 54, "Nasal Reconstruction."

Patients with head and neck cancers often have had multiple treatment modalities over a prolonged period of time. They present unique reconstructive problems. Oftentimes because of the previous resections with tissue rearrangement, a large composite defect is left (Figure 1). The area previously treated with radiation as well as a number of local tissue transfers is not able to support local tissue reconstruction with standard flap techniques. Adding to this reconstructive problem is the fact that resection of recurrent neoplasms involves more than single tissue subunits. The orbital contents, maxilla, mandible, auricle, nose, and lateral portion of the temporal bone often require resection. This problem is particularly prominent in primary neoplasms of the upper aerodigestive tract. The reconstruction after large primary and secondary resections can be challenging and requires composite tissue from a distant site.

**TYPES OF FLAPS**

Modern head and neck reconstruction relies heavily on the use of tissue flaps fed by a distinct vascular supply (pedicle). These flaps may consist of:

1. skin and subcutaneous tissue;
2. skin, subcutaneous tissue, and bone;
3. bone alone; and
4. muscle and skin.

Flaps may be further subdivided into pedicled flaps and free tissue transfer flaps:

1. A pedicled flap consists of tissue with a dominant artery that can be transposed into the area of the defect.
2. A free tissue transfer flap is completely removed from its anatomic location, including division of its dominant vascular pedicle and is inset into the recipient location. Flap perfusion is reestablished by creation of vascular anastomosis from the flap pedicle to nearby native vessels with microsurgical techniques.

**PEDICLED MYOCUTANEOUS FLAPS**

Myocutaneous (musculocutaneous) flaps are composite flaps that include skin, subcutaneous fat, fascia, and muscle. The blood supply to this type of flap is based on a single dominant arterial trunk that provides adequate perfusion through an anatomic arterial network to a large volume of muscle, despite ligation of adjacent contributing vascular pedicles. Myocutaneous flaps are utilized in the reconstruction of large defects that require restoration of a cutaneous or mucosal surface and bulk to fill a voluminous defect following resection of the neoplasm. Examples in which a myocutaneous flap would be considered an option for reconstruction include large defects of the scalp, oropharynx, and skull base (these defects may include portions of the facial skeleton, paranasal sinuses, and palate).

**Pectoralis Major Myocutaneous Flap**

The pectoralis major myocutaneous (PMMC) flap has been one of the most versatile flaps for head and neck reconstruction. Its introduction in the 1970s revolutionized the care of these patients by allowing rapid healing and rehabilitation. In the 1970s and 1980s, it was the workhorse flap for regional reconstruction. The introduction of free tissue transfer with the ability to reconstruct composite tissue has relegated the PMMC flap to a secondary role. The four primary indications for this flap are protection of threatened great vessels or free flap vascular pedicles with wound dehiscence due to fistula or infection, prevention of potential wound breakdown in anticipation of compromised healing, coverage of small pharyngeal defects, and protection of the mandible following debridement for osteoradionecrosis.

The pectoralis major is a thick, triangular muscle that forms the anterior wall of the axilla. In the female, it is covered by the breast that is attached to the pectoral fascia. It originates as two heads. The clavicular head from the medial half of the clavicle inserts into the lateral lip of the intertubercular groove of the humerus, deltoid tuberosity, and deep fascia of the arm. The larger sternocostal head originates from the manubrium and body of the sternum, costal cartilages of upper five or six ribs, body of the sixth rib, and aponeurosis of the abdominal external oblique muscle, and it inserts as a bilaminar tendon deep to the insertion of the clavicular head’s fibers. The large pectoral branch of the thoracoacromial artery is the axial vessel upon which the pectoralis major myocutaneous flap is based. The thoracoacromial artery arises from the second part of the axillary artery just behind the medial border of the pectoralis minor muscle. It runs anteriorly around the upper border of the pectoralis minor muscle, pierces the costocoracoid membrane, and divides into four branches: acromial, clavicular, deltoid, and pectoral. The deltoid branch accompanies the cephalic vein in the deltopectoral groove. The largest branch, the pectoral, runs inferomedially along the posterior surface of the pectoralis major muscle within the thin fatty layer between it and the pectoralis minor. There is a natural surgical plane deep to this vessel which allows blunt dissection to separate it and the overlying pectoralis major muscle from the underlying pectoralis minor muscle.

A perforator, branching from the pectoral branch immediately after its branching from the thoracoacromial trunk approximately 2 cm medial...
to the cephalic vein and within 2 cm of the lower border of the clavicle, crosses directly anteriorly from the surface of the pectoralis major muscle to the overlying subcutaneous tissue. Recognition of this vessel accurately localizes the position of the proximal portion of the pectoral branch of the thoracoacromial artery before elevation of the pectoralis major muscle has been started.

This flap is reliable with predictable cutaneous survival. Success rates of over 90% are reported. This flap provides vascularity at the recipient site due to its excellent blood supply. It has sufficient bulk to fill cavities, augment contour, and to provide structural support (Figure 2). Elevated on a narrow muscle pedicle, it can replace the contour of the sternocleidomastoid muscle and restore symmetry to the neck after a radical neck dissection. In addition, if the muscle pedicle is elevated without the overlying skin as a myogenous flap, a skin “paddle” at the end of the muscle can be transported to the recipient site under the neck flaps in one stage without the need for a later division and inset of the flap. The donor site is usually closed primarily by undermining and advancing the adjacent skin.

One of the frequent criticisms of the PMMC flap is the difficulty in working with a thick skin paddle and a tenuous blood supply to the distal skin paddle. In women or obese patients, problems in working with a thick skin paddle may be severe. Combining this with the resultant deformity of the breast makes the authors reluctant to use this flap in women. If skin coverage is required for a portion of the PMMC flap, a split-thickness skin graft may be harvested and sutured to the muscle to provide either internal or external coverage. In some situations, it is preferable to allow the exposed muscle to “mucosalize” when used for internal lining.

Latissimus Dorsi Myocutaneous Flap

The latissimus dorsi muscle is a versatile myocutaneous flap that is commonly used in head and neck reconstruction. It can be transferred either pedicled or as a free flap, depending on the intended position of the flap. Details of this flap as a free tissue transfer flap are covered later in this chapter. As a pedicled rotational flap for reconstruction of neck and inferior scalp defects, the latissimus dorsi muscle has a wide range of rotational motion and can be employed even when the muscle remains attached at its insertion on the humerus. When reconstruction with a pedicled flap is possible, the requirement for microvascular anastomosis is eliminated, reducing operative time.

Fortunately, when the use of a pedicled flap is undesirable or when the defect is distant from the rotational limits of the muscle, the latissimus dorsi is hearty and tolerant of free tissue transfer. The large vessel caliber (1.5 to 4 mm diameter) and pedicle lengths of 6 to 10 cm allow for flexibility in positioning the flap and improves the likelihood that the pedicle will reach larger caliber recipient vessels in the neck. There is minimal donor-site morbidity as resection of the latissimus muscle results in no long-term postoperative functional limitation. The donor defect can generally be closed primarily, avoiding the need for a skin graft. One or two closed suction drains should always be placed at the site of muscle harvest to prevent the accumulation of serum.

As a pedicled flap the most significant disadvantage is the limitation in positioning of the flap in the recipient site. The position of a pedicled flap is limited by the arc of rotation of the muscle and the orientation of the vascular pedicle, so the final positioning of the pedicled flap is less versatile than when the flap is transferred as a free flap. Secondly, the cosmetic appearance of the pedicled latissimus dorsi flap is less acceptable as the bulk of the rotated muscle is visible throughout its course toward the recipient site. Secondary revision operations are sometimes necessary to restore a more cosmetically acceptable contour. The thick skin of the cutaneous paddle (up to 4 mm) and its poor color match with the skin of the head and the neck, although acceptable, reduce the subtlety of this flap in the recipient site.

FREE TISSUE TRANSFER FLAPS

A salient advance in the complete treatment of the patient with a head or neck neoplasm is primary reconstruction. The use of free tissue from a distant site allows for reconstruction with similar tissues. In general, one can envision the three dimensional field that will be created after resection of the neoplasm. Knowledge of various tissue components of various free tissue transfer flaps will allow the reconstructive surgeon to choose a flap that will best mimic the volume as well as the tissue composition of the resected tissue. Even with this ability, patients should be made aware that multiple revisions are often necessary to achieve the desired functional as well as cosmetic goals.

Although over 40 donor sites for free tissue transfer have been described and utilized, a smaller number have been consistently applied for routine reconstruction of large head and neck defects. The radial forearm fasciocutaneous, radial forearm osteocutaneous, and fibular osteocutaneous free flaps account for over 80% of head and neck microvascular reconstructions. This is due in large part to the particular advantages of the characteristics of these flaps that include versatility, high success rate, and low donor-site morbidity. The arterial and venous supply of almost any area of the body can be isolated. However, donor-site selection must take into account characteristics of the defect, including location, volume, quality, and type of tissue required for reconstruction (i.e., skin, muscle, and/or bone) and that the dissection of the flap will not be overly tedious or result in unacceptable donor-site morbidity. Function of the flap in the recipient site is also considered, as nerve anastomosis may be performed to reestablish sensation and mobility to transferred tissue. This is particularly relevant in reconstruction of the oral cavity, wherein sensation and mobility may be restored to a reconstructed tongue, significantly improving postoperative function. With all these factors considered, surgical flaps are divided into several categories based on the type of tissues included in the flap: fasciocutaneous, myocutaneous (musculocutaneous), myogenous, and osteocutaneous. Each of these categories will be discussed, with examples of reconstructive options available within each category.

Fasciocutaneous Flaps

The fasciocutaneous flap is a composite flap that includes skin, subcutaneous tissue, and fascia. The blood supply to the fasciocutaneous flap typically consists of perforating vessels arising from regional arteries coursing through fascial septa, known as septocutaneous perforators. Cadaveric studies have demonstrated that the fasciocutaneous perforators and their fascial plexus lie in the longitudinal axis, and therefore the length-to-breadth ratio is dictated by a longitudinally oriented pattern of blood flow. Fasciocutaneous flaps have the advantage of being thin and pliable and function well for reconstruction of low volume, moderate surface area defects. Many different areas of the body are suitable for harvesting of a fasciocutaneous free flap (Table 1).

Radial Forearm Fasciocutaneous Flap. The radial forearm fasciocutaneous flap is a “workhorse” flap that is the most commonly utilized free flap in of modern head and neck microvascular reconstruction. The radial forearm fasciocutaneous flap may also be elevated as an osteocutaneous flap, inclusive of a segment of vascularized radius bone. This flap is based on the radial artery with its paired venae comitantes and/or the cephalic vein (Table 2). The vascular pedicle is long (up to 20 cm) and the vessels are of large caliber (2.5 to 3 mm). This allows a variety of orientations while maintaining adequate pedicle length for vascular anastomosis to the larger caliber external carotid branch vessels in the neck (facial, superior thyroid, or lingual arteries).

The radial artery, with its paired venae comitantes, courses in the lateral intermuscular septum and has several fascial branches in the forearm that supply the fascia and skin. The proximal extent of the pedicle is defined by the
radial recurrent artery and by the convergence of the two venae comitantes into a single vein, which occurs near the antecubital fossa in over 80% of patients. The skin paddle is incised in the distal forearm, and the dissection is taken to the subfascial level. The pedicle is followed proximally to the antecubital fossa, where it is divided distal to the radial recurrent artery and prepared for microvascular anastomosis. The cephalic vein may additionally be harvested to supplement superficial venous drainage of the flap. When a sensate flap is desired, for example, for tongue reconstruction, the lateral antebrachial cutaneous nerve is identified as it courses near the cephalic vein and is harvested along with the vascular pedicle for anastomosis at the recipient site. Some sensory recovery is also present in most patients when neural anastomosis is not performed, but recovery of sensation is greatly accelerated and enhanced by addition of nerve anastomosis. Once the flap is completely divided from the forearm, the flap is carefully inset into the recipient site and vascular anastomosis is performed under the microscope. The forearm donor site is covered with a split-thickness skin graft and a volar splint is left in place for 5 days postoperatively.

its thinness, pliability, and low volume allow positioning in various three-dimensional orientations in the recipient site (Figure 3). It is used commonly for reconstruction of cutaneous defects of the face and scalp, as well as reconstruction of the oral cavity, tongue, and pharynx. The consistent anatomy and predictable characteristics of its vascular pedicle make this the technically most straightforward flap to harvest. As a result, this flap may be elevated more quickly than do more technically challenging free flaps such as the anterolateral thigh flap. Elevation of the flap can generally be performed simultaneously with the resective procedure when a two-team approach is applied. These factors result in shorter operative times, reduced anesthetic time for the patient, and lower operating room costs.

The main disadvantage associated with use of the radial forearm free flap is unacceptable cosmetic appearance of the forearm following flap harvest and skin grafting. A recent study demonstrated the surface area of the forearm defect is reducible by up to 50% by the application of a purse-string suture circumferentially around the donor site defect. This additional maneuver results in a smaller, more cosmetically acceptable donor site and a reduced requirement for split-thickness skin graft. The postoperative incidence of functional deficits is not increased by this technique. Five to fifteen percent of patients may have at least partial loss of the skin graft. Functional deficits in the donor arm are uncommon, with a prospective study demonstrating some degree of functional deficit in the donor arm in 16% of patients at 1 year. Despite attention to preservation of the superficial branch of the radial nerve during flap elevation, up to 30% of patients report transient paresthesias or dysesthesias in the anatomic snuffbox region, typically resolving within 12 months postoperatively. This may be attributable to operative trauma to the nerve, traction injury, or ischemia related to tense closure of the surgical site.

A devastating complication of radial forearm free flap elevation is the development of hand ischemia. Critical to the selection of donor site is the accurate performance of a preoperative Allen test. This test is an easily executed clinical examination that evaluates the perfusion of the hand by both the ulnar and the radial arterial systems. The radial artery may not be harvested safely in patients with an incomplete palmar arch or compromised perfusion by the ulnar artery.

| Table 1 Similarities and Differences among the Various Fasciocutaneous Flaps Used in Reconstruction of Head and Neck Defects |
| Flap | Advantages | Disadvantages |
| Radial forearm | • Thin, pliable tissue paddle | • Donor site visible |
|  | • Large caliber, long vascular pedicle | • Requires skin graft |
|  | • Consistent anatomy | • Potential for vascular compromise of hand |
|  | • Technically straightforward | |
| Ulnar flap | • Thin, pliable tissue paddle | • Potential for ulnar nerve injury |
|  | • Relatively hairless | • Smaller, shorter vascular pedicle than radial forearm flap |
|  | • Two-team approach possible | • Two venous anastomosis |
|  |  | • Donor site visible |
|  |  | • Requires skin graft |
| Anterolateral thigh | • Large skin paddle available | • Inconsistent vascular anatomy |
|  | • Versatile in volume | • Technically challenging |
|  | • Primary closure usually possible | • Poor color match |
|  | • Low donor-site morbidity | • Lateral thigh numbness |
| Lateral arm | • Thin, pliable tissue paddle | • Small caliber, short vascular pedicle |
|  | • Donor site easily hidden | • Potential for radial nerve injury |
|  | • Primary closure usually possible | • Poor color match |
|  |  | • Two-team approach difficult |

and alternate reconstructive options must be explored.

**Ulnar Fasciocutaneous Flap.** The ulnar fasciocutaneous free flap shares many of the advantageous characteristics of the radial forearm fasciocutaneous flap (see Table 2). The ulnar flap may be selected when preoperative physical examination (Allen test) of the nondominant hand is suggestive of inadequate radial arterial perfusion. In this setting, reconstructive surgeons often elect to pursue harvest of a radial forearm free flap from the dominant side. In the setting of a complex head and neck reconstruction, which often includes temporary tracheostomy, a 5-week postoperative splinting of the dominant donor arm also limits the patient's ability to communicate in writing, which may be highly frustrating.

The ulnar flap is based on the ulnar artery and its two venae comitantes. In a 2002 review, the dimensions of the vascular pedicle proved to be quite consistent, with average ulnar artery diameter measuring 2.5 mm and average diameter of the two venae comitantes measuring 1.0 to 1.5 mm. In contrast to the radial forearm flap pedicle, the two venae comitantes rarely converge into one larger vein, and therefore two venous anastomoses are generally required, slightly lengthening the operative time. Pedicle length is usually greater than 10 cm, which allows for versatility in positioning the flap in its recipient location. The medial antebrachial cutaneous nerve provides sensation to the skin paddle, and it may be harvested as a sensate flap (Figure 4).

Advantages of the ulnar flap, like its radial counterpart, are its reliable, soft, pliable, and moldable in three dimensions characteristics and option of additional bulk with inclusion of the underlying palmaris longus tendon. Because the skin paddle is centered more medially than that of the radial forearm flap, it has the advantage of containing less hair-bearing tissue than does the radial forearm flap. This may be a consideration in hirsute patients undergoing oropharyngeal reconstruction. The location of the skin paddle at the distal part of the forearm allows for simultaneous elevation of the flap with the resective procedure when a two-team approach is employed. The ulnar fasciocutaneous flap can be used as an alternative to the radial forearm free flap in certain settings and is suitable for reconstruction of cutaneous defects of the face and scalp, as well as for reconstruction of the oral cavity, tongue, and pharynx.

There are several disadvantages of this flap that limit its use as a primary reconstructive option. The ulnar flap is technically more difficult to harvest than the radial forearm free flap. The ulnar artery is less superficial than the radial artery and runs adjacent to the ulnar nerve. Multiple small perforators travel from the ulnar artery to the ulnar nerve, and meticulous dissection is crucial to avoid functional morbidity associated with damage to the nearby nerve. Although uncommon, it is devastating when it occurs, as it results in functional limitation of the muscles of the hand and the forearm. A smaller disadvantage of the ulnar flap in comparison to the radial forearm flap is that the vascular pedicle is somewhat less favorable, as the ulnar artery averages 1 mm less than the diameter of the radial artery. In spite of this disadvantage, the arterial diameter of 2 to 2.5 mm is adequate to match reliable recipient vessels in the head and neck. More significantly, the perforators of the venae comitantes are small and do not generally converge into one larger vein resulting in slightly longer operative times. Overall, in the presence of contraindications to the use of the radial forearm free flap, the ulnar flap is an excellent alternative when the desirable characteristics of the radial forearm flap are required.

**Anterolateral Thigh Fasciocutaneous Flap.**

The anterolateral thigh fasciocutaneous flap is a versatile fasciocutaneous flap that is a potential source of a large skin paddle, making it ideal for reconstruction of large cutaneous and oropharyngeal defects. Topographically, the skin paddle of the anterolateral thigh flap lies on the middle third of the axis of the septum dividing the vastus lateralis and the rectus femoris muscles. This is conceptualized as an imaginary line connecting the anterior superior iliac spine and the lateral border of the patella. A ridge from the profunda femoral trunk, the lateral femoral circumflex artery distributes both ascending and descending branches. This descending branch supplies the perforators coursing deep within the intramuscular septum, often deep in the septal plane, but on occasion within the substance of the rectus femoris muscle. This septal plane can be used to identify the artery and flap blood supply if the septum is accompanied by at least one septocutaneous perforating artery and vein. If no septocutaneous perforators are present, the superior portion of the septal plane that meets the tensor fascia lata muscle can be used to find the lateral femoral circumflex vessels of the descending branch. Because of the variability of arterial anatomy, in up to 80% of patients, the anterolateral thigh flap is not solely supplied by fasciocutaneous perforators and the surgeon must be prepared to dissect the musculocutaneous perforators traversing the rectus femoris muscle meticulously to maintain optimal flap perfusion. This can be difficult when the entire course of the artery is in the substance of the rectus femoris muscle. The flap is innervated by a large branch of the lateral femoral cutaneous nerve and this nerve, can be dissected with the pedicle to create a sensate flap with neural anastomosis at the recipient site (see Table 2).

The descending branch of the lateral femoral circumflex artery is a large caliber pedicle (1.5 to 3.5 mm), with length up to 7 cm. In most instances, two veins accompany the artery. A skin paddle as large as 8 cm x 25 cm can be harvested with wide skin paddles (Figure 5). The use of a split-thickness skin graft to close the donor site is usually necessary.

The flap is innervated by a large branch of the lateral femoral cutaneous nerve. The nerve can be dissected with the pedicle at the superior aspect, and can be traced inferiorly to create a sensate flap with neural anastomosis at the recipient site (see Table 2).

Despite the potential for a technically challenging operation, the advantages of the anterolateral thigh flap include its high success rate, large skin paddle, the ability to perform flap elevation simultaneously with the resective procedure, resulting in reduced operative time. Donor-site morbidity following harvest of the anterolateral thigh flap is low, and patients recover function quickly postoperatively. A 2002 report of a series of 672 anterolateral thigh flaps reported a success rate of 95.7%, with complete flap loss occurring in 1.8% of patients. Flap volume is quite versatile and can be easily tailored to the recipient site by either thinning subcutaneous tissues or by adding volume with inclusion of vastus lateralis, rectus femoris, or tensor fascia lata muscle to provide additional soft tissue bulk. For this reason, the anterolateral thigh flap is an excellent source of soft tissue for the reconstruction of medium- to large-volume defects, including those involving the lateral part of the temporal bone or maxilla. Success rates of the anterolateral thigh flap are similar to those of the widely used radial forearm free flap, and the anterolateral thigh flap is preferred when larger volume reconstruction is required or in the presence of contraindications to the use of the radial forearm free flap.

In addition to the technical challenge of anterolateral thigh flap elevation, several disadvantages...
of this flap should be noted. Whereas the flap volume is versatile, the orientation of this flap in the recipient site is less flexible as the flap is dense and not amenable to complex molding in three dimensions. The cosmetic result of anterolateral thigh flap reconstruction of head and neck defects is acceptable, but not ideal. The color match to the skin of the head and neck is poor, and the pale appearance of the flap persists, reducing the subtlety of the reconstruction. Finally, some functional morbidity may result from division or resection of the regional nerves. When a sensate flap is elevated to include the lateral femoral cutaneous nerve, numbness involving the entirety of the lateral thigh is perceived by the patient and may be bothersome but does not typically limit the patient functionally. True functional morbidity is uncommon but generally is the result of mild to moderate lower extremity weakness. This postoperative complication may occur because the femoral nerve branch to the vastus lateralis muscle travels with the pedicle and, because of its intimate relationship to the supplying vessels, occasionally must be divided to dissect the full length of the pedicle.

Lateral Arm Fasciocutaneous Flap. The lateral arm fasciocutaneous flap was first described in 1982 by Song, and its application to head and neck reconstruction was reported by Sullivan and colleagues in 1992. Similar to the radial forearm free flap, it provides thin, pliable tissue with skin quality well suited for the head and neck reconstruction. The volume of the lateral arm flap is intermediate between the volumes of the radial forearm flap and the anterolateral thigh flap, and thus, the lateral arm flap is suitable for reconstruction of low- to medium-volume defects (Figure 6).

The skin paddle topographically lies between the lateral epicondyle and the insertion of the brachioradialis muscles. This flap may be transferred as a sensate flap based on the posterior cutaneous nerve of the arm. If the size of the skin paddle is limited to 6 to 8 cm width, the donor site can generally be closed primarily after wide undermining of the adjacent soft tissue, avoiding the need for skin grafting.

Several disadvantages of the lateral arm flap have resulted in its diminishing use in the present era of the head and neck reconstruction. First, dissection of the flap and pedicle proceeds in close proximity to the radial nerve. There is, therefore, risk of injury to this important nerve during flap elevation. The morbidity of radial nerve injury is significant, resulting in loss of finger and wrist extensor function and loss of sensation over the dorsal arm and hand. Even incomplete injury of the radial nerve may result in temporary or permanent pain, paresthesias, and dysesthesias. Ultimately, the consequence of radial nerve injury is functional loss involving hand and wrist, which is poorly tolerated by patients. The second disadvantage of this flap is relatively small vessel caliber (1.25 to 1.75 mm) and short pedicle length (maximum of 8 to 10 cm). In practice, it is difficult to obtain more than 6 cm of pedicle length, as additional pedicle dissection requires detaching a large amount of the triceps muscle and increases the risk of injury to motor branches of the radial nerve. The two-team approach of simultaneous tumor resection and flap elevation may be possible, but it is more difficult than with the use of a forearm donor site, and limited by awkward patient positioning, prolonging operative time. Finally, color match is generally poor in head and neck reconstruction, and the flap maintains a pale appearance in comparison to its surroundings. Most reconstructive surgeons have abandoned this flap as a primary reconstructive modality, but it should still be considered an alternate reconstructive method when other options are unavailable or unsuitable.

Scapular Fasciocutaneous Flap. The scapular fasciocutaneous flap is used primarily as an osteocutaneous flap in head and neck reconstruction and is discussed in detail later in this chapter but may also be used as a fasciocutaneous flap for reconstruction of soft tissue defects (see Table 2).

The blood supply of the scapular fasciocutaneous flap is from the circumflex scapular artery, a branch of the subscapular artery. The arterial diameter averages 4 mm and pedicle length of 7 to 10 cm; however, with dissecting along the subscapular artery proximally, an arterial diameter up to 6 mm and pedicle length up to 11 to 14 cm can be obtained. Although there has been success with the experimental use of the dorsal cutaneous rami of the T1 or T2 spinal nerves for flap nerve anastomosis, there is not a dominant segmental nerve supply to the skin of this region; and, therefore, this flap is not considered to have the potential for transfer as a sensate flap.

The skin paddle of this flap is soft and pliable and has a good color match to the surrounding skin of the head and neck. Because the vascular pedicle is long, there is great versatility in positioning the flap in its recipient location. The branching vascular supply of the flap allows individual components of the flap to be positioned in various three-dimensional orientations relative to one another, resulting in great versatility in the reconstruction of large defects. The skin paddle can be designed horizontally (scapular-based on the transverse cutaneous arterial branch) or vertically (parascapular-based on the descending cutaneous arterial branch). Two separate skin paddles may even be elevated in continuity with the bulk of the flap, allowing ideal reconstruction of defects that require both intraoral mucosal and external skin coverage. For high-volume defects, the bulk of this flap may be expanded further by harvest of underlying muscle (latissimus dorsi and/or serratus anterior muscle), creating potential for use as a myocutaneous flap to fill maximal defect volume (Figure 7). The donor site can generally be closed primarily owing to the surrounding soft tissue pliability, avoiding a skin graft.

The main disadvantage of the use of this flap is the need to reposition the patient in the lateral decubitus position during the operation, which limits the two-team approach for simultaneous resection of the neoplasm and flap elevation. This may prolong operative and anesthetic times and increase hospital costs. There is also limited potential for a sensate flap although some success has been achieved with use of the dorsal cutaneous rami of T1 or T2 spinal nerves for nerve anastomoses.

Jejunal Free Flap
Jejunal free flap reconstruction is used to reconstruct circumferential defects of the upper aerodigestive tract, commonly after laryngopharyngectomy. It is a good replacement owing to its tubed nature and the presence of lubricating mucus glands.

Tube lengths of up to 30 cm can replace lost segments of the cervical esophagus from the
nasopharynx to the thoracic inlet. Defects that extend into the chest, placing the anastomotic site in the chest, can potentially result in mediastinitis should a leak occur. A gastric pull-up or colonic interposition is performed in these cases. With an intact larynx, if the jejunal free flap is not below a functioning cricopharyngeus, the normal secretions from the jejunum may result in aspiration. An alternate tubed free flap may be needed in these situations.

The small bowel is composed of three distinct anatomic and physiologic segments. The jejunum, the second segment, begins at the ligament of Treitz and extends distally 6 to 8 ft. Its vascular supply is the superior mesenteric artery and vein; these pass over the mid duodenum and enter the mesentry of the jejunum. A single arcade is formed in this mesentery, which gives rise to the vasa recta supplying the jejunum.

This single arcade allows a closer relationship between the superior mesenteric jejunal artery and the vascular territory of the jejunum it perfuses. Distally in the small bowel, the number of vascular arcades increases in the ileum, and therefore, indistinct perfusion patterns of single arterial pedicles arise. Typically, the second jejunal branch is the pedicle of choice. When the dissection is carried right down to the superior mesenteric artery, arterial pedicles up to 3 to 4 mm in diameter and up to 10 cm in length can be obtained. Transilluminating the mesentery greatly aids harvest of the pedicle.

The desired length of jejunum is excised marking out the proximal or distal end. The flap is moved to the neck and inset into place under a little tension because when perfusion is reestablished with microvascular anastomosis, the jejunum tends to lengthen. Kinking or bowing of the jejunum impairs food passage. A voiding kinking of vascular pedicle also decreases the chances of venous thrombosis. An end-to-end enteric anastomoses is performed, in an isoperistaltic fashion. The microvascular anastomoses are then completed. We usually design a sentinel-monitoring loop of jejunum that is left free and brought out through the skin incision as a postoperative monitor. This monitor loop is removed 1 week postoperatively (Figure 8).

Spatulation proximally of the enteric anastomosis may be necessary to allow the small-calibre jejunum to fit larger defects. Triangular interdigitation distally into the esophagus decreases the incidence of stricture formation. Excess mesentery available can be used to reinforce the enteric anastomosis.

Complications can occur in the donor area, the microvascular anastomoses, or at the enteric anastomoses. Each can compromise reconstructive efforts or the patient’s life. This flap has poor ischemia tolerance. Regular monitoring of the external monitoring segment for signs of arterial or venous compromise, allows timely rapid vascular reanastomosis and salvage. Fistula formation and stricture formation can occur with any reconstructive technique and are more frequent with prior radiation. The rate of fistula formation is reported at 18%. Of these, over two-thirds close spontaneously. Larger, more persistent leaks may respond to pectoralis major myocutaneous flap reinforcement. There is a low rate (8%) of stricture formation.

Structures may be due to fibrosis of the distal anastomosis or from kinking of the jejunal segment. Dysphagia due to strictures can be treated with endoscopic dilatation or exceptionally excision of the redundant segment may be needed. Dysphagia may also result from dyskinetic peristalsis due to delayed emptying of the jejunal segment particularly with solids. Flap success rates are around 98%. Voicing with tracheal puncture provides acceptable speech, but one of the most significant problems with jejunal reconstruction is the “wet” and relatively poor quality of voice.

Myocutaneous Free Flaps

Myocutaneous flaps are composite flaps that include skin, subcutaneous fat, fascia, and muscle. The blood supply to this type of flap is based on a single dominant arterial trunk that provides adequate perfusion through an arborizing arterial network to a large volume of muscle, despite ligature of adjacent contributing vascular pedicles. The overlying skin and subcutaneous tissue are supplied by secondary terminal perforating branches running vertically from the underlying muscular branches. It is the cutaneous portion of the myocutaneous flap that is most vulnerable to ischemia, as it relies on these small caliber perforators for perfusion. Because of this pattern of perfusion, it is the number of musculocutaneous perforators and their particular distribution that defines the limit of the skin paddle size, shape, and orientation. Vascular insufficiency to the skin paddle can result in partial flap loss, with necrosis of the skin and the subcutaneous tissue, but the muscle is preserved. Also as a consequence of this vascular pattern, the skin is anchored to the underlying muscle, and therefore, the flap is not pliable in three dimensions. Because a skin paddle is excised with the myocutaneous flap, donor-site complications resulting from excessive tension on the closure (eg, wound dehiscence, patient discomfort, or requirement for a skin graft) are slightly more common than seen with a myogenous flap without a skin paddle. Overall, donor-site morbidity following harvest of myocutaneous flaps is acceptably low as surrounding tissues are generally pliable and amenable to primary closure. A comparison of the common myocutaneous free flaps used in the head and neck are described in Table 3.

Figure 9 The latissimus dorsi free flap provides the greatest volume of free tissue that can be transferred. It may be transferred as a muscle only or with the overlying skin.

diameter and pedicle lengths of 6 to 10 cm allow for flexibility in positioning the flap and improves the likelihood that the pedicle will reach larger caliber recipient vessels in the neck. There is minimal donor-site morbidity as resection of the latissimus muscle results in no long-term postoperative functional limitation. The donor defect can generally be closed primarily, avoiding the need for a skin graft. One or two closed suction drains should always be placed at the site of muscle harvest to prevent the accumulation of serum.

Since the inception of free tissue transfer, the latissimus dorsi free flap has been recognized as an excellent option for scalp reconstruction because of its large surface area, long vascular pedicle, ease of harvest, and provision of well-vascularized tissue for compromised recipient beds. The length of the thoracodorsal vascular pedicle is usually sufficient to reach recipient vessels in the neck although reconstruction of defects of the scalp vertex may require use of the more superiorly located superficial temporal vessels as recipient vessels. A diling to its versatility, the latissimus dorsi can be transferred as either a myogenous or a myocutaneous flap, depending on the desired flap volume and the presence or absence of a cutaneous defect. The myogenous flap without overlying skin and soft tissue reduces bulk and improves contour on the scalp. Transfer of a myogenous flap requires coverage with a split-thickness skin graft. Cosmetic outcomes are acceptable, as the latissimus flap atrophies and appears much like normal scalp once the skin graft matures. The incidence of major complications in the setting of scalp reconstruction is low and flap loss is reported to occur in 3 to 5% of cases.

The major disadvantage of the latissimus dorsi flap is that the patient generally must be repositioned into the lateral decubitus position in the operating room for harvest of the flap. This lengthens operative time and often prohibits simultaneous resection and flap elevation. The large latissimus dorsi muscle is prone to a significant amount of atrophy and volume loss with deconditioning. When the bulky muscle is inset as a reconstructive flap, the ultimate flap volume that will remain after the muscle atrophies is unpredictable. For this reason, defects are generally overlapped with a large-volume flap, and if frequently requires subsequent revision to tailor volume and contour to the recipient site. The secondary revision rate has been reported to be as high as 20 to 32%. Because of the large surface area of the muscle, marginal flap necrosis may occur over the most distal aspects of the flap. In the event of marginal necrosis, local debridement may be necessary to remove necrotic debris. When possible, the most proximal aspect of the muscle should be used for calvarial and cranio-plasty coverage and the most distal (least reliable) aspect of the flap positioned distally so that morbidity is minimized in the event of partial flap loss.

As a pedicled flap the most significant disadvantage is the limitation in positioning of the flap in the recipient site. The position of a pedicled flap is limited by the arc of rotation of the muscle and the orientation of the vascular pedicle, so the final positioning of the pedicled flap is less versatile that it is when the flap is transferred as a free flap. Secondly, the cosmetic appearance of the pedicled latissimus dorsi flap is less acceptable as the bulk of the rotated muscle is visible throughout its course toward the recipient site. Secondary revision operations are sometimes necessary to restore a more cosmetically acceptable contour. The thick skin of the cutaneous paddle (up to 4 mm) and its poor color match with the skin of the head and the neck, although acceptable, reduce the subtlety of this flap in the recipient site.

**Rectus Abdominis Myocutaneous Flap.** The rectus abdominis myocutaneous free flap is an excellent choice for reconstruction of medium-to-large-sized head and neck defects. The rectus abdominis muscle is easy to harvest, has a long vascular pedicle, and may be transferred as a myocutaneous or a myogenous flap, depending on the amount of skin and soft tissue volume required (see Table 4).

The arterial supply is based on the deep inferior epigastric system of the external iliac vessels, and its takeoff defines the transition from external iliac to the common femoral vessels. After elevation of the flap, the pedicle is followed to its origin, that is, the external iliac vessels, and a pedicle length of 8 to 10 cm is attainable. The vessel caliber is also well suited for microvascular anastomosis, with an average diameter of 3 to 4 mm. Few variations of the vascular supply have been described, so the dissection of the pedicle is generally predictable because of the rich system of perforators in the periumbilical region.

This allows for the entire muscle or a large-sized skin paddle to be utilized to reconstruct large-volume defects such as large cutaneous ones those due to, total glossectomy or skull-base resections or medium-volume defects including cutaneous ones or those due to hemiglossectomy. The flap is highly reliable in the head and neck reconstruction, with published 0 to 2% failure rates. The rectus abdominis flap can usually be

---

**Figure 9** The latissimus dorsi free flap provides the greatest volume of free tissue that can be transferred. It may be transferred as a muscle only or with the overlying skin.
elevated simultaneously with the resective procedure; reducing operative times (Figure 10).

The potential morbidity of this operation is the development of a ventral hernia, and prevention of this complication is accomplished by conscientious repair of fascial layers after harvest of the muscle. The rectus abdominis muscle is invested by anterior and posterior fascial layers, the anterior and posterior rectus sheaths, that provide support to the ventral abdominal wall. When the muscle is resected without overlying tissue, that is, as a myogenous flap, the posterior rectus sheath is left intact and the vertical incision in the anterior rectus sheath is closed primarily to maintain the continuity of both the anterior and the posterior fascial layers. When a portion of the overlying fascia is resected, either for additional bulk or when the muscle is harvested to include subcutaneous tissue and skin, that is, as a myocutaneous flap, the anterior rectus sheath is repaired with prosthetic or biologic mesh. A 1995 review of 268 patients who had undergone rectus abdominis muscle harvest for breast reconstruction demonstrated a low incidence of abdominal wall complications, with a 2.6% rate of ventral hernia and a 3.8% rate of perceptible abdominal bulges.

On anesthetic level, the disadvantage of the rectus abdominis flap is that the skin is a poor color match for the head and neck reconstruction. The skin of the abdomen contains a lower concentration of melanocytes, and therefore the flap appears pale in comparison to the surrounding skin of the head and neck. The flap may also be bulky until the muscle scars and atrophies in its recipient position and occasionally requires revision or liposuction to gain acceptable esthetic contour. Because of the wide variability in abdominal wall thickness among patients, body habitus is an important consideration when selecting the rectus abdominis muscle as a myocutaneous flap. A thick panniculus or loose, floppy abdominal wall (frequently present in multiparous women) may render a myocutaneous flap unacceptable for free tissue transfer, as the resultant flaps are highly bulky with unreliable cutaneous perforators.

**Gracilis Myocutaneous Flap.** The gracilis myocutaneous flap is a thin muscle flap utilizing this narrow adductor muscle of the medial aspect of the thigh. The dominant blood supply of the flap is the terminal branch of the adductor artery, which is a branch of the profunda femoris artery. The artery of the pedicle enters the muscle at a relatively constant 8 to 10 cm below the pubic tubercle, and is accompanied by paired venae comitantes. While blood supply to the muscle is relatively predictable, there is some variability of the blood supply to the skin. This supply may arise from musculocutaneous perforators, septocutaneous vessels, or from an inferior branch of the superior external pudendal artery. Motor innervation of this muscle is a branch of the obturator nerve. Since the gracilis muscle functions as one of the several hip adductors and knee flexors, patient mobility and strength are not diminished by harvest of this muscle (see Table 4).

The use of this flap became more common with the advent of its use as a myogenous flap in dynamic facial reanimation surgery, which is performed for permanent facial nerve paralysis. In this procedure, the thin muscle is transferred, revascularized, and nerve anastomosis is performed to the facial nerve directly or with a sural nerve graft. The dynamic facial reanimation operation has been demonstrated to restore facial movement and expression in long-term follow-up and is considered a reliable reconstructive and rehabilitative procedure. As a myocutaneous flap, however, the gracilis is mainly useful for reconstruction of small- to medium-sized cutaneous defects.

Disadvantages of this flap are a short pedicle length (up to 4 cm) and small caliber vessels (1 to 2 mm). This limits the versatility of positioning the flap and its use in the head and neck for facial reanimation in reconstruction of smaller- to moderate-sized cutaneous defects.

**Myogenous Free Flaps.** The myogenous flap is composed of muscle and fascia, but unlike the myocutaneous flap, it does not include the overlying subcutaneous tissue and skin. This flap, like the myocutaneous flap, is utilized for defects that require large volume for reconstruction but either do not require reconstruction of a cutaneous surface or include a cutaneous deficit in which the surface area is sufficiently large that it is best reconstructed with a split-thickness skin graft overlying the transferred muscle. Any muscle that can be used as a myogenous flap can also be transferred as a myogenous flap (see Table 4). The disadvantage of free transfer of a myogenous flap without overlying skin and subcutaneous tissue, however, is that muscle can be expected to undergo a significant amount of atrophy in its recipient environment, particularly if the muscle is anticipated to fill a large volume, the ultimate volume of the flap after atrophy is unpredictable and atrophic degeneration may result in insufficient volume filling at long-term follow-up.

The region of the myocutaneous flap most vulnerable to ischemia is the skin paddle, as it relies on small caliber perforators for perfusion. In the myogenous flap, perfusion is dictated by the main pedicle and its branches, and the absence of a skin paddle reduces the likelihood of flap ischemia. In addition, donor-site morbidity is lower for myogenous flaps than for myocutaneous flaps. The main reason for this difference in morbidity is that the skin and subcutaneous tissue of the donor site after myogenous flap harvest can be reapproximated without tension and without the need to undermine the subcutaneous tissues widely, which is often required when closing the donor-site defect after elevation of a myocutaneous flap. The potential need for skin grafting at the donor site is also avoided, eliminating possible complications related to skin grafting. Myogenous flaps include the latissimus dorsi, rectus abdominis, and gracilis as well as many other muscles amenable to free tissue transfer.

**Osteocutaneous Free Flaps.** When treatment for the neoplasm requires resection of the underlying bone, particularly the mandible, an osteocutaneous flap may be utilized to reestablish mandibular continuity, allow dental rehabilitation and restore masticatory function. Resected calvaria and facial bone, most commonly the maxilla, also often require reconstruction at the time of resection. Modalities utilized for reconstruction of bony defects in this setting include nonvascularized bone grafts with plate and screw fixation, alloplastic materials (eg, methyl methacrylate and hydroxyapatite cement), and vascularized bone or osteocutaneous free tissue transfer. The osteocutaneous flap is the most histologically diverse of the flaps, and includes skin, subcutaneous tissue, bone, and generally a cuff of muscle. When a vascularized bone flap is utilized, the success rate is greater than 90%. This success is attributable to the vascular supply of the transferred bone, allowing rapid healing and incorporation into the remaining mandible independent of the vascularity of the recipient bed. Vascularized bone is well suited for the previously irradiated oral cavity, where nonvascularized methods (such as bone grafts) are prone to failure, with failure rates as high as 75% in the acute setting. Bony healing and integration of osteocutaneous flaps are similar to fracture healing in its time course, and this more rapid healing allows patients the return of function earlier than with the use of nonvascularized bone grafts. Enosseous dental implants can be inserted into the bone graft at the time of primary reconstruction, and dental prostheses may be fitted 4 to 6 months postoperatively to allow resumption of normal masticatory function. A comparison of the common osteocutaneous flaps used in head and neck reconstruction is in Table 5.

**Fibula Osteocutaneous Flap.** The osteocutaneous fibula free flap is a reliable source of well-vascularized bone and soft tissue, and has become the mainstay of modern mandibular reconstruction. Up to 25 cm of bone is available for harvest, and because the fibula is not a load-bearing
bone, its resection has no functional consequence at the donor site once the wound has healed. With strategic placement of osteotomies and metallic plate fixation, the fibula can be curved to match the contour of the mandible, and both functional and cosmetic outcomes are good. The fibula is the only vascularized bone flap that is versatile and hearty enough to be used for total mandibular reconstruction, as its rich blood supply will allow for multiple shaping osteotomies without compromising perfusion of the bone (Table 6).

The fibula will also support enosseous dental implants for future dental rehabilitation, allow-

When dental implants are not planned, however, the “neomandible” can be a difficult surface to fit with dentures and plates, and in certain cases, this may limit the patient to a soft diet.

The fibula is a long, thin bone of the lateral lower leg whose arterial supply is derived from the most lateral of the three major perforation trunks of the lower extremity, the peroneal artery. With its venae comitantes, this pedicle provides long and large caliber vessels (1.5 to 4 mm) for microvascular anastomoses at the recipient site. The peroneal artery is positioned close to the fibula and sends perforators laterally to the skin both through a septocutaneous route (through the lateral intermuscular septum) and via muscular perforators. The skin paddle is designed with its epicenter over an axis just posterior to the fibula, where septocutaneous perforators are predicted to be centered and skin perfusion is maximal. The skin paddle is marked and dissection of the flap proceeds in an anterior to posterior direction, with identification of septal perforators. If no septal perforators are identified, then posteriorly based muscular perforators are preserved by including a cuff of soleus muscle. The appropriate length of fibula is then resected, with caution to preserve the distal 6 to 8 cm of fibula in order to spare the ankle mortise. When the paddle is less than 5 to 7 cm in width, the skin of the lower leg may be closed primarily after undermining of the soft tissues. If a wider skin paddle is required, or if there is tension in closure, a skin graft is used to close the donor site (Figure 11).

The peroneal artery that supplies the fibula flap is one of the three major arteries providing perfusion to the lower leg and foot. Since these vessels are prone to atherosclerotic disease, particularly in the elderly, smokers, and diabetics, it is crucial to confirm adequate three-vessel inflow to the distal part of the lower extremity prior to resection of the peroneal artery. Failure to confirm adequate arterial flow to the lower leg and foot preoperatively can result in devastating ischemic consequences if the peroneal arterial inflow is interrupted in already compromised vascular supply. Because of this risk, harvest of the fibula free flap is absolutely contraindicated in patients with significant arterial ischemic disease of the lower extremities and in patients with inadequate arterial inflow to the distal part of the lower extremity via the posterior tibial and anterior tibial arteries. Historically, routine preoperative arteriography was performed on patients being considered for fibula free flap, but arterial duplex ultrasonography has largely replaced angiography as an inexpensive, noninvasive imaging modality effectively utilized for this purpose.

The primary disadvantage of the fibula osteocutaneous flap is that the limits of the skin paddle are defined by the location of the septocutaneous perforators. To enhance cutaneous vascular supply, a cuff of soleus muscle may be included with the flap to preserve musculocutaneous perforators. Even when all identifiable perforators are preserved, the skin paddle may not be large enough to provide adequate cutaneous coverage...
and a split-thickness skin graft may be required as an adjunct to free flap reconstruction. An additional limitation of this flap is that the skin paddle is tethered to the underlying fibula, and therefore, positioning and orientation in the recipient site are limited by relatively fixed anatomic relationships within the flap.

Published reports of donor-site complications of fibula osteocutaneous flap harvest have been variable, ranging from 15 to 55%. A 2001 retrospective review of donor-site complications following fibula free flap reported a 39% complication rate with primary closure and a 19% complication rate when a skin graft was employed for closure of the donor site. This difference was hypothesized to be the result of reduction in local ischemia in the setting of tension-free wound closure. Studies of postoperative functional deficits following fibula free flap harvest have generated similar variability in their results. Seventy-two percent were free of any donor pain, and the remainder 28% had only occasional mild discomfort. Other complaints included ankle stiffness 41%, mild ankle instability 10%, and transient peroneal motor 7% or sensory 28% loss, which resolved in all patients. A majority of these patients reported satisfaction with their overall quality of life following surgery.

Radial Forearm Osteocutaneous Flap. The radial forearm is a versatile donor site that may be employed as a source of both soft tissue and bone. A portion of the radius with blood supply based on perforators in the intermuscular septum may be utilized for reconstruction of the mandible or maxilla. A segment of radius measuring 10 to 12 cm in length can be harvested without concern for significant forearm dysfunction. A radial forearm osteocutaneous flap can be raised with attention to preservation of the attachment of the lateral intramuscular septum to the periosteum of the radius, the tissue plane in which the radial-artery-based perforators to the radius travel (see Table 6). A small cuff of flexor pollicis longus muscle is taken to facilitate preservation of these small vessels. The volar (palmar) radial cortex is then incised with an oscillating saw, resulting in resection of a monocortical segment of radial bone. When a segment of bone is resected from the radius, the bone is weakened, with increased vulnerability to torsional forces. Pathologic fractures may occur as a sequel of radial bone harvest; thus, most surgeons limit the thickness of bone harvest to 40% of the circumference of the radius. Even using this precaution, pathologic fracture rates averaging 8 to 43% may result.15 A number of surgeons have adopted the practice of routine prophylactic internal plate fixation of the radius at the time of harvest, usually with the assistance of an orthopedic surgeon. The fracture rate has been reduced with keel-shaped osteotomies and prophylactic plating of the donor radius to 1.9% at our institution16 (Figure 12).

The main advantage of the radial osteocutaneous flap is its association with a cutaneous paddle that is large, pliable, and potentially sensate for oral reconstruction. Because of its long pedicle with large caliber vessels, the flap is also versatile in terms of its position in the recipient site and easily reaches large caliber recipient vessels in the neck. With routine internal fixation of the radius, donor-site morbidity is equivalent to that of the radial forearm fasciocutaneous flap. These potential morbidities include partial necrosis and delayed healing of the skin graft, unappealing cosmetic appearance of the donor site, pain, paresthesias, and rarely, arterial insufficiency of the distal part of the upper extremity. Functional deficits in the donor arm have been reported to occur in 16 to 32% of patients undergoing radial forearm osteocutaneous free flap harvest, with these deficits ranging from subtle alterations in grip strength to marked reduction in range of motion.17 Because the blood supply of the radius segment is entirely based on a small number of vertical perforators in the intermuscular septum, osteotomies created for establishment of contour must be limited to one or two. A additional disruption of the continuity of the bone is likely to create free-floating, avascular segments that are prone to fail in the recipient site.

Although a limitation of the osteocutaneous radial forearm flap is the length of the bone available, this flap has been utilized widely for osseointegrated reconstruction in limited mandibular defects. The rate of postoperative complications of the osteocutaneous radial flap has been demonstrated in several independent studies to be lower than that for the oromandibular reconstruction utilizing a radial fasciocutaneous flap reconstruction paired with plate reconstruction of the mandible. While radial bone is not considered to be hearty enough to support dental implants, a mandible reconstructed with radius will generally support a tissue-borne prosthesis (denture). This is in contrast to more widely utilized osteocutaneous flaps including fibula and scapula, which generally are more difficult to fit with dentures due to their breadth and contour. A majority of patients will not cover dental implants, dental rehabilitation is financially less burdensome when radial flap reconstruction is coupled with eventual fitting with dental prostheses.

Scapular Osteocutaneous Flap. The scapular osteocutaneous free flap is considered an extremely versatile flap. A large surface area of skin is available for harvest, and the availability of two underlying muscles (serratus anterior and latissimus dorsi muscles) creates versatility with regard to flap volume. In addition, the thick skin and subcutaneous tissue of the back contribute to the extensive soft tissue bulk that may be harvested from this site. Generally, the soft tissue bulk of this flap is quite durable and persists over years without significant atrophy. The skin, underlying muscles, and scapula are all supplied by one major vascular pedicle that has the advantage of favorable length and vessel caliber. The main arterial supply to the scapular osteocutaneous flap is the circumflex scapular artery. When the pedicle is dissected from its origin, that is, the subscapular artery, arterial diameter averages 4 mm and pedicle length of 7 to 10 cm can be obtained. If a larger caliber vessel or a longer pedicle is required, dissection can proceed proximally along the subscapular artery, where the arterial diameter is up to 6 mm and pedicle length is increased to 11 to 14 cm. There is not a dominant segmental nerve supply to the skin of this region, and therefore this flap is not considered to have the potential for transfer as a sensate flap.

There have been reports, however, of use of the dorsal cutaneous rami of T1 or T2 spinal nerves for flap nerve anastomosis, creating the potential for a sensate flap18 (see Table 6).

Bone harvest is performed at the lateral border of the scapula, with 10 to 14 cm of bone being available from this location. The blood supply to the bone is derived from the periosteal branch of the circumflex scapular artery; and, because the bone is well vascularized, several osteotomies may be performed to create desired contour as long as the highly vascular periosteum is preserved.

The scapular osteocutaneous flap is highly reliable for mandibular reconstruction as the bone of the lateral border of the scapula is well perfused and conforms well to the contour of the mandible (Figure 13). This flap is an excellent choice for reconstruction of complex oromandibular or oromaxillary defects, particularly in complex composite defects involving both the
Iliac Crest Osteocutaneous Flap. Iliac crest bone has long been used as a reliable source of bone for nonvascularized bone grafts. The vascularized iliac crest osteocutaneous flap is an excellent source of bone and soft tissue suitable for use in free tissue transfer reconstruction of mandibular defects. The iliac crest osteocutaneous flap is based on the deep iliac circumflex vessels, which perfuse the bone and provide cutaneous perforators supplying the skin and subcutaneous tissue. Arterial diameter averages 3 mm, and pedicle length is limited to around 6 cm. Up to 16 cm of bone may be harvested, and skin paddle dimensions up to 10 cm x 30 cm may be transferred on the basis of the arterial supply. Because the perforators of the deep iliac circumflex vessels traverse the abdominal oblique muscles, a cuff of muscle is generally taken with the flap to assure preservation of these vessels. Inclusion of a larger volume of internal oblique muscle with the paddle allows for versatility in the volume of soft tissue transferred (see Table 6).

The native curvature of the iliac crest bone lends itself to reconstruction of the ipsilateral mandible and overlying skin and soft tissue. When the peristeum of the iliac crest bone is preserved, several osteotomies can be made to create the mandibular contour without disrupting the blood supply to the bone. Studies comparing dental rehabilitation following various types of mandibular reconstruction have suggested that iliac crest bone provides the highest quality bone for the support of osseointegrated dental implants. The skin paddle is bulky, and thus, the iliac crest osteocutaneous flap is not ideal for intraroral reconstruction but may be an appropriate choice for medium-volume defects requiring both mandibular and cutaneous reconstructions, such as cheek, neck, or chin defects. Because of the bulky soft tissue overlying the bone, the flap is not pliable in three dimensions, and the versatility of its positioning in the recipient site is limited. To reduce the soft tissue bulk, the flap may also be harvested without skin and covered with a split-thickness skin graft at the recipient site.

A disadvantage of the use of iliac crest osteocutaneous flap is postoperative morbidity related to the development of hernia at the donor site. To reduce this risk, attention must be given to meticulous closure of the layers of the abdominal wall. The transversus abdominis muscle and transversalis fascia are sutured to the iliacus muscle, and the transversalis fascia, the external oblique muscle, and the subcutaneous fat are sutured to the abdominal wall. The transversus abdominis muscle and transversalis fascia are sutured to the iliacus muscle, and the transversalis fascia is sutured to the abdominal wall. The transversus abdominis muscle and transversalis fascia are sutured to the iliacus muscle, and the transversalis fascia is sutured to the abdominal wall.

A disadvantage of the use of iliac crest osteocutaneous flap is postoperative morbidity related to the development of hernia at the donor site. To reduce this risk, attention must be given to meticulous closure of the layers of the abdominal wall. The transversus abdominis muscle and transversalis fascia are sutured to the iliacus muscle, and the transversalis fascia is sutured to the abdominal wall. The transversus abdominis muscle and transversalis fascia are sutured to the iliacus muscle, and the transversalis fascia is sutured to the abdominal wall.
Poor retention of the prosthesis can be due to denture bulkiness, poor residual dentition (both quality and quantity), or poor retentive surfaces. This can create leakage and oronasal regurgitation. Furthermore, as more of the zygomatic prominence is lost, the esthetic success and stability of the prosthesis is decreased. Radiotherapy also has a negative effect on the comfort and retention of the obturator and the underlying tissues that support it. Buildup of secretions on the prosthesis contribute to a foul odor that may make it unmanageable.

The theoretical advantage in detection of recurrent tumor with prostheses compared with flap coverage remains unproven, probably because of the accuracy and availability of modern imaging methods that allow accurate assessment of the resection bed without direct inspection. Primary reconstruction is technically superior a secondary procedure although primary use of a reconstructive flaps does not exclude later reconstruction with flaps. Primary reconstruction of a large defect avoids the substantial psychological and emotional distress due to disfigurement. A testing to the complexity of these anatomical defects, several classification schemes exist.

**Palate and Alveolar Ridge**

The amount, location, and quality of residual bone of the midface and dentition or denture-bearing alveolar ridge largely determine whether or not a bone-containing flap is necessary. Small defects involving the alveolar ridge, teeth, and surrounding mucosa with adequate dentition and no oroantral fistula can be allowed to heal by secondary intention or covered with a local flap such as the palatal-island flap (greater palatine vessel based).

Soft tissue reconstruction, without bony reconstruction, with free flaps may be adequate for patients with dentition and those who do not or cannot undergo more complex reconstructive procedures. Bony reconstruction partly preserves the three-dimensional ridge and allows use of osseointegrated implants for functional dentition when adequate bone stock is replaced such as fibula, iliac crest, and scapula.

**Inferior Maxillectomy**

Defects that leave an oroantral or oronasal fistula should be closed. In the presence of pre- or postoperative radiation, the radial forearm flap can be used for deep central palatal defects. The pedicled temporalis flap plus skin grafting with or without calvarial bone is another alternative. The length and width of the bony component of the radial osteocutaneous free flap is limited to small anterior defects not requiring dental implantation. A cephalic esthetic result without retraction of the upper lip and normal speech may be achieved. For larger defects, the rib bone, iliac crest, or scapular osteocutaneous flaps with appropriate often multiple osteotomies to donor bone for contouring may be necessary. If the patient needs a dental implant, it can be placed easily as early as 6 to 8 weeks after the reconstruction.

**Total Maxillectomy with Orbital Preservation**

When the inferior orbital wall is resected there is loss of support of the globe. Without adequate support of the orbit, enophthalmos, "hypophthalmos," and diplopia will result. Various reconstructive techniques range from a prosthetic device to free tissue transfer. Prosthetic reconstruction for orbital support is normally not a good option. Soft-tissue pedicled flaps, such as the temporalis flap, rotated through the osteotomies of the zygomatic arch, are useful in patients who cannot undergo free-tissue transfer. The pedicled temporalis and vascularized calvarial bone flap offers appropriately thin and high-quality bone to support the orbit and the important zygomaticomaxillary buttress in these patients. Thus, this flap might be used for patients who are not candidates for free-tissue transfer. Since total maxillectomy defects involve multiple soft tissue and bony components of the midface, this option can be combined with other soft-tissue flaps, which could provide bulk to refill the midface contour, for example, a latissimus dorsi flap or a rectus abdominis free flap. These soft-tissue reconstructions, however, do not include the maxillary bony skeleton, particularly the orbit, zygoma, and alveolar ridge which may require vascularized soft-tissue flaps with primary or secondary nonvascularized bone grafting. Rigid globe support may be maintained with cranial or rib bone grafts, whereas the remainder of the defect is filled with the fat and muscle free-tissue transfer. The palate is sealed with soft tissue only. Then free tissue is used to reconstruct the maxillary defect, and alloplastic material is used for orbital reconstruction. Titanium mesh or porous polypropylene can be used.

**Total Maxillectomy with Orbital Removal**

Reconstructive options after total maxillectomy and orbital exenteration depend on the amount of remaining dentition. If enough teeth and alveolar arch remain, a prosthesis can be used although with poor cosmesis and all of the issues mentioned above. A better approach is to complete the palate and alveolar arch with a prosthetic device in conjunction with a bulky myocutaneous flap, such as the rectus abdominis to fill the midface volume, including the orbit. The free flap obliterates the dead space and separates the remaining midface sinonasal structures from the oral cavity. Often it is problematic to set a prosthesis that fits.

The bony options described above can be used for both the infraorbital and zygomatic regions and the alveolar arch, but adequate soft tissue should be harvested to fill or line the orbital component of the defect. If the barrier between the brain and the sinuses has been removed with resection of the neoplasm, it must be replaced with vascularized tissue to seal the skull base.

In a study of 16 patients, those who had defects resulting from orbital removal and had less than 30% of the bony orbital rim received reconstruction with an osteocutaneous forearm flap. By contrast, patients who only had cavities where the orbit had been removed received reconstruction with fasciocutaneous forearm flaps. Finally, for radical orbital exenteration cavities with resection of overlying skin and bony malar eminence, osteocutaneous scapula flaps were used. This study cited advantages of autologous tissue reconstruction of the orbit to include durability, defect size kept to a minimum, avoidance of potential accidental displacement of a patch or prosthesis, and the tendency for other peoples’ attention to be drawn toward the functional eye instead of a static ocular prosthesis. Additionally, when the eyelids and orbicularis oculi muscles remain unresected, the lids could be sewn together, skin color matched, and facial expression, including the blink reflex, preserved.

**Mandible**

Segmental mandibulectomy defects after oral cancer resection are usually associated with composite bone and soft tissue defects. Although this discussion focuses on the bony aspects, it must be remembered that the ultimate reconstruction paradigm should factor in the following associated constructs. An ideal reconstruction should restore mandibular continuity, maintain dental occlusal relationships, and restore the contour of the lower third of the face.

The advent of osteocutaneous free flaps has greatly increased the reliability of bone graft for immediate reconstruction of segmental mandibular defects. In the previous era of immediate mandibular reconstruction using nonvascularized bone grafts, the rate of successful restoration of mandibular continuity was only about 50%. A considerable experience with vascularized bone containing free flaps has shown that the rate of successful immediate mandibular reconstruction exceeds 90%. The fibular osteocutaneous, radial osteocutaneous, and scapular osteocutaneous flaps may be used depending on the defect and the osteocutaneous tissue available in an individual patient.

A combination of bridging mandibular reconstruction plates may be used to span lateral mandibulectomy defects, with a low volume and a short length of mandibular resection along with a soft tissue free flap. A titanium hollow screw reconstruction plate provides a mechanism for osseointegration at the bone-to-screw interface as well as a locking mechanism at the screw-to-plate interface, resulting in superior hardware stability. Complex three-dimensional composite defects of the lateral parts of the mandible and oropharynx, when the soft tissue resection includes the base of the tongue, lateral oropharyngeal wall and tonsillar fossa, and the soft palate, can be reconstructed using a thin and pliable fasciocutaneous radial forearm free flap and bridging plate. However, bridging plates are not suitable as permanent mandibular substitutes with anterior mandibular defects due to...
an unacceptably high incidence of intraoral plate extrusion. Further, in select cases, plates may be used with free cancellous iliac bone grafts.

CONCLUSIONS

The advent of free tissue transfer has widely expanded the capabilities of the reconstructive surgeon to recreate acceptable form and function following extensive tissue resection. Selection of a flap for reconstruction is dependent on the characteristics of both the donor and the recipient sites and should be individually tailored to suit each case. Advantages of each flap are weighed against potential morbidity; and, ultimately, a flap is chosen on the basis of its overall suitability for reconstruction of the recipient site. Detailed knowledge of reconstructive options enables the surgeon to select an appropriate reconstructive modality that will achieve an acceptable functional and aesthetic outcome for each patient.

Rejuvenation of the Upper Face and Midface

Theda C. Kontis, MD
John S. Rhee, MD, MPH

As the face ages, forehead horizontal rhytides develop and deepen, eventually followed by vertical lines in the glabella. The eyebrows begin to descend and flatten, resulting in lateral hooding of the upper eyelid region. Lax and redundant eyelid skin, along with the appearance of fat protrusion, is also a component of the aging upper third of the face. Ptosis and soft tissue hollowing of the malar complex are the key aging changes of the midface, which result in changes in the lower eyelid complex as well as the nasolabial fold (Figure 1). Rejuvenation of the upper one-third of the face consists of treating the forehead, eyebrow, and periorbital complex. Rejuvenation of the midface consists of addressing the malar complex and its relationship to the lower eyelid and nasolabial fold.

The primary focus of the chapter is to provide an overview of the surgical techniques that are available for addressing the aged mid and upper thirds of the face.

APPLIED SURGICAL ANATOMY

Forehead

The central forehead and scalp is composed of five distinct layers, described by the mnemonic device SCALP: skin, subcutaneous tissue, galea aponeurosis, loose areolar tissue, and pericranium (Figure 2). The skin is thick and densely adherent to the underlying subcutaneous tissue. The galea aponeurosis is a thin, mobile, fibromuscular sheet that envelops the entire skull and splits anteriorly to encase the frontalis and procerus muscles. The galea is an extension of the superficial musculoaponeurotic system (SMAS) in the face and the temporoparietal fascia of the temple. The loose areolar tissue plane is a relatively avascular plane and the traditional layer of dissection for coronal approaches. This layer is continuous with the loose connective tissue which separates the temporoparietal fascia and the deep temporal fascia. The pericranium is a thickened layer of connective tissue adherent to the skull and is continuous with the periorbita at the level of the supraorbital ridges.

The sensory innervation of the forehead and scalp is supplied by the supraorbital and supratrochlear nerves, which are divisions of the ophthalmic branch of the trigeminal nerve. Both nerves exit the frontal bone through a notch or foramen, pierce the orbital septum, turn upward to pierce the corrugator supercilii muscle, and travel on the superficial aspect of the frontalis muscle (Figure 3).

The actions of the muscles of the brow and forehead are listed in Table 1. The temporal branch of the facial nerve innervates all of these muscles. It is the mimetic actions of these muscles...
that produce the wrinkles and furrows in the skin of the forehead and glabellar areas. The corrugator and procerus muscles are usually surgically weakened in the correction of the aging brow and forehead. These muscles are also the targets of temporary chemodenervation by the injection of botulinum toxin.

**Temporal Fossa**

The transition from the forehead to the temporal fossa occurs at the superior temporal line, demarcated by the conjoint fascia, a condensation of the pericranium and the deep temporal fascia. The temporal fossa is bounded inferiorly by the zygomatic arch and anteriorly by the frontal process of the zygomatic bone. The fascial layers of the temporal fossa have been prone to confusing and conflicting nomenclature (see Figure 2).

The temporoparietal fascia is a thin, vascular layer, densely adherent to the overlying subcutaneous tissue and skin. This layer is continuous with the galea aponeurosis of the scalp and SMAS of the face. The deep temporal fascia envelops the temporalis muscle and divides into a superficial and deep layer at approximately 2 cm above the zygomatic arch. The arch and the temporal fat pad are ensheathed by the superficial and deep layers of the deep temporal fascia.

Understanding the course of the temporal branch of the facial nerve is critical to safe dissection in this area. The nerve enters the temporal fossa by crossing superficially over the midportion of the zygomatic arch. It travels in the temporoparietal fascia layer and then exits the temporal fossa to course along the deep aspect of the frontalis muscle, supplying the muscles of the brow and forehead (see Figure 3).

**Periorbital Complex**

The eyelids are formed by multiple soft tissue layers and are divided into an anterior lamella, composed of skin and orbicularis muscle, and a posterior lamella, composed of the tarsus and conjunctiva. The upper and lower eyelids are composed of analogous structures that are better defined in the upper lid (Figure 4).

The orbital septum is a fibrous structure that lies superficial to the orbital fat pads. With aging, the septum weakens allowing prolapse of the fat pads. The preaponeurotic fat is subdivided into two compartments in the upper lid: medial and central. The lacrimal gland fills the lateral compartment. In the lower lid, the fat lies in three compartments: medial, central, and lateral. The inferior oblique muscle lies between the medial and central compartments. Relatively large blood vessels supply the fat pads.

The levator palpebrae superioris muscle is the primary elevator of the upper eyelid and is innervated by the oculomotor nerve. The levator muscle arises from the orbital apex and courses anteriorly where it thins to a broad aponeurosis that inserts onto the anterior surface of the tarsal plate. The supratarsal crease is created by anterior extension of some of the fibers to attach to the dermis of the eyelid skin. In the Asian lid, aponeurotic fibers do not attach to the skin, which results in a “single eyelid,” without a supratarsal crease. A acquired ptosis of the upper eyelid often is a result of levator dehiscence from the tarsal plate and must be identified preoperatively.

**Midface**

The midface is the triangular region bounded by the inferior orbital rim, nasolabial fold, and anterior border of the masseter muscle. The malar fat pad is a large fibrofatty subcutaneous pad which lies superficial to the zygomaticus major and minor muscles. The zygomatic branch of the facial nerve travels deep to the superior aspect of the zygomaticus muscles. In the youthful face, the suborbicularis oculi fat (SOOF) pad lies between the orbicularis muscle and orbital rim periosteum at the level of the arcus marginalis (Figure 5). The arcus marginalis is the attachment of the orbital septum to the periosteum of the inferior orbital rim. The orbital septum inserts into the inferior tarsal margin. Fat repositioning procedures target the arcus marginalis as the site of fat release.

The levator labii superioris muscle arises on the medial aspect of the inferior orbital rim, and the SOOF envelops it in youth. The infraorbital nerve foramen and nerve are located just deep to the origin of the levator labii superioris muscle. The SOOF in the aging face is often located below the origin of the levator labii superioris muscle. Midfacial rejuvenation techniques target resuspension of the SOOF and/or malar complex. In addition, blepharoplasty techniques now emphasize orbital fat preservation and repositioning to improve the tear trough deformity. The tear trough deformity, or nasojugal groove, is a depression of the soft tissue between the medial canthus and the lateral nasal sidewall (see Figure 1).

**ESTHETIC CONSIDERATIONS**

**Brow and Forehead**

The eyebrow is shaped as a graceful, gentle arch. The ideal position and shape of the eyebrow is quite subjective and varies according to gender, ethnicity, and current fashion trends. As a general rule, the medial brow has a clubhead configuration and begins at a point tangent to a vertical line drawn through the medial canthus and lateral nasal ala margin (Figure 6). The brow gradually tapers to a handle shape, with the lateral third of the brow coursing above the superior orbital rim in women and at the rim in men. It terminates laterally at a point tangent to an oblique line drawn from the lateral nasal ala to the lateral canthus. Depending on one’s esthetic sense, the apex of the brow arch should lie between the lateral limbus of the cornea and the lateral canthus.

The upper third of the face is a focal point for expression and emotions. With the aging process, there is loss of tissue elasticity, decrease in the bulk of the subcutaneous tissue, and an increase in skull bone resorption. Excessive displacement of the medial portion of the eyebrows along with deep glabellar furrows may project expressions of anger or malice. A similar lateral hooping or drooping of the eyebrows suggests a fatigued or sad appearance.
Some surgeons have turned to more objective parameters when assessing harmony of the upper third of the face. McKinney and colleagues described the existence of brow ptosis when the distance from the midpupil to the top of the brow was less than 2.5 cm (see Figure 6). In addition, they noted that the female forehead should measure 4 to 6.2 cm (mean 4.8 cm). Farkas and Kolar found that the most attractive women had a relatively smaller upper third of the face compared to the middle and lower thirds of the face. It is important to remember that certain browlifting techniques can raise the hairline which can significantly alter the harmony and balance of the horizontal facial thirds.

Periorbital Complex

The ideal esthetic appearance of the upper eyelid varies with gender and ethnicity. In Caucasian women, the tarsal crease lies 10 to 11 mm above the lash line. In men, the crease lies only 8 to 10 mm above the eyelid margin. Approximately 50% of Asians have an absent tarsal crease.

The upper eyelid should cover the corneal limbus by approximately 1 to 2 mm. If the sclera is visible between the lid margin and limbus, lid retraction is present and may be due to thyroid ophthalmopathy. Ptoxis, or drooping of the upper eyelid, can be congenital or acquired and should be evaluated preoperatively.

Midface

A prominent malar complex is generally associated with youth and beauty. Because the midface ages as a result of both volume loss and the effects of gravity on the tissues, the goal of midface rejuvenation is the restoration of volume as well as repositioning the ptotic tissues.

As one ages, the soft tissues of the malar complex become ptotic, accentuating the infraorbital bony rim. The nasolabial fold deepens, and the lower eyelid becomes lax, increasing scleral show. The distance between the inferior lid and malar crescent widens, and the nasojugal or “tear trough” deformity appears. Pseudoherniated fat lies above the orbital rim and the descended malar pad below, creating a double convexity deformity of the lower lid midface complex (see Figure 1).

SURGICAL APPROACHES

Brow and Forehead

Careful patient selection and appropriate surgical goals will help to ensure optimal results. In evaluating candidates for rejuvenation of the upper third of the face, it is important to keep in mind the esthetics of the brow and the upper third of the face. The need for an upper lid blepharoplasty may either be obviated by a brow lift or it may markedly reduce the requirements for skin excision. The entire orbital complex, brow position, frontal hairline, hair density,
forehead contour, forehead rhytides and furrows caused by the actions of the underlying musculature should all be considered in the preoperative assessment.

There are several surgical approaches, endoscopic, coronal, trichophytic, direct, and mid forehead. The latter two choices are less commonly used and more appropriate for facial paralysis patients or in men with thick and heavy skin with prominent forehead rhytides. The ideal candidate for the endoscopic approach has the following characteristics: female, low hairline, abundant hair, flat contour of the forehead, normal or thin skin, and moderate brow ptosis.

Patients requiring extensive bone recontouring may be better treated with an open procedure. Patients with thick, heavy sebaceous skin and severe brow ptosis are less favorable candidates and may be better served with conventional open skin excision techniques (coronal or trichophytic approaches). Also, surgical weakening of the brow depressor muscles is often technically easier using the open approaches. Finally, patients with high hairlines, sparse hair, male pattern baldness, and rounded foreheads are less ideal candidates for the endoscopic approach.

Regardless of the choice of incisions or approaches, there are basically four steps in executing the brow lift: (1) placement of precise incisions, (2) dissection and adequate release of the scalp and forehead, (3) myotomy of the desired facial expressive muscles, and (4) elevation and fixation of the forehead to the desired level.

The endoscopic forehead lift has been described using four, five, or six incisions placed 2 to 3 cm behind the hairline (Figure 7). The central incision marks the midline and is the main endoscopic port. The two paramedian incisions are placed at the level of the lateral limbus or canthus. The two temporal incisions are needed for dissection over the temporalis fossa and allow better positioning of the lateral portion of the brow.

For the coronal brow lift approach, the skin incision is fusiform and placed 5 to 6 cm behind the anterior aspect of the hairline. A curvilinear incision is drawn parallel to the hairline with the blade beveled parallel to the natural axis of the hair follicles. The amount of skin excised is determined preoperatively, generally about 1 to 2 cm. The main disadvantages of this approach include undesirable elevation of the hairline, potential alopecia and more visible scars, and paresthesia behind the scalp incision. Usually the paresthesia resolves over time, but it can be bothersome to patients during the recovery.

Candidates who have a high hairline may be best served with a trichophytic approach. The incision is made in the gradual transition zone between the thick hair of the scalp and the thin wispy hair at the true hairline. The incision parallels the natural curvature of the hairline, and the excision pattern resembles a gentle W-plasty. The lateral extensions proceed into the temporal hairline. The goal is to allow the hair follicles along the anterior hairline to grow through the incision to help camouflage the scar. As in the coronal approach, usually about 1 to 2 cm of scalp is excised. Meticulous closure of the anterior hairline is essential for a successful cosmetic outcome. The main disadvantages of this approach are potentially a more visible incision compared to the endoscopic approach and paresthesia behind the incision line.

In all browlifts, regardless of the surgical approach, the plane of dissection over the skull can be either subperiosteal or subgaleal. The temporal incision is extended down to the superficial layer of the deep temporalis fascia. Using a freer elevator, the dissection is continued along this plane and the temporal dissection is connected to the subperiosteal plane of the forehead by sharply dissecting the transition zone at the temporal crest line.

The temporal dissection is continued to the level of the zygomatic arch and the zygomatico-frontal suture line. If the dissection is in the correct plane, the temporal fat pad in the elevated flap should become visible as one nears the zygomatic arch. A branch of the zygomaticotemporal communicating vein (“sentinel vein”) is often encountered when dissecting near the zygomatico-frontal suture line. The vein can either be cauterized with a bipolar cautery or gently dissected from the surrounding tissue. The temporal branch of the facial nerve runs in close proximity to the vein. Bleeding caused by injury to this vein can lead to poor visualization, and possibly inadvertent injury to the facial nerve from cautery or further dissection. Overzealous upward retraction in the temporal area should be avoided as it may cause traction neuropraxia of the frontal branch of the facial nerve.

It is important to release fully the entire length of the superior arcus marginalis to achieve adequate brow elevation. The periosteum and galea are horizontally scored at this point, exposing the corrugator muscle, procerus muscle, supraorbital nerve, and supratrochlear nerve. In patients in whom glabellar muscle modification is desired, the supratrochlear and supraorbital nerves are dissected from the corrugator muscles by using a gentle vertical spreading motion with Takahashi forceps.

Once the nerves are safely separated from the corrugator muscle, the muscle is gently avulsed or transected. The procerus muscle can be approached in similar fashion. The subcutaneous fat will become visible upon removal of the muscle. Care should be taken not to remove any subcutaneous tissue, as dimpling or contour irregularities will occur. It is not necessary to remove all of the muscle fibers to achieve the desired result; the extent of the resection should be tailored to the preoperative assessment of the severity of the glabellar frown lines.

Surgeons differ in their use of fixation methods to reposition the forehead soft tissues. Central brow fixation techniques include the use of miniplates, screws, bone bars, bioabsorbable fixation devices (ENDOTINE Forehead device, Coapt Systems, Inc., Palo Alto, CA), and various suture techniques.15–16 (Figure 8). The temporal fixation determines the final position of the lateral brow. In the endoscopic approach, the anterior corner of the lateral canthus.
the incision is engaged and secured to the desired point on the temporalis fascia, determined by the desired vector pull. Regardless of the method of fixation, adequate dissection and mobilization of the forehead tissue are paramount for successful brow elevation. In the skin excision techniques, deeper fixation is not necessary; but, as mentioned above, complete release and mobilization of the brow and forehead are necessary for a successful outcome.

Blepharoplasty

Upper Blepharoplasty. Surgery of the upper eyelids involves excision of an ellipse of skin, just superior to the tarsal crease. The lower limb of the incision is placed in the natural upper lid crease. In cases in which the natural crease is not well demarcated, then the lower incision is made 10 to 11 mm above the lash line in women and 8 to 10 mm above the lash line in men. The incision extends from the level of the punctum medially to a natural crow’s feet crease laterally at the level of the lateral orbital rim. The shape of the excised skin is generally elliptical, with the incision tapered gently medially and wider laterally to address lateral hooding. The incisions must be drawn symmetrically or in such a way to account for preoperative asymmetry. If a browlift is to be performed, it is performed first to prevent excessive removal of upper eyelid skin during blepharoplasty.

Once the skin and subcutaneous skin is removed, the orbicularis muscle is divided which reveals the fine connective tissue of the orbital septum. This area is carefully separated to expose the medial and central fat pads. In some cases, a strip of obicularis muscle can be removed parallel to the skin incision to accentuate the creation of the upper lid crease or to remove hypertrophic muscle. The orbital septum is opened to expose the two fat pads of the upper eyelid. The fat is conservatively removed from the medial and middle compartments, and hemostasis is meticulously obtained. The skin edges are then reaproximated (Figure 9).

Lower Blepharoplasty. Surgical approaches used to remove prolapsed fat from the lower eyelids can be performed through subciliary or transconjunctival incisions. The subciliary approach is generally selected when excess lower lid skin must be excised. The plane of dissection is usually under the orbicularis muscle. When this approach is used, care must be taken to assess the laxity of the lower lid. By using a “snap” or “pinch” test, the resiliency of the lower lid can be ascertained. When a lower lid is pulled down and slowly returns to its original position or is pinched and slowly returns to touching the globe, a tarsal suspension procedure must be performed to prevent postoperative ectropion. The transconjunctival approach to the lower lids was developed mainly to prevent ectropion.

After performing the lower lid incision, the three orbital fat compartments (medial, central, lateral) are exposed. Each fat pad is dissected free, cauterized, and excised. Because the fat pads retract after manipulation, meticulous hemostasis is necessary to prevent an orbital hematoma. Increased pressure in the globe from a hematoma can cause a decrease in retinal artery flow and potentially result in blindness.

Because modern techniques of facial rejuvenation focus on volume restoration, often fat preservation rather than removal is performed on the lower lids, especially in the presence of a tear trough deformity (Figure 10). This area can be approached by either a subciliary or transconjunctival incision. Once the three fat
pads are isolated, conservative removal of fat from the lateral compartment is performed. Fat from the central pocket may be removed conservatively, if required. The white band of the arcus marginalis is identified on the bony infraorbital rim and divided, exposing the anterior maxilla. The subperiosteal plane is dissected to allow insertion of the freed fat pad. Dissection can instead be performed in the supraperiosteal plane, but dissection through the orbicularis muscle makes this a bloodier plane. The fat pad is dissected to allow sufficient rotation and the pedicle thinned to a width of 0.5 to 1.0 cm. The pedicled fat pad is actually a random flap, despite the presence of somewhat large feeding vessels. Suture stabilization of the fat pad can be performed by suturing to the SOOF or by imbrication. Once the fat is positioned, a forced duction test of the globe is performed to ensure no restriction of extraocular movement with upward gaze. Patients may experience prolonged edema from subperiosteal dissection. The fat pedicle may become hardened for 3 to 6 months postoperatively. Long-term fat survival rate may vary, but most patients maintain improvement in the nasojugal region. This approach specifically targets the tear trough deformity and does not elevate the SOOF or malar pad.

Midface

Transblepharoplasty Midface Suspension. With the transblepharoplasty midface suspension, an extended subciliary approach allows elevation of the malar complex at the same time as softening of the nasojugal groove. The subciliary incision is extended 1.5 cm lateral to the lateral canthus. A skin-muscle flap is elevated in the plane between the orbicularis muscle and orbital septum. An incision is created along the arcus marginalis, and the subperiosteal dissection is performed along the anterior aspect of the maxilla. The dissection extends laterally to the zygomatic arch and medially to the nasolabial fold, with care to protect the infraorbital nerve. The orbital septum is opened and the infraorbital fat from the medial and/or central compartments is draped over the inferior orbital rim, softening the nasojugal groove. Through a temporal hairline incision, the superficial layer of deep temporal fascia is isolated for suture suspension of the malar soft tissue complex in the vertical direction. Alternatively, an absorbable Endotine implant may be placed on the inferior orbital rim by screw fixation and used to suspend the malar complex. A canthoplasty or canthopexy is usually performed to prevent postoperative ectropion. Conservative eyelid skin removal may be performed. The skin blood supply is not compromised because of the deep plane of dissection, and laser resurfacing or chemical peels can be performed at the same time.17

Endoscopic Midface Suspension. Since the introduction of endoscopic sinus techniques, the endoscope is used to perform browlifts and midface elevations. Multiple techniques for midface elevation exist, most have in common the approach and differ mainly in how the midface is suspended. These techniques provide significant elevation of the ptotic malar complex and can be easily combined with an endoscopic browlift.

Release of the midface tissues is accomplished by creating either a lower blepharoplasty incision or a gingival-buccal sulcus incision and a temporal incision. Through the intraoral or blepharoplasty incisions, soft tissue is freed from its attachments to the anterior maxilla via extensive...
subperiosteal dissection. Care is taken to preserve the infraorbital nerve as it exits from its foramen along the inferior orbital rim. The temporal incision is carried down to the superficial layer of the deep temporal fascia. This dissection is carried inferriorly to the zygomatic arch, where the two pockets are joined over the zygomatic arch. (see Figure 2). The endoscope may be used during the temporal dissection, or a lighted A ufretch retractor may also be used. The temporal dissection follows the temporalis fascia to the zygomatic arch. The sentinel vein in identified and dissection proceeds lateral to the vein.

Once the temporal and malar dissections have been connected over the zygomatic arch, the tissue must be suspended. Many techniques for suspension exist. Sutures can be placed in the malar mound, passed through the tunnel, and sutured to the temporalis fascia. This technique is difficult to perform because the sutures can cause puckering of the cheek skin, and it is difficult to obtain symmetry.

In the past, endoscopic suspension techniques were technically difficult and often required special instrumentation. For these reasons, we prefer to use the ENDOTINE Midface ST implant for midface suspension (Figure 11). This implant, a copolymer made of 82/18 L-lactide/glycolide, is biodegradable 6 months after placement. The implant is placed in the midface through the tunnel created over the zygomatic arch. The five prongs are used to grasp the malar soft tissue, and the extension or “leash” is pulled superiolaterally and sutured to the temporalis fascia. This maneuver elevates the malar complex and slightly flattens the nasolabial fold (Figure 12). The implant is resorbed in approximately 6 months, after the tissue has become adherent to the maxilla.

COMPLICATIONS

Brow and Forehead Lift

The incidence of complications for this procedure is quite low. Hypesthesia over the forehead and scalp due to traction neuropraxia of the sensory nerves is usually temporary and returns to normal in 6 to 10 weeks. There have been some anecdotal reports of temporary weakness of the frontal branch of the facial nerve following the procedure. Permanent facial nerve paralysis has not been reported to date.

Imprecise surgical technique may result in asymmetrical brows, excessive brow elevation or, more commonly, recurrence of brow ptosis. Sufficient release of the brow at the level of the orbital rim and adequate fixation will prevent the recurrence of brow ptosis. There may be some temporary local alopecia at the incision sites, and bunching of the skin usually resolves in 2 months.

Blepharoplasty

A symmetry of the upper eyelid tarsal creases is a risk of upper blepharoplasty. Failure to recognize a lid ptosis preoperatively can result in an asymmetric result. Lagophthalmos, the inability to close the lid, can result from excessive upper lid skin excision. For that reason, the young surgeon is cautioned to remove conservative amounts of skin during upper lid blepharoplasty. If necessary, redundant skin may be removed after the patient has healed, but it is difficult to replace skin postoperatively if the lid is too short.

A retained fat pad is a common cause of revision surgery of the lower eyelids. Occasionally a fat pad is inadequately excised, and a noticeable prominence is present especially on upward gaze. These can usually be removed easily by the transconjunctival approach. Serious complications of blepharoplasty include injury to the ocular muscles and hematoma. Unlike the upper lid, the lower
lid fat is associated with the globe. A hematoma of the upper lid is not as serious a problem as it is in the lower lid. Meticulous hemostasis is imperative in lower lid blepharoplasty to avoid retro-orbital hematomas. Hematomas of the globe can increase intraocular pressure and diminish bloodflow through the retinal artery, ultimately resulting in blindness. In addition, extraocular muscles can be injured during lower blepharoplasty.

**Midface**

The most common complication of midface surgery is asymmetry. There do not appear to be any significant complications from the fixation devices themselves. Care must be taken intraoperatively to ensure symmetric elevation of the malar complex. The infraorbital and frontal nerves must be protected from traction injury.

**CONCLUSIONS**

Aging of the upper face and midface is secondary to a variety of causes: the effects of gravity pulling the soft tissues inferiorly, loss of skin elasticity due to aging, sun exposure and smoking, and loss of volume of the facial soft tissues. Many surgical techniques are available to remove prolapsed fat, remove excess skin, and reposition ptotic soft tissues.

No one operation is right for every patient. Once the patient identifies the areas of concern, the surgeon may recommend several procedures which can be used to correct such areas. Minimally invasive procedures, like botulinium toxin and dermal filler injections, can be used for early signs of aging. Once the patient has lost tissue elasticity and support, rejuvenation of the upper face and midface may be necessary. Surgical techniques have progressed significantly in these areas in the past 15 years. Tissue preservation rather than complete removal is being practiced. We can predict that in the future even less invasive techniques will be developed with minimal morbidities and more rapid recovery times.

Rejuvenation of the Lower Face and Neck

Craig S. Murakami, MD
Bryan T. Ambro, MD, MS

Despite the ever-evolving standards of beauty, several classic characteristics of facial beauty have undoubtedly stood the test of time. The full, ovoid face highlighted by taut skin, high cheek bones, and an angular neck line remains the esthetic ideal for the youthful face and neck. A ging of the lower face and neck is complex and varies from one individual to the next. Generally speaking, cervicofacial aging can be characterized by four changes: (1) ptosis of fat and soft tissue, (2) volumetric loss of facial adipose, (3) bony resorption, and (4) laxity of the overlying skin. It naturally follows that surgical strategies aimed at rejuvenation of the lower face and neck involve correction of these signs of aging.

The goal of this chapter is to provide an overview of the relevant anatomy of aging, appropriate analysis of aging, and, lastly, the corrective surgical options available. The reader is reminded that not all techniques for lower cervicofacial rejuvenation are covered in this chapter. Less invasive procedures such as soft tissue fillers and skin resurfacing, although effective in an adjunctive role, are presented in Chapter 57, "Scalp Revision and Skin Resurfacing." Although much of this text reflects the philosophy of the authors, we have attempted to present a thorough review of the literature highlighting the many different surgical strategies available.

HISTORICAL PERSPECTIVE

In the early part of the twentieth century, European surgeons pioneered the surgical treatment of rhytides (rhytidectomy—Greek for removal of wrinkles). By simply undermining and removing the excess skin, the subcutaneous rhytidectomy was, for nearly a half century, the gold standard for aging face surgery. Unhappy with its limited duration of benefit, Skoog, in 1974, published improved, longer lasting results in the lower third of the face by dissecting in a "subfascial plane." Two years later, Mitz and Peyronie, described in detail this muscle and fascial plane of the face, naming it the superficial musculoaponeurotic system (SMAS). With better, longer-lasting results in the neck and jowls, the sub-SMAS procedure emerged as the new standard in facelift techniques.

The literature is replete with further modifications of the SMAS rhytidectomy technique (e.g., deep plane, composite, triplane rhytidectomy) as well as isolated procedures for the aging anterior part of the neck or midface, giving today's facelift surgeon many rejuvenation options. Particularly important, however, is the surgeon's ability to recognize the differing degrees of aging from one individual to the next and to tailor the surgical strategy accordingly.

SURGICAL ANATOMY AND ANALYSIS OF THE AGING FACE

A thorough understanding of the relevant anatomy is essential to achieving the optimal surgical result. Accurate preoperative analysis of the aging anatomy should include all tissue layers of the face and neck, beginning superficially with the skin and working deep through the subcutaneous adipose, fascia layers, cervicofacial musculature, and the underlying bony framework.

Skin and Adipose Tissue

The condition of the skin plays a significant role in the appearance of youth. With aging, the skin undergoes a progressive loss of elastic and collagen fibers and a decrease in the amount of ground substance (hyaluronic acid). This results in an overall decrease in thickness and loss of elasticity allowing for the formation of rhytides. Chronic sun exposure (photoaging) and habitual tobacco use greatly accelerate this process as well as contribute a coarse, leathery texture to the skin. Further "sagging" of the skin can also be attributed to laxity of underlying fasciocutaneous and osteocutaneous ligaments. These facial retaining ligaments allow the skin to resist downward effects of gravity by providing support from rigid underlying muscle and bone. Habitus facial expressions caused by underlying mimetic muscles can also lead to progressive recontouring of the skin and subsequent rhytide formation. With advancing age and the extended effects of gravity, the malar fat pad descends by sliding over the SMAS in an inferomedial direction. This ptosis can contribute to the appearance of increased fullness in the nasolabial fold, hollowness in the submalar area, and skeletonization of the orbital rim. The vertical repositioning of the ptotic malar fat pad is key to restoring a youthful appearance in the aging midface.

Superficial Musculoaponeurotic System and Neurovascular Structures

The SMAS is a fibromuscular layer investing and interlinking the muscles of facial expression. As originally described, the SMAS is a facial layer superficial to and separate from the underlying parotid fascia. The term musculoaponeurotic was used due to occasional muscular fibers seen in the fascia overlying the parotid. Moreover, the SMAS contains fibrous septa that extend through the fat and attach to the overlying dermis. As a result, the SMAS acts as a network to distribute facial muscle contractions to the skin (Figure 1).
Superiorly, there is a discontinuity of the SMAS at the level of the zygomatic arch because of various attachments of fascial layers at the bony arch. Above the arch in the temporal region, the SMAS becomes confluent with the temporoparietal fascia. Inferiorly in the neck, the SMAS represents the caudal extension of the deep layer of the superficial cervical fascia investing the platysma. It is here that the extended effects of gravity on the SMAS are most often noted. SMAS ptosis and age-related laxity contributes to inferiomedial platysmal migration and the development of jowls and anterior neck banding. Facelift techniques that resuspend the ptotic SMAS are the primary surgical options available to correct aging in this region.

There are important regional variations in the relationship of the SMAS to the key neurovascular structures. In the lower face and neck, the facial nerve branches are always deep to the SMAS and platysma and innervate the facial mimetic muscles through their undersurface. The exception to this rule is the deep facial muscles: the levator anguli oris, the buccinator, and the mentalis, which are all innervated through their surfaces. The vessels and sensory nerves in the lower part of the face similarly arise deep to the SMAS and remain at that level, except for their terminal branches. These structures are thus protected if dissection is superficial to the SMAS and platysma. The marginal mandibular nerve lies deep to the platysma muscle and, therefore, is fairly well protected throughout its course along the mandible. As it approaches a point 2 cm lateral to the corner of the mouth, it becomes more superficial and dissection past this point should be avoided. In the midface, the facial nerve branches are protected if dissection is superficial to the facial muscles, for example, the zygomaticus major muscle.

The temporal branch of the facial nerve emerges from the parotid beneath the midpoint of the zygomatic arch. The nerve crosses over the periorbital fascia and subcutaneous fat immediately beneath the subcutaneous fat and continues superiorly on the deep surface of the temporoparietal fascia before entering the undersurface of the frontalis muscle. To avoid injury to the temporal branch when elevating flaps, the dissection should be in the immediate subcutaneous plane or deep to the temporoparietal fascia.

The vascular supply of the lower face is, primarily, provided by branches of the external carotid artery. The anterior part of the face is supplied by musculocutaneous perforators from the facial and infraorbital arteries, while the posterior part of the face receives additional blood flow from the transverse facial and postauricular branches. Blood supply, as it relates to facelift surgery, is dependent on the surgical technique utilized. Methods that employ more extensive subcutaneous dissection create large subcutaneous skin flaps that rely on the subdermal plexus fed by the anteriorly located facial artery. Techniques, such as the deep-plane rhytidectomy, minimize subcutaneous dissection and create a composite flap of skin and SMAS that has a more robust blood supply, making it less likely to be compromised in suboptimal conditions, for example, increased wound tension and tobacco use.

In the cheek region, the skin and subcutaneous tissue is easily dissected free of the underlying SMAS. As one continues to dissect the skin flap anteriorly, several retaining ligaments of the face are encountered (Figure 2). These fibrous bands are known as fasciocutaneous and osteocutaneous ligaments. The fasciocutaneous ligaments, particularly dense at the anterior border of the masseter muscle, emanate from the SMAS and attach to the overlying dermis. The osteocutaneous ligaments are the strongest of the ligament attachments and exist between the periosteum and the overlying skin. These stout ligaments emanate from the periosteum of the zygoma and mandible and are termed the zygomatic cutaneous ligaments (McGregor patch) and the mandibular cutaneous ligaments. Release of these attachments is essential to gaining adequate mobilization of the overlying soft tissue structures such as the malar fat pad.

**Mimetic Facial Muscles**

The noteworthy facial muscles important in rejuvenation of the lower face and neck are the zygomaticus major and minor and the platysma.

Originating superiorly at the zygoma, the zygomaticus muscles insert into the modiolus and act as elevators of the corner of the mouth and lip. They serve as important landmarks for deeper dissection plane techniques. The zygomatic branch of the facial nerve, which innervates these muscles from their undersurface, is protected from injury when a plane of dissection superficial to the muscle is undertaken.

The platysma is a broad, flat sheet of muscle arising inferiorly from the fascia of the pectoralis major and deep to the deltoid muscles. Its fibers cross the clavicle and extend obliquely and upward along the side of the neck. Superiorly and laterally, the fibers extend across the angle of the jaw and insert into the skin and subcutaneous tissue of the lower face as well as blend into the SMAS layer. Medially, the platysmal fibers insert into muscles and subcutaneous tissue surrounding the lower part of the mouth as well as the mandibular periosteum. Below the mentum, the muscle fibers from each side interdigitate and form an inverted V. The apex of the inverted V is quite variable from one individual to the next, with its vertical position being at the mentum, 1 to 2 cm below the chin (most common) or at the level of the thyroid cartilage. The platysma muscle is innervated by the cervical branch of the facial nerve, and its primary action is to depress the lower lip.

With aging, the medial portion of the muscle becomes lax and separates to form two diverging vertical bands. Platysmaplasty is performed to correct this banding by reapproximating the muscular diastasis. When this is performed in conjunction with the posterior pull of facelift,
a hammock-like muscular sling is recreated to restore cervicofacial definition.

**Bony Anatomy**

Choosing the optimal strategy for correction of cervicofacial aging requires an understanding of not only the soft tissue structures but also the bony components of the region. A precise analysis of key osseous elements should include: (1) assessment of projection and resorption of the chin/mandible and (2) the position of the hyoid bone relative to the mandible. The relationship between these two structures is key to determining the cervicofacial angle, which is defined as an intersection of two cephalometric lines. In the lateral view, the first line is drawn from the menton to the hyoid and the second from the hyoid to the sternal notch. The ideal angle created by the intersection of these lines should approximate 90°. An underprojected chin or a low, anterior hyoid can cause the angle to become more obtuse and thus less attractive. Currently, there are no procedures to correct a malpositioned hyoid; therefore, patients with this configuration should be counseled on the limits this places on outcomes (Figure 3). If, however, the same patient has a small chin, surgical efforts should be directed toward chin projection as a means of improving the angle.

A well-defined mandibular line and chin with appropriate height and projection has certainly remained a constant esthetic ideal. Perhaps the simplest way to determine ideal chin projection is to drop a vertical line from the vermilion border to the pogonion, then the chin is underprojected. Micromelia is a term used to describe a congenital small chin with normal dental occlusion. This must be distinguished from retrognathia (underprojected chin with Angle class II malocclusion) and mandibular hypoplasia (age related loss of bony projection), as the treatment options can differ between the three. Micromelia and mandibular hypoplasia are more likely to be corrected by alloplastic implantation or sliding genioplasty (if also vertically deficient), whereas retrognathia often requires mandibular osteotomies and advancement.

The aging process can lead to varying degrees of bony resorption of the mandible (mandibular hypoplasia). The presence or absence of dentition plays a significant role in the amount of bone loss, especially at the alveolar ridge. One specific area of age related resorption occurs between the chin and jowl that, when combined with overlying soft tissue atrophy, creates a vertical groove termed the prejowl sulcus (see Figure 3). This is of significance because although a facelift can correct jowling, it will leave the prejowl sulcus behind. Specific types of extended chin implants or soft tissue fillers are often utilized to augment this atrophic region.

**Assessment of the Neck**

With an understanding of the anatomy of cervicofacial aging, it is quite obvious that each individual’s face ages differently. It naturally follows that the surgical approach to rejuvenation will vary from one patient to the next and that careful preoperative analysis is essential to achieve optimal results.

The Dedo classification system of the aging neck is a useful tool for evaluating patients for rhytidectomy (Figure 4). It identifies six classes of neck anatomy based upon the deepest affected tissue layer, that is, skin, fat, muscle, and bone. A Class I neck is typically seen in younger patients with a well-defined cervicofacial angle, good skin and muscle tone, and absence of submental fat. A Class II neck demonstrates mild skin laxity without underlying muscle or fat deformity. This class of neck is rare as even early signs of aging usually occur in all tissue layers. These patients are counseled that surgical correction will require wide skin undermining and some degree of lateral SMAS tightening. The Class III patient shows evidence of subcutaneous and submandibular fat accumulation. This can either be congenital or age related. Rejuvenation begins with liposuction and can also require facelift if there is concomitant SMAS and skin laxity. A Class IV neck refers to anterior banding of the platysma muscle. Corset platysmaplasty (anterior platysma plication) with lateral lift and suspension is utilized to correct this type of neck. The Class V neck reveals either a congenital microgenia of retrognathia or an age related chin hypoplasia. Corrective measures should include some type of chin augmentation as previously discussed. Lastly, a Class VI neck is characterized by a low-lying hyoid bone with or without any of the others signs of aging. These patients are counseled that there is an anatomical limitation of the result that can be achieved in the neck.
laxity in the submental region. Closeup photos taken to document specific areas are done on an individualized basis. We do not routinely offer digital image morphing in our consultations but do perform it upon patient request.

SURGICAL PLANNING

Anesthesia and Perioperative Medications

We typically perform cervicofacial rejuvenation procedures under general anesthesia, although intravenous sedation is acceptable. Prophylactic intravenous antibiotics (cefazolin 1 gm or clindamycin 600 mg if penicillin allergic) are routinely given preoperatively and are continued orally until the seventh postoperative day. Intravenous dexamethasone (10 mg) and odansetron (400 mg) are also given preoperatively.

Facelift Incisions

There are several important considerations when planning the placement of facelift incisions. The preauricular tuft of hair is the key determinant of what type of temporal hair incision we make. If the tuft of hair is more than 2 cm below the superior helical attachment, then a curvilinear incision is carried into the temporal hair in a more vertical direction (Figure 5). This allows for a greater posterior-superior vector of pull in the temporal and lateral brow area, while maintaining a cosmetically acceptable temporal hair tuft position at or below the helical insertion. If the hairline is at or above the helical insertion point, the temporal incision made in a V-Y fashion above the helical root and then gently curved anteriorly just above the inferior border of the sideburn. This configuration avoids the unnaturally raised temporal hairline seen in the “facelift cripple” (Figure 6), and can actually lower a preexisting high hairline. All incisions in hair bearing skin are beveled in the direction of hair shafts to preserve follicles and allow growth of hair through the scar.

When planning the preauricular incision, we typically follow a retrotragal line in women and a pretragal incision in men. The posttragal incision in men will displace hair-bearing skin onto the tragus which can be problematic. If a scar from a prior facelift exists, this is excised; and an attempt is made to cosmetically position the new incision. Postauricularly, the incision is directed 5 mm up onto the posterior surface of the conchal cartilage, so that during healing contracture the scar ultimately falls in the sulcus and not onto the non–hair-bearing surface of the mastoid. The posterior limb of the incision is gently sloped into the occipital hair at the point of posterior most projection of the pinna to maximize incision coverage in the profile view.

SURGICAL TECHNIQUE

Because the face and neck age as a whole, many patients undergoing rhytidectomy elect to have additional facial procedures performed in combination. If procedures such as brow lift or blepharoplasty are indicated, these are performed prior to the facelift. Fat grafting and skin resurfacing are routinely performed after rhytidectomy. By performing the facelift at or near the end of the operative sequence, we minimize the time the patient is without a compressive cervicofacial dressing.

Neck and Chin

Submental Liposuction and Platysmaplasty

(Submentoplasty). The submentoplasty can be performed alone or in combination with a facelift to achieve the optimal esthetic result in the lower face and neck. It is comprised of two separate procedures: submental liposuction and anterior platysmaplasty. Although they are commonly performed together in the patient with an aging face, isolated submental liposuction may be all that is required for younger patients (Dedo class III) with excess adipose tissue. Both liposuction and platysmaplasty are always performed before rhytidectomy, as the liposuction helps raise the neck skin flaps and the midline platysma plication is difficult if attempted after lateral SMAS/platysmal flap tightening.

Removal of excess submental fat has long been recognized as a relatively simple method to improve neck line aesthetics. The excess adipose tissue is usually located in the subcutaneous
or supraplatysmal layer, however, it can also accumulate deep to the platysma. Numerous methods for fat removal have been described, for example, open lipectomy, liposuction, or lipo-shaving, with liposuction being the most commonly employed technique.

Preoperatively, it is important to mark the areas of fat removal with the patient sitting upright, as the appearance of submental fat changes in the supine position. After induction of general anesthesia, 0.5% lidocaine and 0.25% bupivacaine with 1:200,000 epinephrine are injected under the neck skin flaps to provide both anesthesia and vasoconstriction. The patient is prepped and draped, and a 15 blade is used to make 1 cm stab incision in the submental crease. A liposuction cannula (2 to 4 mm) is introduced into the subcutaneous layer, and dry tunnels, that is, no suction applied, are made in the fanlike fashion from one inferior mandibular border to the other. We recommend staying below the mandibular border as this minimizes the risk of injury to the marginal mandibular nerve. Great care is also always taken to position the cannula holes facing deep, away from the skin flap as trauma to the overlying dermis can result in scarring and contour irregularities. The nondominant, guide hand is used to tent up the skin as well as help advance to the tissue toward the cannula. The suction (1 atmosphere negative pressure) is then applied, and fat is aspirated until the desired contour is created. Some authors recommend two other stab incisions just posterior to the ear lobules to facilitate submandibular and posterior neck line contouring. In younger patients with good skin tone, the overlying skin flaps typically contract down favorably to the recreated neck line, whereas, in older, inelastic skin often requires some degree of lateral re-draping and excision to prevent contour irregularities. In selected cases, where excessive submental fat deposition obscures the platysmal muscle edges or discrete subplatysmal fat pads remain after liposuction, a conservative open lipectomy with scissors may be performed. When performing submental lipectomy, great care must be taken to avoid uneven cervical contour or worse yet a “cobra” deformity caused by excessive removal of fat. To avoid this complication, conservative removal of fat is stressed, and the anterior platysmal borders are often suture approximated after central lipectomy is conducted.

In general, we perform a relatively aggressive posterior tightening of the platysma and do not routinely perform anterior platysmaplasty unless significant banding is noted during preoperative examination. If correction of platysmal banding is planned, the submental incision is extended to 3 cm. Using a lighted retractor and scissors, subcutaneous dissection under direct vision is performed until the medial borders of the dehiscent platysma muscle are identified. The anterior muscle edges are plicated with several buried 4-0 polydioxanone sutures beginning at the thyroid notch and working superiorly to create a midline corset (Figure 7). If severe platysmal laxity is noted, the redundant edges of muscle are grasped with a clamp and excised prior to placement of sutures. Meticulous hemostasis with bipolar cautery should be exercised, as even small collections of blood under the flaps during the healing phase can lead to irregular scarring and contour irregularities.

Despite the effectiveness of the submentoplasty, patients should be counseled about the rebound relaxation inherent to soft tissue that can lead to the reappearance of submental muscle or skin laxity. Revision submentoplasty rates ranging from 15 to 50% have been reported. To combat this tissue relaxation, as well as improve neck contouring without the need for rhytidectomy, several authors have used suture techniques and expanded polytetrafluoroethylene.
Cervicofacial rhytidectomy, or facelift, is a procedure to rejuvenate the aging lower face and neck. The literature is replete with various facelifting techniques, each with advantages and disadvantages that many surgeons have debated for years and continue to do so. For example, there exists a school of thought that contends that a simple SMAS plication/imbriication yields more than adequate, long lasting results in the neck and jowl region. However, others (we included) believe that a deeper plane of dissection produces better elevation of the ptotic midface. While it is important to be familiar with these points of discussion, it must be stressed that not all patients age the same and that the optimal technique for each individual patient can vary considerably. A surgical strategy that yields the best results, while minimizing unnecessary surgery and risk, should be the ultimate goal for any facelift surgeon.

Chin Augmentation. If surgical augmentation of the deficient chin is planned it should be performed at this time, after submentoplasty and prior to rhytidectomy. As discussed previously, chin augmentation can be performed with an alloplastic implant (mentoplasty) or with a sliding genioplasty (which can correct horizontal and vertical deficiencies). As the focus of this chapter is on rejuvenation of age-related changes, we will concentrate our discussion on alloplastic mentoplasty which constitutes greater than 95% of the chin procedures in our aging face practice.

Decision as to what shape and size of chin implant to use should be made during the preoperative evaluation. Patients with congenital microgenia who require only several millimeters of anterior projection typically have a standard chin implant (thicker in the center) inserted. This type of implant, however, does not possess sufficient lateral bulk to correct the aging chin’s characteristic prejowl sulcus—a vertical groove formed between the chin and jowl as the underlying bone and soft tissue of this region atrophies. The patient with microgenia and significant prejowl sulci will require an implant designed with lateral extensions intended to augment this atrophic area.

Currently there are several commonly used alloplastic materials (silastic, polytetrafluoroethylene, mersilene) used to construct chin implants. The type of implant material chosen is ultimately dependent on the individual surgeon’s experience and preference.

The submental incision utilized for submentoplasty is also used for insertion of the alloplastic implant. The chin is infiltrated with 5 mL of 1% lidocaine and 0.25% bupivacaine with 1:200,000 epinephrine. Timing the injection in this fashion allows for maximal anesthesia and vasoconstriction. Similarly, the left side of the face should be injected prior to completion of the right side.

The previously delineated rhytidectomy incisions are made starting superiorly in the temporal area and continued inferiorly around the ear ending in the postauricular hairline. If a vertical oriented temporal incision is chosen to improve the temporal or lateral brow region, dissection is carried down through the scalp layers to identify the temporalis fascia. Undermining can be performed superficial to the deep temporal fascial layer all the way down to the lateral brow and superior border of the zygomatic arch. Utilization of the sideburn sparing incision requires the dissection to be in a subcutaneous plane, so as to avoid injury to the temporal branch of the facial nerve as it crosses over the zygomatic arch. Vertical retraction with skin hooks and countertraction on the flap allow for sharp facelift scissors easily to elevate the skin flap anteriorly into the cheek. Transillumination of the flap with an overhead light directed through the flap allows for the identification of the proper dissection plane and aids in maintaining the appropriate flap thickness. The cheek skin is typically elevated anteriorly to a line drawn between the malar eminence and the mid mandible (mandibular notch). Minimizing the extent of skin separation from the underlying SMAS creates a more vascular, composite flap that is less likely to be compromised. In the occipital area, care must be taken to avoid the hair follicles to avoid alopecia while staying superficial to the sternocleidomastoid fascia. The cervical skin flap is elevated in the subcutaneous plane to the second major cervical rhytid and extends to the midline. The subcutaneous elevation avoids injury to the marginal mandibular and cervical nerves.

Rhytidectomy

Cervicofacial rhytidectomy, or facelifting, remains the most powerful surgical procedure to rejuvenate the aging lower face and neck. The SMAS can be suspended by several different techniques. SMAS plication is the most direct method and suspends by simply folding redundant SMAS onto itself and securing the fold with permanent sutures. Imbrication of the SMAS layer involves incision and resection of lax SMAS with reapproximation of the cut edges. A variable amount of SMAS flap elevation can be performed prior to suture reapproximation. There are still many surgeons that utilize plication or imbrication as the cornerstone of their facelift operation. As stated before, we prefer a deep plane dissection that is described below.

Once the skin flap has been elevated, the SMAS is incised from the malar eminence to a point 1 cm below the ear lobe. A down Brown forceps are used to grasp the anterior SMAS edge gently and a sub-SMAS dissection is continued over and anterior to the parotid by gentle, vertical spreading with scissors. The zygomatic major muscle is identified and blunt dissection is performed on the surface of this muscle releasing the zygomatico-cutaneous ligaments of McGregor patch to release and mobilize the malar fat pad into a posterior superior position.
superior position. Inferiorly the dissection is then carried deep to the platysmal muscle for approximately 3 or 4 cm. In this region, care is taken to avoid injury to the external jugular vein, greater auricular nerve, and cervical branch of the facial nerve. The SMAS-platysmal flap is then trimmed. Beginning at the superior margin, a strip of SMAS is incised down to a point 2 to 3 cm from the free edge of SMAS anterior to the lobule. This creates an inferiorly based SMAS flap that is rotated posterior to the pinna and suspended to the mastoid periosteum with interrupted 4-0 polydioxanone or 4-0 prolene sutures (Figure 9). The next suspension suture is placed from the postero-superior SMAS margin to the temporalis fascia anterior to the helical root. It is this suture that repositions the malar fat pad. A third fixation suture is placed at the level of the lobule. The last few interrupted suspension sutures are used to fixate the free edge of platysma to the mastoid periosteum. It should be stressed that a superior vector of pull on this tissue is critical to establishing a well-defined cervicomental angle. The preauricular skin flap is redraped with a similar vector of pull, while the postauricular skin flap is draped in a more superior fashion (Figure 10). The skin closure should be tension free, as the underlying SMAS closure should provide all the support necessary for the repositioned tissue.

The hair-bearing skin is reaproximated with staples, and the remaining preauricular and postauricular skin is closed under minimal tension with 4-0 polydioxanone sutures buried in the deep layer and interrupted 5-0 sutures superficially (nylon for preauricular skin and chromic in the postauricular skin). A 5-0 polydioxanone suture placed from the pretragal soft tissue to the overlying dermis recreates the pretragal crease. The skin advanced over the tragus is thinned, and a 6-0 fast absorbing gut suture is used to close the post-tragal incision.

We do not routinely use drains. At the conclusion of the procedure, white petrolatum is applied to the suture lines and petroleum smeared anteriorly to recreate, without notching, the posterior hairline.

**POSTOPERATIVE CARE**

On postoperative day one, the dressing is removed and flap viability is assessed. If any small collections of serosanguinous fluid or clot are palpated these are gently expressed through the postauricular incision. A new lighter dressing is applied and left in place until the third postoperative day. The patient is then instructed to wear a commercial elastic dressing around the clock for the remainder of the first week after the operation. During this period, a regimen of cleaning fl ap ecchymosis, and bleeding from the incisions. In cases where treatment is delayed, pressure under the fl aps can lead to skin necrosis. Treatment should include immediate clot evacuation, irrigation, and identification and cautery of bleeding vessel(s). In our experience, it is often difficult to identify one discrete vessel, rather than a diffuse oozing that requires careful cautery of many suspicious sites in the dissection bed. A compressive dressing is reapplied, and the patient is reevaluated the following morning.

**Hematoma**

The most common complication after rhytidectomy is formation of hematoma, occurring in 2 to 15% of patients.2,3 Risk factors for hematoma formation include hypertension and usage of products that inhibit platelet or clotting function, for example, aspirin, nonsteroidal anti-inflammatory drugs, and vitamin E. Postoperative vomiting and coughing can also predispose to bleeding. Male patients tend to have a higher incidence of hematoma formation, which is thought to be due to an increased blood supply to the hair follicles of the bearded skin.

The majority of reported hematomas are minor, small collections of fluid or clot that are identified in the first week after surgery. Often these can be managed by removing one or two of the postauricular sutures and gently expressing the clot. If the clot has already liquefied then an 18-gauge needle can be used to aspirate the collection. Unrecognized small collections can lead to infection, scarring, and skin discoloration.

Major hematomas requiring exploration and drainage usually occur within the first 12 hours after the operation. Clinical signs and symptoms include increasing unilateral pain, edema, skin flap ecchymosis, and bleeding from the incisions. In the rare case of frank abscess formation, drainage, culture, and broad-spectrum oral or intravenous antibiotics should be implemented as indicated.

**Infection**

The rich facial blood supply and the routine use of prophylactic antibiotics are the principal reasons that postrhytidectomy infection is seldom seen. In the rare case of frank abscess formation, drainage, culture, and broad-spectrum oral or intravenous antibiotics should be implemented as indicated.

**Skin Flap Necrosis**

Rhytidectomy skin flaps receive their blood supply through the subdermal plexus in a random fashion. Compromise of this vascular supply can lead to necrosis and loss of skin, most commonly seen in the distal portion of the flaps, that is, periauricular skin. Risk factors include excessive thinning of the flap, excessive closure tension, hematoma, smoking, and systemic disorders, for example, diabetes mellitus. Techniques such as the deep-plane rhytidectomy theoretically should have less risk of flap complications.
often heal well but certainly carry an increased risk of undesirable scarring.

**Nerve Damage**

The most commonly injured sensory nerve is the great auricular nerve, occurring in up to 7% of cases. The nerve, along with the external jugular vein, crosses the anterior border of the sternocleidomastoid muscle several centimeters below the angle of mandible. Injury to the nerve can occur when attempting to obtain hemostasis from inadvertent injury to the vein. If the nerve is transected, an end-to-end anastomosis with epineural repair should be attempted. Failure to repair such as injury can result in formation of a painful neuroma. Injury to this nerve is often permanent, however, the affected sensory area usually decreases over time.

Injury to motor branches of the facial nerve is far less common, occurring in 0.5 to 2.6%. Injuries of the temporal and marginal mandibular branches are the two most often reported. The
buccal branches are also susceptible to injury when extended dissection techniques, for example, deep-plane lift, are used. The cervical branch can be injured while mobilizing the lateral edge of the platysma muscle resulting in a “pseudomarginal” nerve paresis. Damage to the cervical branch can be distinguished from marginal mandibular nerve injury by the fact that the patient will be able to evert the lower lip due to a functioning mentalis muscle. As mentioned earlier in this chapter, a thorough understanding of the facial nerve anatomy can help avoid these complications.

Fortunately, the majority of nerve injuries are neurapraxic in nature. This temporary paresis often resolves over the first few months after injury. In our experience, the majority of immediate postoperative paralysis or paresis is due to local anesthetic effects, which dissipate in several hours.

**Hypertrophic Scarring**

Excessive skin closure tension is commonly regarded as the primary cause of hypertrophic scars after rhytidectomy. Other predisposing factors include race, skin type, and prior history of abnormal scarring. Most commonly located in the postauricular region, these scars usually develop in the first 3 months after the operation. Initial treatment consists of intralesional corticosteroid injections (triamcinolone 5 to 10 mg/mL) at 3-week intervals. Excision of these scars should be delayed for 6 to 12 months, and potential recurrence of lesions can be lessened with judicious use of deep sutures.

**Alopecia and Ear Lobe Deformity**

Alopecia is usually due to excessive closure line tension causing transient shock of the hair follicles. Patients are reassured that recovery is usually within 3 to 6 months. If follicles do not fully recover, the hairless skin can be excised and closed primarily. The use of hair transplantation techniques can also be employed to fill in bare areas or restore loss of the temporal tuft.

Post-rhytidectomy ear lobe deformity (pixie ear) can be a sequela of poor incision placement, malpositioning of the lobule at closure, and tension on the closure. Correction of this complication can be challenging, often requiring an advancement flap technique with closure tension supported by deeper layers.

**Parotid Injury**

Inadvertent injury to the parotid gland can occur during SMAS flap or platysma elevation. The subsequent formation of a glandular pseudocyst (sialocele) or salivary fistula is seldom seen but is a potential concern. If parotid parenchyma is exposed during the dissection, the overlying fascia should be sewn over the defect. Postoperative seroma formation in the area of the mandibular angle should raise suspicion of sialocele formation. Conservative treatment with oral anticholinergics, serial aspirations, and pressure dressing are recommended. Recurrent collections may require surgical exploration and placement of a suction drain.

**CONCLUSIONS**

Performed alone or in combination, procedures such as submental liposuction, platysmaplasty, chin augmentation, and rhytidectomy can provide a dramatic rejuvenation of the lower face and neck. A thorough understanding of the relevant anatomy coupled with an accurate preoperative analysis of the aging anatomy is essential to determining which procedures are to be recommended as well as achieving the optimal surgical result.

PEDIATRIC OTORHINOLARYNGOLOGY

62

The child born with a malformed ear faces a lifelong hearing and communication impairment along with the social stigma of a facial deformity. Associated disturbances of the vestibular system may add to the developmental hurdle of a motor delay. Frequently, there are additional anomalies, such as mandibular hypoplasia, as well as other facial and skeletal deformities. There may be dysfunction of associated neural pathways, including cranial nerves and intracranial structures. Additionally, there are psychological factors to be considered, including parental guilt, peer ridicule, and the shame of “being different.” Educationally and economically, these hearing-impaired children face the prospect of limited opportunities. The appropriate management involves recognizing the problems and limitations of therapy, which need to be thoroughly understood by the parents and, when appropriate, the patient.

EMBRYOLOGY OF ATRESIA AND MICROTLIA

In the 3 to 4 mm embryo (3 to 4 weeks), the first indications of aural ontogenesis are the first and second branchiomeric structures and the otic placode, an ectodermal thickening on the lateral surface of the head opposite the fourth ventricle. The placode invaginates to first form a pit and then a vesicle detached from its surface origin. This otocyst forms the inner ear membranous structures, with the endolympathic duct developing first at the 6 mm stage, followed by the appearance of the semicircular ducts and the cochlear diverticulum at the 15 mm stage (6 weeks). By the end of the third month, the cochlea is fully coiled.

The cranial nerves entering the otocyst exert an inductive influence to produce neuroepithelium, for which retinoic acid is a potent morphogen. Retinoic acid receptors are uniquely expressed in the developing organ of Corti; medications that affect retinoic acid metabolism, such as isotretinoin (Acutane, Roche, Nutley, New Jersey), can lead to embryopathies, including inner ear malformation.

The cochleovestibular ganglia develop from the otic placode epithelium. The nerve fibers themselves not only influence sensory cell development but are also directed to the developing inner ear by the sensory cells.

As the membranous structures of the inner ear form, they become enveloped in a cartilaginous capsule, which eventually gives rise to the petrous portion of the temporal bone. Concurrently, the structures that originate from the first pharyngeal pouch develop separately but adjacent to the otic capsule derivatives. The pouch begins to form in the 3 to 4 mm embryo and expands into a tubotympanic recess, which will eventually give rise to the eustachian tube, middle ear space, and mastoid air cell system. The third branchial arch migrates superiorly to the level of the recess, and its artery (the internal carotid) comes to lie dorsal to the eustachian tube. Variations in this relationship may result in a lateralized displacement of the internal carotid artery into the middle ear space. In adults, an ectopic carotid artery can be mistaken for a middle ear mass, such as a glomus tumor.

As the pharyngeal pouches form in the 3 to 4 mm embryo, corresponding grooves develop on the external surface of the nascent cervical region. The first of these branchial clefts deepens until it approaches the tubotympanic recess, being separated only by the thin layer of mesoderm destined to become the middle fibrous layer of the tympanic membrane. Subsequently, in the 30 mm embryo (8 weeks), the primordial external canal becomes occluded by an ectodermal plug. By the twenty-first week, this begins to resorb to form the definitive external auditory canal, replete with its hair and glandular appendages.

Aberations in the canalization process can lead to stenosis, canal tortuosity, or fibrous or osseous obliteration. Since middle ear structures develop independently, the tympanic cavity and ossicles may be normal.

Defects in the canalization process may also be associated with faulty formation of the pinna, which arises in the 8 to 11 mm embryo from six mesodermal thickenings. These hillocks surround the entrance of the first branchial cleft. The first branchial arch cartilage (Meckel cartilage) forms the tragus and superior helical crus; the remainder of the pinna derives from the second arch cartilage (Reichert cartilage), although some authorities posit a hyoid arch derivation for all but the tragus. The developing auricular appendage migrates from its initial position in the lower face toward the temporal area. This movement occurs along the fusion plane of the first and second branchial arches. The auricle is initially located anteriorly in a horizontal axis; with development of the branchial structures it migrates from its original position in the lower face laterally, and as its axis rotates, it assumes a more vertical angulation. Branchial cleft dysmorphogenesis can impede this migration and leave the pinna in a low, transverse orientation (Figure 1).

As the middle ear forms, the separation between the first pharyngeal pouch and cleft is filled in by mesenchyme. In the 8 mm embryo (6 weeks), part of the connective tissue condenses to form the malleus handle; the subsequent expansion of the tympanic cavity...
ETIOLOGY OF AURAL ATRESIA

Atrisia and microtia are part of several known syndromes associated with inherited defects or acquired embryopathies owing to intrauterine infection (rubella, syphilis), ischemic injury (hemifacial microsomia), or toxin exposure (thalidomide, isotretinoin).

Although inner ear abnormalities, such as Usher syndrome, Waardenburg syndrome, and the neurofibromatoses, are becoming understood on a molecular biologic basis, the genetic basis of external and middle ear anomalies generally remains poorly characterized. Aural atresia occurs in approximately 1 in 20,000 live births. Although the inner and middle ears develop separately, inner ear abnormalities coexist in 12 to 50% of cases. Atrisia is bilateral in 30% of cases, occurring more commonly in males and in the right ear.

Microtia occurs in 1 in 7,000 live births and can be associated with aural atresia. Microtia represents a failure of normal development of first and second branchial arch fusion. It is more common in males (two-thirds) and in the right ear (60%). Ten percent of cases are bilateral.

Prenatal maternal history is not associated with ear (60%). Ten percent of cases are bilateral. Although inner ear abnormalities, such as high jugular bulb, perichondral emissaries, and fistulae, may be produced by a transverse and low-set orientation. There may be accessory appendages of the pinna (pretragal tags with or without cartilage) and preauricular sinus tracts. The external canal may be stenotic or atretic to varying degrees (Figure 5). In cases of stenosis, entrapped squamous cell epithelium may lead to a retention cholesteatoma with bone destruction.

Schuknecht observed that in 7 ears with congenital meatal stenosis, all had cholesteatomas, whereas 3 of 11 ears with partial atresia and narrowed canals had cholesteatoma. In 50 ears with complete atresia, only 2 had cholesteatomas. Abnormalities of the tympanic cavity alone may occur with a normal tympanic membrane and external ear. In ears with conductive hearing losses and normal otoscopic examinations, isolated ossicular anomalies should be suspected (Table 1). Ossicular fixation can be produced by a variety of abnormalities and may involve the stapes, incus, or malleus. Alternatively, there may be a failure of bone development producing an ossicular discontinuity, which generally involves the incus and/or stapes arch. Ossicular malformations caused by abnormalities related to first or second branchial cartilaginous derivatives can frequently be surgically repaired (see Table 1, groups I and II). However, ossicular fixations owing to cochlear capsule abnormalities, especially when associated with an abranted facial nerve, may not be surgically correctable (see Table 1, group III). Otic capsule abnormalities producing stapedial fixation are frequently associated with abnormal communication between the inner ear and the subarachnoid space. In these instances, manipulation of the stapes results in a persistent gusher of cerebrospinal fluid. Vascular malformations also occur in the middle ear, such as high jugular bulb, persistent stapedial artery, and anomalous course of the carotid artery.
Further delineation of structural abnormalities requires computed tomography (CT). Younger children may require sedation if they are unable to cooperate. The images are processed with a bone algorithm image enhancement using 1.5 mm slices at either 1.5 or 1 mm intervals. Optimally, both axial and coronal scans are obtained, although reformatted coronal or sagittal images may be adequate. Three-dimensional reconstruction may be useful in visualizing the temporal bone topography. Auditory brainstem responses (ABRs) should be performed in all children born with either microtia or atresia as neonates. In cases of microtia with fairly normal canals, an ossicular malformation producing a conductive hearing loss may be present. In patients with unilateral atresia, it is not unusual for the seemingly normal contralateral ear to have a hearing loss. Bilateral involvement may cause masking dilemmas; such is the case when one ear has a conductive loss and the other a sensorineural loss. These dilemmas may be minimized by using multichannel analysis of ipsilateral versus contralateral responses to determine the laterality of wave I. As the infant matures, behavioral audiometric evaluations must be obtained to confirm the neurophysiologic tests of hearing. In children older than 1 year, conditioned free field play audiometry should help to quantify the overall hearing levels. Eventually, pure-tone and speech testing with masking should be obtained in children with fairly normal canals. Impedance and stapedial reflex measures in a seemingly normal ear can provide valuable information as well as more extensive malformations occurring in Treacher Collins syndrome and hemifacial microsomia. CT studies allow determination of the degree of the canal atresia, the thickness of the atresia plate (Figure 6A), the extent of pneumatization of the middle ear and mastoid, the distance between the glenoid fossa and mastoid, the intratemporal course of the facial nerve, the status of the malleus and incus, and, in some instances, the presence or absence of the stapes and oval window (Figure 6B). However, subtleties of oval and round window anatomy are often not revealed. An unsuspected cholesteatoma may also be apparent. The normalcy of the osseous inner ear structures is also revealed by CT.
Figure 6 (A) A coronal computed tomographic (CT) scan showing a bony atresia plate (arrow). The middle ear space is normally pneumatized. (B) Coronal CT scan showing a low-lying tegmen (T), which precludes construction of an external canal. The middle ear cleft has not developed. A rudimentary antrum is un aerated (A). Atresia surgery is contraindicated in this case.

Evaluation of the function of other organ systems should be considered by the otologist. For example, some of the syndromal associations of atresia involve mandibular and laryngeal anomalies that can lead to airway obstruction; cardiac, renal, endocrine, and immune function should be ascertained in selected instances.

MANAGEMENT OF AURAL ATRESIA AND MICROOTIA

Nonsurgical

The prime concern in the young child is the assessment and improvement of hearing. When ear deformities are present, the ABR techniques outlined above are helpful in determining the type and severity of hearing loss and should be performed as early in life as possible. Early amplification, auditory training, and speech therapy can improve speech and language skills. In children with bilateral atresia, amplification with bone-conduction aids should be provided as soon as possible, preferably within the first few months of life. In infants with a unilateral atresia and conductive hearing loss in the seemingly normal ear, an air-conduction aid should be fitted to the ear with a canal.

Surgical

In the unilateral case with normal contralateral hearing, repair of either the microtia or the atresia is considered elective, and there is less urgency to intervene during childhood. When the atresia is bilateral with acceptable-appearing auricles, reconstructive surgery can be performed at a fairly young age. However, in cases of microtia that require reconstruction, atresia repair should be deferred until the initial stages of the auricular repair are completed. Generally, microtia surgery requires a cartilage graft that is obtained from the lower costochondral region. An adequate graft requires sufficient growth and fusion at the donor site, which has usually occurred by 5 to 6 years of age. Additionally, in bilateral cases, many authorities recommend postponing surgery for the restoration of hearing until at least age five so that pneumatization can develop. In children with frequent upper respiratory infections and suspected eustachian tube dysfunction, it may also be necessary to delay hearing reconstructive surgery.

Surgical Treatment of Congenital Conductive Hearing Loss. The success of the surgical correction of congenital conductive hearing losses is related to the abnormality since a wide range of malformations is possible. Surgery in an ear that has an isolated ossicular malformation with an otherwise patent canal, intact tympanic membrane, aerated middle ear cleft, normal facial nerve, and mobile stapes has the potential for excellent hearing (Table 2, class I). Conversely, an ear with canal atresia, a narrowed and poorly aerated middle ear space, and an anomalously positioned facial nerve occluding the oval window is destined to have poor postoperative hearing (see Table 2, class III). Between these two extremes is an array of anomalies with variable surgical outcomes. Even with sophisticated imaging techniques, the preoperative prediction of what awaits the otologist is not always accurate.

Surgeons wishing to correct congenital conductive hearing losses are embarking on a procedure with significant potential complications. Generally, the initial attempt is the procedure most likely to improve the hearing. Unplanned revisions are often more complex and less successful. Additionally, if a significant sensorineural hearing loss occurs after surgery in a patient with bilateral malformations, the opposite ear is effectively excluded from surgical correction since it becomes the better hearing ear. Before assuming this responsibility, especially in children, the otologic surgeon must have sufficient experience to maximize the likelihood of a successful outcome.

The presence of a conductive hearing loss in an ear with a normal canal and mobile drumhead generally indicates that the ossicular chain is not transmitting sound energy to the cochlea. Isolated ossicular malformations involving the stapes arch and long process of the incus may not be appreciated on CT studies. In these cases, the middle ear can be explored by elevating a tympanomeatal flap and assessing the normalcy of the ossicular transduction mechanism. If the canal is small, a postauricular approach will improve operative exposure. Frequently, even the young child’s ear canal has a sufficient diameter to admit an adequately sized ear speculum, even though the length of the canal is shorter.

Once the middle ear is entered, the surgeon needs to decide if the chain is fixed. If so, what is the cause of the fixation (see Table 1). First, the motility of the incus and malleus is ascertained. Is the fixation in the epitympanum and, if not, where (Figure 7)? Drilling away the bone over the malleus head and body of the incus provides the required exposure to explore this area. Is the stapedial tendon ossified? If the stapes is fixed, mobilization may produce a sustained improvement. Alternatively, a stapedectomy using a replacement prosthesis with an oval window tissue graft to
In some cases, the surgeon may elect to defer stapes surgery until the child is grown. A gap interrupting the ossicular chain’s continuity occurs most commonly at the incudostapedial joint, either owing to absence of the lenticular process or long process of the incus or the stapes arch. The presence of a mobile stapes facilitates the surgery and greatly improves the operative result. A variety of techniques have proven useful in the restoration of ossicular chain continuity by means of bridging an existing gap. If there is a small distance between the stapes capitulum and the long process of the incus, a tragal cartilage graft can successfully negotiate the gap. Deficiencies of the long process of the incus can be corrected by either interposing the reshaped incus between the mobile stapes and the malleus handle or using an alloplastic prosthesis designed for this purpose (type III tympanoplasty). When the stapes arch is absent, similar procedures can be performed to bridge the gap from either the malleus handle or the undersurface of the drumhead to the mobile footplate (type IV tympanoplasty). A coexisting fixation of the stapes or obstruction of the oval window by the facial nerve increases the technical difficulty, yields poorer hearing results, and increases the chance of complications, such as sensorineural hearing loss or facial nerve injury.

Surgery for Microtia and Canal Stenosis or Atresia. Congenital malformations of the auricle, external canal, and middle ear may occur as isolated abnormalities or in various combinations. Reconstruction of the external ear is usually performed by a plastic surgeon, whereas external auditory canal and middle ear defects are corrected by the otologist; both work as a team to achieve the optimal result. Microtia surgery is technically difficult, and not infrequently, the results are somewhat disappointing. The surgery should be performed by individuals with special expertise. Auricular reconstruction is an elective procedure. The deformity can usually be masked by a longer hair style. Generally, the slight deformity of a grade I microtia may be cosmetically acceptable. Reconstruction of a moderately deformed grade II microtia must be individualized. Correction of a severe grade III microtia requires several staged procedures.

Treatment of microtia must begin with a frank discussion of the surgical and nonsurgical options with the patient’s parents, as well as surgical timing considerations. Generally, surgery is deferred until the child reaches 5 to 6 years of age. Prior to this, the contralateral ear is undersized and underdeveloped and available costal cartilage is limited; moreover, the child is not sufficiently mature to comply and assist with postoperative care. Significant children younger than 5 years of age generally have not been stigmatized because of their deformity by their peers.

The standard surgical technique for microtia reconstruction has been well-described by Tanzer and subsequently refined by Brent. During the first stage, costal cartilage is harvested from the contralateral sixth to eighth ribs using a curvilinear incision near the medial aspect of the costal margin. A template based on the contralateral ear is made from sterilized, exposed radiographic film and accurately copies the contour and size of the pertinent structures of the normal auricle (Figure 8). Using the template as a guide, the appropriate sections of costal cartilage are harvested. The medial portion of the seventh rib will serve as the posterior rim of the conchal bowl and superior crus, and the synchondrosis between the sixth and seventh ribs is harvested en bloc with the seventh rib and is later sculpted to serve as the inferior crus. A segment of the eighth rib is harvested separately and is used to...
construct the helical rim which generally requires at least an 8 cm long segment. Great care is taken to dissect in a subperichondrial plane on the deep side to avoid puncture of the parietal pleura and a pneumothorax. Once all cartilage is harvested, meticulous hemostasis is ensured. The wound is then filled with warm, sterile saline, and positive pressure ventilation manually applied and held by the anesthesiologist for 10 seconds. If no bubbles indicative of an air leak are observed, the wound is drained and closed in layers; however, if an air leak is identified, the site of pleural injury is identified. If small, a red rubber catheter is placed through the pleural tear, and a purse string suture is placed around the periphery of the tear. The suture is then tied as suction is applied through the catheter as it is withdrawn. Patients are followed by serial chest X-rays to ensure that a pneumothorax does not develop. Larger pleural injuries may require chest tube placement.

The individual pieces of cartilage are then carved using the template as a guide. Finally, the eighth rib is thinned to allow it to be curled around the conchal and antihelical framework, and the two pieces are sutured to each other with clear nylon sutures. It is important when constructing the framework to exaggerate features, as these will be blunted by the thicker temporal skin.

Next, the unusable portion of microtic appendage is removed, generally consisting of the superior “knot” of deformed cartilage; the inferior portion is retained for later reconstruction of the lobule. Using the contralateral ear as a guide, the ideal position of the reconstructed auricle is determined and marked. A 2 cm curvilinear incision is then made approximately 2 cm above the location of the superior part of the helix, and a subcutaneous dissection is performed under the markings for the auricle location and carried approximately 1 cm beyond these markings to allow for appropriate skin draping. The framework is then carefully positioned in the skin pocket, with care taken to ensure proper positioning and orientation. Residual cartilage is banked subcutaneously under hair bearing temporal skin. Two 4 mm drains are then positioned to coapt the skin to the framework and to evacuate any blood or serum and are left on gentle

Figure 12 During the third stage of microtia repair, the framework is elevated from the temple, the posterior scalp is advanced into the postauricular sulcus and the bare areas of the auricle and sulcus covered with a skin graft.

Figure 13 Healed auricle after three stages of repair, prior to atresia repair. Blue dotted line indicates incision that will be made for the atresia repair.

Figure 14 Placement of osseointegrated implants for attachment of a prosthetic pinna. (A) The percutaneous abutments and associated wire framework used to attach the right prosthetic pinna via clips. (B) The normal left pinna can be seen. (C) The right prosthetic pinna in place. It should be noted how similar the prosthesis appears compared to the normal pinna seen in B. (D) Oblique view of the prosthetic pinna. (Published with permission, copyright © 2007 P. A. Wackym, M.D.)
Figure 15 Surgery for canal atresia. A postauricular incision is made. While exposing the mastoid cortex and dysmorphic tympanic bone, the previously implanted cartilaginous auricular scaffold should be protected during retraction.

Two to three months after the first stage, lobule creation can be performed. Essentially, Z-plasty double transposition flaps reorient the vertically positioned skin tag to align with the inferior part of the helical tail while the skin from this area is transposed anteriorly to close the donor site (Figures 10 and 11). In conchal remnant microtias, transposition of the remnant can construct an inferior conchal bowl, lobule and, occasionally, an antitragus.

Two to three months later, the third stage of reconstruction is performed. A split thickness skin graft (0.015 to 0.020 in. thick) is harvested from the posterior aspect of the thigh. An incision is then made approximately 8 to 10 mm peripheral to the buried framework, from the anterior part of the helix down to the repositioned lobule. The framework is then elevated, leaving a generous amount of scar and subcutaneous tissue on the medial aspect of the framework. The banked costal cartilage is retrieved and sutured to the anteromedial aspects of the framework to maintain lateralization. Posteriorly the scalp is undermined widely and advanced into the postauricular sulcus, and the portions of the sulcus and auricle still bare are covered with the skin graft. A bolster dressing is placed into the postauricular sulcus and left for 1 week (Figure 12). A tragus repair can be performed 3 to 4 months later (Figure 13). An additional stage can reconstruct the tragus using a portion of the contralateral conchal bowl as a composite graft several months after atresia repair.

Figure 16 Construction of a canal is begun by drilling between the glenoid fossa anteriorly and the superior temporal line. The latter roughly corresponds to the tegmen (floor of the middle cranial fossa). When possible, entry into the mastoid air cells is avoided. TMJ = temporomandibular joint.

The ossicular chain is reconstructed by interposing the malformed, sculpted ossicle onto the stapes. Silastic sheeting, 0.005 in. thick, is positioned to prevent bony ankylosis.

Figure 17 Drilling is continued until a normal-sized middle ear opening has been created. Great care is taken not to drill on a mobile, deformed, but intact ossicular chain. The anteriorly coursing facial nerve is identified.

Figure 18 The ossicular chain is reconstructed by interposing the malformed, sculpted ossicle onto the stapes. Silastic sheeting, 0.005 in. thick, is positioned to prevent bony ankylosis.

Figure 19 Temporalis fascia is used to construct a tympanic membrane.

The timing of the microtia and atresia repairs requires close communication between the surgeons. Because scarring interferes with the auricular repair, reconstruction of the atresia is deferred until the auricular cartilaginous scaffolding is completed. However, it is important to position the reconstructed auricle correctly so that it aligns with the meatal opening and the middle ear. The meatal, canal, and middle ear reconstruction is frequently performed as part of the second or third stage of the auricular reconstruction.13,26

A postauricular approach is used, with great care being taken to avoid exposing the scaffold (Figure 15). Temporalis fascia is harvested for reconstruction of the tympanic membrane. The peristeum of the lateral surface of the temporal bone is elevated. A bony circular canal is created by drilling between the glenoid fossa anteriorly and the tegmen plate superiorly while trying to avoid entering mastoid air cells posteriorly (Figure 16). Continuous suction irrigation cools the bone and clears away blood and bone dust while the water enhances the translucency of the wet bone. This permits visualization of structures such as dura, facial nerve, and glenoid fossa through the intact thinned bone. The surgeon should anticipate that the facial nerve will be located more anteriorly and more laterally than in the normal temporal bone. The nerve frequently follows a C-shaped path in its course between the geniculate ganglion and its point of emergence from the temporal bone. The purposeful identification of the facial nerve will prevent inadvertent injury. A facial nerve monitor may facilitate identification of the nerve in atretic ears.

Visualization of the facial nerve as a landmark permits the opening of the atresia plate to approximate the size of a normal middle ear opening. While drilling on this plate, it must be remembered that the malleus handle may be fused to it. Precautions must be taken to avoid drilling on the mobilized atresia remnant since this may transmit traumatic vibratory energy through the ossicular chain to the inner ear and result in a permanent sensorineural hearing loss (Figure 17).

The status of the ossicular chain is assessed. If the stapes is mobile, an appropriate ossicular reconstruction is performed (Figure 18). If it is fixed or the oval window is obscured by the facial nerve, the ossicular reconstruction should be deferred. Temporalis fascia is used to fabricate a
new tympanic membrane (Figure 19). A meatal opening is made in the area of the imperforate concha, incising the skin to create a rectangularly shaped, anteriorly based conchal skin flap. The underlying cartilage and soft tissue are removed to debulk the flap and create an opening that communicates with the drilled out external canal (Figure 20). The conchal flap is rotated to resurface the anterior third of the external canal and is stabilized by suturing it to the adjacent soft tissues (Figure 21). A thin split-thickness skin graft is harvested from the lower part of the abdomen and is used to resurface the remaining ear canal. The canal is packed snugly with Gelfoam (Upjohn, Kalamazoo, Michigan) to compress the skin graft against the underlying bone and soft tissue. The postauricular incision is reapproximated using absorbable sutures.

**Risks and Benefits of Atresia Surgery.** Atresia surgery is technically demanding. The results achieved are directly related to the experience and skill of the operating surgeon. Generally, hearing improvement to a serviceable level can be achieved in approximately 65 to 75% of selected patients. Complications of surgery include the small risk of facial paralysis, a severe to profound sensorineural hearing loss, stenosis requiring additional surgery, persistent otitis media, and tympanic membrane graft failure with perforation.

In children with a unilateral atresia and a normal contralateral ear, surgery may not be routinely indicated. The potential benefit of this sophisticated surgery, that is, achieving binaural hearing, may not justify the risk of complications. In binaural cases, the successful creation of an external canal, even when hearing cannot be improved, will allow the use of an ear-level air-conduction hearing aid to restore hearing without using a cumbersome bone-conduction aid. Thus, in unilateral cases in which the facial nerve obstructs the oval window or when a hearing improvement cannot be achieved, providing the patient with a stable, skin-lined canal is a worthy goal in and of itself.

Another hearing restorative technique for external auditory canal atresia is the placement of a bone anchored hearing aid (BAHA). This procedure involves implanting a titanium post which becomes osseointegrated into the calvaria. A special hearing aid is attached to this post via a percutaneous abutment and uses bone conduction to stimulate the cochlea. The titanium post requires a 3-month period for osseointegration in an adult and a 4- to 6-month period for children, before the external appliance can be attached to the abutment. The use of the BAHA requires at least a bone conduction threshold in one ear to be at a minimum of 40 to 45 dB to be effective.

In adults, placement of the BAHA is usually performed in a one-stage procedure to implant the titanium post and abutment. In children, the two-stage procedure can be employed which involves the placement of the post only and allowing it to osseointegrate for 3 to 6 months. A second stage is then carried out which includes the thinning of the skin flap for efficient transcision as well as placement of the percutaneous abutment. The external processor is fitted 3 to 4 weeks after the skin flap heals. Frequently, a second “sleeper” fixture is placed at the same time, which allows its immediate use in the future should the first fixture ever extrude or fail to osseointegrate.

The BAHA system has some distinct advantages which make this procedure a viable option for atresia patients. The hearing result with the BAHA is superior to an atresia repair which usually results in a mild conductive hearing loss in the best circumstances. Furthermore, this procedure poses no risk to the facial nerve and is not dependent on a patent external auditory canal. Successful atresia surgery involves a split-thickness skin graft to resurface the bony canal. This may require that the child take water precautions to keep the ear dry. This is not a problem with the BAHA. Drawbacks include failure to osseointegrate, loss of post fixation over time, and periodic infections around the abutment if daily cleaning is not performed. In addition, there are the cosmetic issues of a permanent percutaneous abutment and the depilated skin around the fixture. The cosmetic issue is usually more of a concern for boys or for girls with short hair as the abutment is more apparent in these situations.

Anatomy and Physiology of the Oral Cavity

Margaret A. Kenna, MD, MPH
Manali Amin, MD

The oral cavity is important for many vital bodily functions including speech and swallowing. It is a complex space, bounded anteriorly by the lips and posteriorly by the oropharynx. Its two compartments are the vestibule, or external compartment, and the internal compartment. The vestibule is the space lateral to the alveolar ridges and medial to the lips and buccal mucosa. The oral cavity proper is bounded by the alveolar ridges laterally, the hard and soft palates superiority and posteriorly, and the floor of mouth caudally. Its primary contents are the teeth, the anterior two-thirds of the tongue, minor salivary glands, and the parotid and submandibular salivary ducts. The palatoglossus muscles form the anterior tonsillar pillars. All structures anterior to the anterior tonsillar pillars are contained within the oral cavity. All structures posterior to the pillars are part of the oropharynx. The oropharynx contains the posterior one-third of the tongue, the lingual and palatine tonsils, and the paired tonsillar pillars formed by the palatoglossus and palatopharyngeus muscles. It extends from the soft palate superiority to the base of tongue inferiorly.

TONGUE

The tongue is a large muscular organ in the oral cavity. The anterior two-thirds of the tongue is mobile and has four surfaces: the dorsum, the ventral surface, and the lateral borders. The dorsal surface opposes the hard palate and has an irregular mucosal surface covered with multiple epithelial appendages known as papillae. The ventral surface faces the floor of mouth and is covered by a thin mucosal layer that meets in the midline to form a band of tissue known as the frenulum. The mucosa is continuous with the mucosa of the floor of mouth.

All tongue movements are accomplished by the anterior two-thirds of the tongue, also known as the mobile tongue. Tongue movement is accomplished through use of both intrinsic and extrinsic muscles. The tongue is divided into two halves by a median fibrous septum that is fixed to the body of the hyoid bone. Each half of the tongue contains two sets of muscles, extrinsic and intrinsic. The extrinsic muscles are the genioglossus, hyoglossus, and styloglossus. The palatoglossus is sometimes considered an extrinsic muscle of the tongue and sometimes a muscle of the soft palate. The extrinsic muscles allow for tongue movement anteriorly, backward, upward, and downward. The genioglossus functions to protrude and retract the tongue as well as depress its tip. The styloglossus and hyoglossus aid in retracting the tongue and in raising and depressing its margins respectively. The intrinsic muscles are the superior and inferior longitudinal, transverse, and vertical. The intrinsic muscles function to change the shape of the tongue during speech and swallowing. The palatoglossus muscle within the anterior tonsillar pillar also elevates the tongue. Although it helps with tongue movement, the primary function is in the downward movement of the soft palate, and it may be an important regulator in the transition from the oral phase to the pharyngeal phase of swallowing.

Motor innervation of the tongue is almost exclusively through the hypoglossal nerve, that is, CN XII. It innervates all of the extrinsic and intrinsic muscles except for the palatoglossus. The hypoglossal nerve enters the tongue on the lateral surface of the genioglossus muscle, anastomosing with fibers from the lingual nerve. The paired motion of the genioglossus allows for straight protrusion of the tongue. When one of the hypoglossal nerves is paralyzed, the tongue will deviate to the side of the paralysis upon protrusion. The palatoglossus is innervated by branches from the pharyngeal plexus which is derived from the vagus nerve, that is, CN X.

Sensory innervation of the tongue is somewhat more complex (Table 1) (Figure 2). General sensation (touch, pain, and temperature) of the anterior two-thirds of the tongue is carried by afferent fibers from the third or mandibular division of the trigeminal nerve (CN V 3) in the form of the lingual nerve. Taste in the anterior two-thirds of the tongue is carried by afferent fibers of the seventh cranial nerve in the form of the chorda tympani nerve. By contrast, both general sensation and taste to the posterior one-third of the tongue are carried by afferent fibers of the glossopharyngeal nerve.

Taste Receptors

Taste is mediated through specialized receptors known as taste buds. Taste buds are located within epithelial appendages on the dorsal surface of the tongue known as papillae (Figure 3). In addition, taste buds are found in the epithelium of the soft palate, pharynx, larynx, epiglottis, and esophagus. Their distribution varies widely both within an individual and among individuals. In general, newborns and children have a higher number of extralingual taste buds than adults.

Taste buds are oval sensory end organs composed of 50 to 150 spindle-shaped, epithelial cells with receptor properties. They are involved in the perception of chemical stimuli and in taste transduction. A single taste bud is an almost ovoid structure, 70 μm in height with a diameter of approximately 40 μm and a central opening on its epithelial surface, known as the taste pore. The taste pore, approximately 2 to 10 μm in size, exposes the apical surface of receptor cells to molecular food particles dissolved in saliva.

Ultrastructurally, the taste bud is composed of three types of cells: basal cells, edge cells, and taste receptor cells. Basal cells are undifferentiated cells from which the other taste receptor cells are derived. Edge cells, as their name suggests, define the lateral aspect of the taste bud. Three different types of taste receptor cells have been identified: dark cells (type I cells), light cells (type II cells), and intermediate...
cells (type III cells). Type I cells are known as dark cells because they contain dense granules near their apex. Type II cells are known as light cells because they lack these dense granules. Intermediate cells are felt to be intermediate between the other two types of cells. The function of these cells and how they differ from one another or whether they represent a progression, is not well understood. All three of the receptor cell types contain microvilli at their apical end and synapse with afferent nerve endings at their basal end. The microvilli project into the taste pore and expose the taste receptors to gustatory stimuli. The two primary classes of receptors are the seven-transmembrane G-protein coupled receptors (GPCRs) and ion channels. The GPCR proteins consist of a second messenger transduction, irrespective of the receptor type. The fungiform, circumvallate, and foliate papillae, collectively referred to as the gustatory papillae, contain approximately 1,000 taste buds on the human tongue. The foliate papillae are found on the posterolateral surface of the tongue. There are 200 to 300 fungiform papillae containing a total of nearly 1,600 taste buds on the tongue surface. There are 200 to 300 fungiform papillae containing a total of nearly 1,600 taste buds on the human tongue. The foliate papillae are found on the posterolateral surface of the tongue. There are a total of 8 to 12 circumvallate papillae, containing approximately 250 taste buds each. The circumvallate papillae are associated with deep lingual salivary glands also known as von Ebner glands. The fungiform papillae, as their name suggests, are mushroom-shaped, raised structures found on the anterior two-thirds of the tongue surface. There are 200 to 300 fungiform papillae containing a total of nearly 1,600 taste buds on the human tongue. The foliate papillae are found on the posterolateral surface of the tongue and contain approximately 1,000 taste buds. Finally, the circumvallate papillae are found in an inverted V-shape along the anterior margin of the sulcus terminalis. Similar to the sulcus, it marks the division between anterior and posterior parts of the tongue. There are a total of 8 to 12 circumvallate papillae, containing approximately 250 taste buds each. The circumvallate papillae are associated with deep lingual salivary glands also known as von Ebner glands. The fungiform papillae, as their name suggests, are mushroom-shaped, raised structures found on the anterior two-thirds of the tongue surface. **FLOOR OF THE MOUTH**

The floor of the mouth is a muscular sling formed primarily by the paired mylohyoid muscles. The muscles arise from the medial surface of the mandible and extend toward the midline where they insert with muscle fibers from the opposite side, forming a midline raphe. The posterior most aspect of the mylohyoid musculature inserts into the body of the hyoid bone. The anterior belly of the paired digastric muscles bound the sling inferiorly. A majority of the submandibular gland also lies beneath the mylohyoid muscles. A smaller portion of the gland curves around the posterior border of the muscle and lies above it, along with the sublingual gland, the lingual and hypoglossal nerves and the tongue vasculature. Medial to the nerves and vessels lie the paired geniohyoid muscles. The geniohyoid muscles arise from the mental spine and internal surface of the mandible and insert onto the hyoid bone, lateral to the midline. Covering the structures superior to the mylohyoid is a layer of superficial cervical fascia. There is a potential space between the fascia and the mylohyoid muscle. An abscess in this potential space is known as Ludwig angina and is considered a potentially life threatening airway emergency.

All of the muscles that combine to form the floor of the mouth, including the digastric muscles, mylohyoid muscles, stylohyoid muscles, and the geniohyoid muscles elevate the hyoid bone and assist in swallowing.
The hard palate is covered by a layer of mucosa that is firmly adherent to the underlying periosteum. The mucosa contains numerous minor salivary glands. As is evident from patients with cleft palates, the palate is vital in the process of swallowing and in speech articulation. As with the palate, the other skeletal component of the oral cavity, the mandible, is crucial to oral cavity function. The mandible is the most prominent bone surrounding the oral cavity and forms the inferior part of the face. It is the strongest and largest of the facial bones. The different parts of the mandible are the body (horizontal part), the angle, and the ramus (vertical part). The two sides are fused embryologically at the midline, an area known as the symphysis. At the anterior most aspect of the symphysis is the mental protuberance, a triangular bony prominence. The ramus ends in two bony projections. The condylar process is on the posterior aspect of the ramus. The coronoid process is anterior to the condylar process and separated by the mandibular notch. The lateral pterygoid muscle inserts on the pterygoid fovea on the neck of the condylar process. A portion of the temporalis inserts on the coronoid process. Other muscles that attach to the mandible include the masseter, medial pterygoid, genioglossus, geniohyoid, the mylohyoid, and the anterior bellies of the digastric muscles. The masseter attaches to the lateral aspect of the mandibular angle and ramus whereas the medial pterygoid inserts on the mandibular angle. Together they form a muscular sling around the mandible. The bone of the mandibular angle may be slightly raised on either or both the lateral and medial aspect, known as the masseteric tuberosity and pterygoid tuberosity, respectively. The genioglossus and geniohyoid insert on the mental spine (genial tubercle). The mylohyoid attaches to the mylohyoid line, a line that runs up and back from the sublingual fossa. The anterior belly of the digastric attaches at the digastric fossa.

The mandible has multiple other bony grooves, markings, and foramina. On the medial surface of the mandible, in addition to the mental spine, digastric fossa and mylohyoid line are found. The sublingual and submandibular fossae, the mylohyoid groove and the mandibular foramen. The mylohyoid groove carries the mylohyoid nerve and vessels anteriorly and inferiorly after they exit from the mandibular foramen. The sublingual and submandibular fossae shield the respective salivary glands. externally on the body of the mandible is the oblique line, the mental foramen, and the mental protuberance. The mental foramen is the terminal aspect of the mandibular canal, a bony canal that starts at the mandibular
The blood supply of the tonsils is derived from multiple vessels: the ascending pharyngeal artery, tonsillar branches of the external maxillary artery, the tonsillar branch of the dorsal lingual artery, and the descending palatine artery from the IMAX (Figure 5). The tonsillar branch of the dorsal lingual artery, the ascending palatine branch of the external maxillary, and the tonsillar branch of the external maxillary are typically found at the inferior pole. The superior pole is supplied by the ascending pharyngeal artery and the descending palatine artery.

The venous drainage of the oral cavity, pharynx, and Waldeyer ring is through multiple smaller veins to the internal and anterior jugular veins.

**Waldeyer Ring**

Waldeyer ring is a ring of lymphoid tissue found in the pharynx. It is composed of the adenoid superiorly in the nasopharynx, both palatine tonsils laterally in the oropharynx and the lingual tonsil inferiorly in the hypopharynx and posterior one-third of the tongue. In addition, it includes the lateral pharyngeal bands and scattered lymphoid follicles throughout the pharynx, particularly adjacent to the eustachian tubes. Lymphoid tissue in this ring provides the body’s first line of defense against inhaled or ingested pathogens. Waldeyer ring is involved in the production of immunoglobulins and the development of both B and T cell lymphocytes.

**Adenoid**

The adenoid, also known as the pharyngeal tonsil, is on the posterior wall of the nasopharynx extending toward the eustachian tubes. Unlike palate and lingual tonsils, the pharyngeal tonsils does not contain crypts. It is formed by vertical folds of respiratory epithelium from which extend the Arey glands. There is no distinct capsule which surrounds the adenoid. Enlargement of the tissue can interfere with eustachian tube function and result in nasal obstruction with difficulty breathing. The adenoid is discussed in Chapter 64, “Diseases of the Oral Cavity, Oropharynx, and Nasopharynx,” and Chapter 66, “Sleep Ape in Children.”

At the posterior midline of the pharynx just above the superior constrictor muscles lies a small sac-like depression known as the pharyngeal bursa. It is occasionally the site of a cystic formation known as Tornwaldt cyst.

**Palatine Tonsils**

The palatine tonsils are dense, compact bodies of lymphoid tissue. They are located within a fossa created by the palatoglossus muscle anteriorly and the palatopharyngeus muscle and superior constrictor muscles posteriorly and laterally. The tonsil has a thin but distinct capsule on its lateral surface which is formed from condensation of the pharyngobasilar fascia. The fascia extends into the tonsil itself forming septa which allow for passage of nerves and vessels. Whereas the capsule is densely adherent to the tonsillar tissue, it is readily separated from the underlying pharyngeal musculature. Continuous with the palatoglossal arch and the tonsillar capsule is a layer of mucosa and connective tissue known as the triangular fold. In rare instances a similar fold may be seen posteriorly. In approximately 40% of people, a fold of tissue known as a semilunar fold is found at the superior pole.9

The medial or free surface of the tonsil is covered by a thin layer of stratified squamous cell epithelium (mucosa). Epithelial tubules extend from the surface deep into the tonsil, forming tonsillar crypts. There is some evidence to suggest that the epithelium lining the crypts is semipermeable, allowing sampling of ingested material. Although they extend from the surface, the deepest parts of the crypts remain stable. The growing end is closest to the surface and is often narrower, preventing material from escaping once it has entered a crypt. There are a total of 8 to 10 crypts per tonsil.9

Tonsillectomy is one of the most common surgical procedures performed in children. They are generally removed for obstructive sleep apnea or chronic tonsillitis. In children, large palatine tonsils may occupy a significant portion of the oropharynx resulting in obstructed breathing and dysphagia. Some individuals have chronic colonization of the tonsillar crypts with streptococcus and other bacteria. These individuals may have frequent infections and halitosis. Others may have infections which result in the accumulation of pus between the tonsillar capsule and the pharyngeal musculature, referred to as a peritonsillar abscess or quinsy. This can lead to fibrosis of the capsule to the underlying pharyngeal musculature.
A surgeon removing a tonsil must be cognizant of the fact that the pharyngeal musculature is fairly thin and that there are numerous structures lateral to the fossa. For instance, the glossopharyngeal nerve lies on the lateral surface of the musculature. If it is injured, it can lead to a taste disturbance affecting the posterior one-third of the tongue. Indeed, it is not uncommon to see a transitory taste disturbance resulting from edema of CN IX following a tonsillectomy. Other structures that may be in close proximity include the stylopharyngeus and styloglossus muscles, the stylohyoid ligament, the ascending pharyngeal artery, the ascending palatine branch of the facial artery and in rare instances, an aberrant vertebral or tortuous internal carotid artery.

**Lingual Tonsil**

The lingual tonsil is lymphoid tissue found in the base of the tongue. It extends from the foramen cecum to the epiglottis. Irregular folds of lymphoid tissue are covered by a thin layer of stratified squamous cell epithelium which invaginates to form small crypts. The lymphoid tissue lacks a distinct capsule or separation from the tongue musculature, preventing complete removal.

**LYMPHATICS OF THE ORAL CAVITY**

The oral cavity is drained by a dense network of lymphatic vessels. The most peripheral part of the lymphatic collecting system is a collection of a valvular capillaries with wide lumina, up to 100 µm in diameter. These capillaries are surrounded by an elastic fiber network which helps to regulate fluid and cell transport into and out of the lymphatic channels. There are both superficial and deep networks which help to drain the tissues of the head and neck. The superficial network is composed of a valvular capillaries and drains into precollecting vessels found at the mucosa-submucosa junction. Multiple precollecting vessels join to drain into a lymph node. Another set of vessels, known as postcollecting vessels, carry the lymph from the nodes to the right and left. Lymphatic ducts into the jugular veins. The lymphatic ducts drain into the jugular vein at its junction with the subclavian vein.

The highest concentration of lymph vessels in the oral cavity are found in the floor of the mouth (FOM). Lymphatic vessels in the FOM drain lymph from the tongue, FOM, and mandibular gingival (Figure 6). Although several smaller collecting vessels in the anterior part of the FOM drain directly into submental lymph nodes, drainage in the FOM primarily occurs through collecting vessels in a direction along the mandibular axis and into both ipsilateral and contralateral submandibular lymph nodes. A portion of the ventral surface of the tongue also drains into the submandibular lymph nodes, similar to FOM drainage pathways. The remainder of the ventral surface of the tongue drains into the upper jugular nodes.

**MINOR SALIVARY GLANDS**

Between 600 and 1,000 minor salivary glands are found throughout the upper aerodigestive tract including the palate, buccal areas, and lips. These glands have excretory ducts. The highest concentration of minor salivary glands is found on the palate, with approximately 250 on the hard palate and 150 on the soft palate. The glands on the palate receive parasympathetic innervation from the sphenopalatine ganglion while those in the remainder of the oral cavity and oropharynx are innervated by parasympathetic fibers from the lingual and glossopharyngeal nerves. These glands contribute to the overall production of saliva.
PHYSIOLOGY

The oral cavity is involved in two main functions: speech and swallowing. A third function, production and excretion of saliva, also occurs in the mouth and upper aerodigestive tract.

Salivary Production and Regulation

Saliva is produced by the paired parotid, submandibular and sublingual glands as well as the numerous minor salivary glands. The average person produces 1.5 L of saliva daily. Unstimulated whole saliva flow is estimated to be 0.33 to 0.65 mL/min. This can increase to 1.7 mL/min in the stimulated state. The major contributor to unstimulated salivary flow is the submandibular gland (69%). A lesser degree, the parotid glands (26%) and sublingual glands (5%) also contribute to total unstimulated salivary flow. It is interesting to note that subjective sensation of dry mouth in patients on anticholinergic medications is not reported until resting salivary flow decreases by 40 to 50% of initial values. Unstimulated and stimulated salivary flow may be altered by many factors including age, hormones, systemic disease states, circadian rhythms, diet, mastication, hydration, and drugs. The largest volumes of saliva are secreted in response to cholinergic stimulation. Drugs, especially anticholinergic drugs, may therefore result in a decrease in salivary flow. Similarly, age has been shown to produce a decrease in salivary flow. Disease states such as diabetes are associated with decreased salivary flow. However, it is unclear as to whether this is the result of the disease itself or of the medications used as treatment. By contrast, mastication has been associated with an increase in salivary flow. In fact, one study demonstrated that chewing four pieces of sugar-free gum daily for a total of 8 weeks resulted in an increase in basal flow of whole saliva. Furthermore, chewing sugar-free gum has been shown to stimulate saliva and, thereby, enhance remineralization of teeth.

The composition of the saliva secreted by the three major salivary glands varies somewhat in that the parotid glands produce a more serous saliva while the submandibular glands produce a higher mucin containing saliva. Hence, high mucin containing submandibular saliva makes up a greater proportion of resting saliva, whereas parotid saliva composes a greater percentage of stimulated saliva. The more serous, highly buffered saliva produced by the parotid protects the oral cavity from the detrimental effects of acid and is secreted principally upon stimulation by eating. Similarly, the unstimulated secretion of submandibular saliva has a higher mucin content to provide continual oral comfort through lubrication. The chemical composition of saliva is complex and contains a myriad of proteins and minerals including amylase, statherin, histatins, mucins, lysozyme, lactoferrin, peroxidases, secretory IgA, proline-rich proteins, thiocyanate, salts, gases, and other organic substances. It initially begins as an isotonic plasma-like fluid secreted by acinar cells within the salivary gland that undergoes active reabsorption of Na\(^+\) and Cl\(^-\) as it progresses through the duct resulting in a final product that is hypotonic.

Saliva has many important functions in the oral cavity. The hypotonic nature of saliva facilitates taste. The inorganic constituents of saliva such as bicarbonate and phosphate allow buffering while phosphate and calcium function to maintain the mineral integrity of teeth. Each of the salivary proteins contributes to overall oral and systemic health in different manners. Amylase aids in digestion while histatins have antifungal effects. Lactoferrin, lysozyme, peroxidases, and IgA all have antibacterial effects. Mucins provide lubrication and help to protect the esophagus in gastroesophageal reflux disease. Statherins aid in the maintenance of dentition, and proline-rich proteins protect the teeth from the detrimental substances in the human diet. Indeed, saliva has been credited with numerous functions including lubrication of the oral cavity, taste, digestion, and protection against infection. A thorough consideration of saliva’s effect on caries have been inconsiderable. Saliva has, however, been shown to regulate the pH of plaque.

Speech

Speech is the production of meaningful sounds for the purpose of communication. It is the result of coordinated activity of the respiratory tract including the larynx as well as the pharynx and palate and related structures. Specifically, the soft palate frequently apposes the nasopharynx during speech allowing the passage of air through the oral cavity. While the production of the voice is unilaterial, the modification of the voice and articulation of speech occurs throughout the upper aerodigestive tract and is mediated by many structures including the pharynx, palate, mandible, tongue, teeth, and lips. Alterations in any of these structures may be associated with alterations in speech, as is often seen in children with velopharyngeal insufficiency and in patients who have undergone surgical resection of any part of the upper aerodigestive tract for treatment of a malignancy or other lesion. Speech production is discussed in Chapter 73, “Assessment of Vocal Function,” and Chapter 74, “Disorders of Speech and Language.”

Swallowing

Swallowing is generally divided into three phases: the oral phase, the pharyngeal phase, and the esophageal phase. The oral phase is further subdivided into the oral preparatory phase and the oral transit phase. During the oral preparatory phase, ingested food is mixed with saliva and formed into a bolus by mastication. The food bolus is contained within the oral cavity anteriorly by sealing the lips and holding the cheek musculature close to the teeth. Posteriorly, the soft palate contacts the tongue preventing the bolus from entering the pharynx too soon. As a person chews, the food bolus is constantly repositioned within the oral cavity and held anterolaterally along the hard palate by the tongue. The food bolus must be the right size, consistency and temperature before initiating the oral transit phase. Once the bolus is ready to be swallowed, the tongue propels the entire bolus posteriorly into the oropharynx with sequential supero-posterior movements. The sequential tongue movements initiate the pharyngeal reflex and pharyngeal phase of swallowing.

The pharyngeal phase is characterized by multiple, simultaneous actions including velopharyngeal closure, laryngeal elevation, contraction of the pharyngeal constrictor muscles, and cricopharyngeal relaxation. These actions are reflexive and associated with a temporary apnea, which in adults may last anywhere from 0.5 to 10.0 seconds. This is followed in rapid succession by superior and anterior movement of the hyoid bone and laryngeal elevation and closure. The arytenoids cartilages closely approximate the epiglottis. Once the bolus has passed, the arytenoids separate from the epiglottis and the hyoid returns to its resting position. Breathing is once again initiated. The bolus is propelled through the pharynx and into the esophagus by contraction of the three pharyngeal constrictor muscles and relaxation of the cricopharyngeal muscle. Relaxation of the cricopharyngeus allows for passage of the bolus into the esophagus and the start of the final stage of swallowing. The esophageal phase is also an involuntary phase. The bolus is transmitted to the stomach by peristalsis of the esophageal musculature. Additional information on swallowing is contained in Chapter 82, “Imaging of the Larynx, Trachea, and Esophagus,” and Chapter 85, “Esophagology.”

REFERENCES

Diseases of the oral cavity, oropharynx, and nasopharynx are among the most commonly seen disorders in pediatric otolaryngology. Although each subunit is anatomically distinct, the entire area may be conceptualized as a single functional unit (Figures 1, 2, and 3). These areas have contiguous anatomy and are subjected to the same causative factors of disease. The oral cavity is defined anteriorly by the vermilion border and posteriorly by the circumvallate papillae and junction of the hard and soft palate. The oral cavity includes the lips, oral tongue, floor of mouth, maxillary and mandibular alveoli, hard palate, gingiva, and buccal mucosa. The oropharynx extends posteriorly from the oral cavity to the valleculae. Structures of the oropharynx include the tongue base, palatine and lingual tonsils, soft palate, and uvula. The nasopharynx is the space bounded by the posterior part of the nasal cavity and skull base to the level of the posterior surface of the soft palate. This includes the adenoid, eustachian tubes, and fossae of Rosenmüller. Functionally, these portions of the pharynx contribute to speech, swallowing, and respiration. This chapter will address common pediatric diseases of the oral cavity, oropharynx, and nasopharynx.

**DISEASES OF THE TONSILS AND ADENOID**

Lymphatic tissue of Waldeyer ring in the nasopharynx and oropharynx comprises the pharyngeal tonsil (adenoid), palatine tonsils, and lingual tonsil. There has been much historic debate regarding indications for and cost-effectiveness of adenotonsillectomy. Currently, much of the controversy exists in the field of pediatric obstructive sleep apnea (OSA) and sleep disordered breathing. Chapter 66, “Sleep Anea in Children,” contains a discussion of pediatric OSA. Indications for tonsillectomy with or without adenoidectomy are listed in Table 1.

**Adenotonsillar Hypertrophy**

Acute and chronic upper airway obstruction due to adenotonsillar hypertrophy is a common chief complaint faced by pediatricians and otolaryngologists. The relative overgrowth of lymphoid tissue to skeletal growth during ages 3 to 8 years may initiate symptoms such as snoring, mouth breathing, apnea, and dysphagia. These symptoms may be chronic or may be acutely exacerbated by viral or bacterial pharyngitis. Further history may reveal snoring, gasping, hyponasal speech, restless sleep, enuresis, growth disturbance, and even failure to thrive. Physical examination may reveal tonsillar hypertrophy, and endoscopy or lateral soft tissue radiographs may confirm adenoid hypertrophy. Lymphoid hypertrophy and relaxation of the pharyngeal musculature during sleep increases the obstruction. Children with craniofacial anomalies or neuromuscular disorders are more susceptible to this process. To confirm sleep apnea, polysomnography (PSG) must be performed. During PSG, the frequency of apneas, hypopneas, and arousals...
are measured. The number and degree of oxygen desaturations are also recorded. Other factors are monitored to determine the obstructive or central component of the respiratory disturbance and to document associated hypercapnia or cardiac arrhythmia. Most studies use a respiratory disturbance index (RDI) greater than one event per hour to diagnose pediatric OSA, although this remains a subject of controversy. However, clinical history and physical examination are often sufficient to infer sleep disordered breathing without the need of a PSG. Adenotonsillar hypertrophy and sleep disordered breathing have become one of the primary indications for adenotonsillectomy in children. Obstructive breathing in children may have detrimental long-term neuropsychologic and cardiovascular effects which can be reversed with surgery when appropriate. In cases of isolated adenoid hypertrophy, a trial of nasal corticosteroids is indicated prior to surgical intervention.

A denotonsillar Infection

A acute tonsillitis is an infectious process causing fever, sore throat, odynophagia, and malaise. Oropharyngeal erythema, edema, and exudates may be present. A associated rash or lymphadenopathy may be present. Group A beta-hemolytic streptococcal pharyngitis is discussed in further detail later in this chapter. Children who experience recurrent episodes of acute tonsillitis may be considered for surgical treatment. In 70% of patients, the core adenoid and tonsil tissue harbor the same pathogens, which are eradicated with adenotonsillectomy. Patients with three or more episodes of acute pharyngitis with significant associated symptoms per year may be candidates for tonsillectomy. Chronic tonsillitis, or persistent tonsillar infection, occurs in older children and young adults. Presenting complaints are constant throat pain, fatigue, halitosis, and expulsion of tonsillar debris. On examination, enlarged tonsillar crypts filled with debris are often visualized.

Tonsillectomy is indicated in chronic tonsillitis when symptoms are severe or quality of life is affected. The adenoid tissue may chronically harbor infection or become acutely infected during respiratory tract infections or sinusitis. Nasal obstruction, purulent secretions, hyponasal speech, postnasal drip, throat pain, or ear pain may be present. Indirect or direct examination may reveal inflamed, exudative adenoid tissue. A acute adenoiditis is treated similarly to acute tonsillitis. Clinically, adenoiditis may be difficult to distinguish from sinusitis. Chronic adenoiditis may be a causative factor in cases of recurrent sinusitis. It has been recommended that adenoidectomy be performed in the child with chronic sinusitis prior to pediatric endoscopic sinus surgery, but its efficacy is unknown. Regardless of size, adenoid tissue may cause extrinsic eustachian tube dysfunction in patients with chronic or recurrent otitis media with effusion. Bacterial colonization of the adenoid may also contribute to recurrent otitis media. A denoidectomy is recommended for children undergoing repeat tympanostomy tube placement over the age of 3 years or those undergoing primary tube placement who have complaints of nasal obstruction due to adenoid hypertrophy.

Peritonsillar infection may occur in any age group but is most common in adolescents and young adults. It is the most common complication of acute tonsillitis. Infection is thought to spread through the tonsillar crypts and capsule into the peritonsillar space. The infection begins as a cellulitis and progresses to an abscess, most commonly near the superior pole of the tonsil. Patients will complain of fever, odynophagia, unilateral sore throat, and otalgia. Classic signs include a muffled voice, trismus, uvular deviation away from the affected side, and soft palate fullness or edema. The oral airway may be compromised, and the patient may have some difficulty with secretions. Diagnosis is usually

Figure 3: Anatomical spaces of the neck.

Figure 4: Postcontrast axial computed tomography (CT) scan, peritonsillar abscess.
made clinically, although it may be difficult to distinguish cellulitis from an abscess, as seen in Figure 4. Hydration, analgesics, and antibiotics are required. If abscess formation is suspected, needle aspiration or incision and drainage is indicated. Both have success rates greater than 90%. Tonsillectomy in the acute setting can be risky due to an increased chance for hemorrhage. Those patients who experience recurrent infections or abscesses are recommended to undergo tonsillectomy when not acutely infected.

**Tonsilloliths**

Tonsilloliths are collections of epithelial debris buried in the tonsillar crypts. Malodorous, granular, white or yellow calculus may be removed with irrigation or instrumentation. They generally tend to recur and can reach sizes up to 1 cm.

**Unilateral Tonsillar Enlargement**

In the routine examination, it is not uncommon for an asymptomatic patient to have the appearance of unilateral tonsillar hypertrophy. In most cases, the tonsil is situated medially in the tonsillar fossa, giving the illusion of a larger tonsil. In other cases, unilateral infection may cause an enlarged tonsil. Rarely is there in underlying malignancy causing unilateral tonsillar enlargement in the pediatric population. Most studies recommend watchful waiting unless there is heightened suspicion for malignancy in the history or physical examination, particularly in the presence of constitutional symptoms.

**Neoplasm**

Nasopharyngeal carcinoma and non-Hodgkin lymphoma may present in the nasopharynx as a painless mass that causes nasal obstruction, rhinorrhea, epistaxis, or serous otitis media. Proper diagnosis and staging requires biopsy and complete radiographic evaluation. Hodgkin lymphoma rarely presents in Waldeyer ring but rather as cervical or supraclavicular adenopathy. Transplant-associated lymphoproliferative disorder is characterized by a spectrum of clinical and histologic entities including lymphomas. Head and neck manifestations include a mononucleosis-like syndrome characterized by constitutional symptoms, cervical lymphadenopathy, pharyngitis, and tonsillar enlargement with or without obstructive symptoms.

Rhabdomyosarcoma is the most common soft tissue malignancy of childhood. It is a highly aggressive, primitive mesenchymal tumor which presents with local symptoms. The head and neck is the most frequent site of origin, where it often presents in parameningeal regions. Although outcome is most closely tied with clinical staging, multimodality treatment using surgery, chemotherapy, and radiotherapy offers the best chance for survival in patients with rhabdomyosarcoma when the tumor presents in an operable location.

The oral cavity and oropharynx contain up to 1,000 minor salivary glands. Salivary gland neoplasms in children are rare. Most salivary gland neoplasms in children are hemangiomas or lymphangiomas. Benign tumors such as mixed tumors, Warthin tumor, oncocytoma, adenomatous tumors, and lymphoepithelial tumors are rare in children. Malignant salivary gland tumors include mucoepidermoid carcinoma, adenocarcinoma, adenoid cystic carcinoma, malignant mixed tumor, and acinic cell carcinoma. These are more likely to occur in the major salivary glands, that is, parotid and submandibular glands.

Juvenile nasopharyngeal angiofibroma (JNA) is a highly vascular, locally aggressive tumor of the nasopharynx. It accounts for only 0.05% of all tumors of the head and neck, and typically affects adolescent males. The tumor originates in the sphenopalatine foramen and expands locally, causing symptoms of nasal obstruction. Preoperative embolization and surgical excision are the appropriate treatment. Endoscopic approaches have proved equally effective to conventional open approaches in the majority of cases. Figure 5 shows an axial view of an extensive, locally destructive JNA. JNAs are discussed in greater detail in Chapter 96, “Neoplasms of the Nasopharynx.”

**Surgical Technique: Adenotonsillectomy**

Many techniques have been used over the years for removal of the tonsils and adenoids. The generally accepted technique for tonsillectomy consists of dissection in the subcapsular plane with a knife or electrocautery under general anesthesia. This dissection may also be achieved with a harmonic scalpel or laser. Hemostasis is achieved with electrocautery, suture ligation, and topical thrombin. The adenoid is most frequently removed with an adenoid curette or may be vaporized with electrocautery.

The patient is intubated and placed in the supine position with a roll under the shoulders. Perioperative corticosteroids are administered for antiemetic effect if not contraindicated. A mouth gag is inserted for proper exposure of the oropharynx. The palate is palpated to ensure an intact palate is present. A denoidectomy is generally performed first unless tonsilar hypertrophy prevents easy access to the nasopharynx. A denoidectomy is contraindicated in the presence of a cleft palate or a submucous cleft. If obstructive sleep apnea occurs in a child with a submucous cleft, only the superior adenoid tissue should be removed accurately and the electrocautery method is preferred to assure velopharyngeal closure. One or two urinary catheters are used to retract the soft palate and the adenoid is visualized with a mirror. A denoidectomy can be performed with an adenoid curette, suction electrocautery, or powered instrumentation. Care should be taken to stay away from the eustachian tube orifice and tonsillar tubarius to prevent scarring and iatrogenic eustachian tube dysfunction.

Tonsillectomy is performed in the following fashion. The superior pole of the tonsil is grasped and retracted medially with an Allis clamp. The mucosa of the anterior tonsillar pillar is incised and the plane of the tonsillar capsule is identified. Dissection continues in this plane with electrocautery or using the cold technique, as the tonsil is retracted medially. The inferior attachment to the lingual tonsil is then divided with electrocautery. Care is taken to preserve normal mucosa of the anterior and posterior tonsillar pillars. A Hurd retractor may be used to aid in visualization of the tonsillar fossa. Hemostasis is achieved using electrocautery or suture ligature. The oropharynx and nasopharynx are irrigated and observed for hemostasis. An orogastric tube is passed and gastric contents are suctioned to limit postoperative nausea and emesis.

Recent trends in the surgical techniques for tonsillectomy include both new instrumentation and subtotal tonsillectomy. New instruments have undergone rigorous clinical trials that utilize the radiofrequency and microdebrider methods. The revival of subtotal tonsillectomy is partly driven by the improved postoperative pain profile of children who have undergone this procedure and is also driven by the easy adaptation of the new surgical instruments. The radiofrequency instrumentation is utilized for both total and subtotal tonsillectomy. Although the pain profile is improved significantly using these instruments and the subtotal technique, continued studies are needed to monitor the cost benefit of such techniques and the long-term sequelae of performing subtotal tonsillectomy in terms of tissue regrowth and eradication of streptococcal disease.

Dehydration, odynophagia, and otalgia are common in the postoperative period. Occasionally, children will need intravenous hydration until adequate oral intake can be maintained. Antibiotics in the postoperative period may aid marginally in return to normal activity, but recent metaanalyses show that their use does not appear to decrease postoperative pain. Post-tonsillectomy hemorrhage is the most common complication, occurring in approximately 2 to 5%, and should be taken seriously. Some can be treated with observation; some may need to be controlled in the operating room. Risk of hemorhage is higher in patients on aspirin therapy or those with bleeding disorders. Hypernasal speech
is common in the postoperative period, but lasting velopharyngeal insufficiency following adenoidectomy is uncommon and estimated to occur in 1:2,000 cases. Treatment for this complication includes speech therapy, or surgical creation of a pharyngeal flap. Nasopharyngeal stenosis can occur with the use of extensive cautery with the KTP laser or with extensive resection of the posterior tonsillar pillars. Obstructing scar tissue forms from the soft palate to the posterior tonsillar pillars or posterior pharyngeal wall at times causing obstructive sleep apnea. Treatment consists of corticosteroid injection, lysis of scar bands, stent placement, and rotation or advancement flaps.

**Infectious Diseases of the Oral Cavity and Oropharynx**

Infections of the oral cavity and oropharynx are common. These infections may be isolated to the head and neck or may represent a part of a systemic disease process. Recognition of the clinical pattern of infections and distinction of these from other patterns of disease, are important clinical skills leading to proper treatment.

Viral infections of the oral cavity and oropharynx are among the most common reasons patients seek medical care. Viral pharyngitis is a syndrome of sore throat with a variety of other symptoms including fever, cough, and congestion. Many viruses can cause pharyngitis, for example, coxsackie virus, rhinovirus, adenovirus, influenza, parainfluenza, coronavirus, enterovirus, and respiratory syncitial virus. Viral studies are usually not necessary, and treatment is symptomatic. Mononucleosis caused by the Epstein-Barr virus is discussed in Chapter 42, "Etiology of Infectious Diseases of the Upper Respiratory Tract."

Herpangina is a common viral infection of young children that resembles bacterial pharyngitis. The etiologic agent is usually coxsackie A or B virus, but other enteric viruses may cause a similar clinical presentation. The peak incidence is during the summer and fall seasons. Symptoms usually consist of sore throat, fever, and malaise. Severe erythema, vesicles, and superficial ulcerations may be present in the posterior aspect of the oropharynx. The disease is usually self-limited, and treatment is aimed at symptomatic relief. Coxsackie A virus is also the pathogen in hand-foot-and-mouth disease. This syndrome is similar to herpangina, except that the oral cavity is more frequently involved than the oropharynx, and vesiculopapular lesions erupt on the palms and soles. Herpes simplex infections may present in one of two ways. Primary herpetic gingivostomatitis is common in the young child; it begins with a prodrome of fever and malaise, with subsequent onset of painful, erythematous oral vesicles. The vesicles rupture within 24 hours, leaving coalescent ulcerations that may form a gray pseudomembrane over the oral cavity. Diffuse lymphadenopathy is almost always present. Diagnosis may be made by viral studies or biopsy. The virus may remain dormant in the patient's neuronal ganglia for life and may be activated to cause a secondary herpetic infection consisting of burning sensation and vesicular eruption in the oral cavity. It is termed herpes labialis when the lips are involved. Precipitating factors include stress, systemic illness, fever, sunlight, bacterial infection, and immunodeficiency. Treatment is symptomatic with spontaneous resolution occurring within 2 weeks. Some studies demonstrate a benefit from antiviral therapy.

Herpes zoster infection presents as a painful, vesicular eruption over the distribution of a branch of the trigeminal nerve. It usually occurs in older patients as a reactivation of dormant varicella virus in the sensory ganglia. Treatment consists of antiviral therapy.

The German measles (rubella) virus infection is uncommon in the immunized population but is a potentially serious systemic infection characterized by cough, coryza, conjunctivitis, and maculopapular rash. The measles (rubella) virus produces a similar though more severe clinical course distinguished by the initial appearance before the rash of red spots with central bluish white specks on the buccal mucosa known as Koplik spots. Infectious complications such as otitis media or pneumonia can occur due to temporary immunosuppression following the disease. Treatment of measles involves vitamin A supplementation and human immunoglobulin in addition to supportive measures. Cytomegalovirus, also a member of the herpes family of viruses, infects immunocompromised patients. Infections are characterized by large mucosal ulcers, exudative pharyngitis, and cervical lymphadenopathy. The disease presents similarly to mononucleosis, and treatment is symptomatic. Recurrent respiratory papillomatosis is a disorder caused by the human papilloma virus and is characterized by the formation of exophytic, cauliflower-like masses. Papillomas may form in the airway or the oral cavity, specifically on the soft palate or tongue. Surgical excision by cold knife, electrocautery, powered instrumentation, or laser is the standard of care. Recurrences in the oral cavity and oropharynx are uncommon after excision, but the recurrence rate is substantially higher in the airway. Recent studies demonstrate an improvement in disease severity and regrowth with repeated intralesional injection of mitomycin or cidofovir in selected patients, although clear evidence from randomized, controlled, prospective studies is lacking.

Bacterial pharyngitis is similar to viral pharyngitis in its presentation but more commonly is associated with malaise, headache, chills, nausea, vomiting, and abdominal pain. Group A streptococcus (GAS) is the most common cause of bacterial pharyngitis.

Other causes of bacterial pharyngitis are addressed in Chapter 42, "Etiology of Infectious Diseases of the Upper Respiratory Tract." Physical findings consistent with, but not diagnostic for, GAS include pharyngeal erythema and exudates, palatal petechiae, and tender cervical lymphadenopathy. Throat culture is considered the gold standard for detection of GAS, but there is a 5 to 10% false negative rate and there are many GAS carriers who will be falsely positive. The majority of rapid detection kits available have a high specificity (95%) and a sensitivity of between 70 and 90% compared with conventional culture on sheep blood agar. White blood cell count, erythrocyte sedimentation rate, and C-reactive protein have low positive predictive values and are not diagnostic of bacterial pharyngitis. Antibody titers do not have a role in acute streptococcal infection. Treatment consists of antibiotics and supportive care. Scarlet fever or scarlatina is an acute exanthematous disease caused by streptococcal pharyngeal infection and production of an erythrogenic toxin. The complications of streptococcal tonsillitis/pharyngitis may be classified as suppurrative and nonsuppurative. The nonsuppurative complications include acute rheumatic fever and poststreptococcal glomerulonephritis. Suppurative complications include peritonsillar, parapharyngeal, and retropharyngeal cellulitis or abscess formation. Periodic fever, adenitis, pharyngitis, and aphthous ulcer (PFAPA) syndrome is in the differential diagnosis for recurrent pharyngitis. These children are frequently seen in the pediatrician's office or the emergency room for high fever. Although cimetidine and corticosteroids purportedly are effective medical treatment, tonsillectomy is an alternative.

Fungal infection of the oral cavity is almost always the result of Candida albicans, an opportunistic microorganism that is part of the normal oral flora. Decrease in host immunity or alteration in the oral flora allows Candida overgrowth and infection. Predisposing conditions include long-term antibiotic use, diabetes, corticosteroid therapy, immunosuppression, and radiation to the oral cavity. Thrush, or pseudomembranous candidiasis, is most common type of oral candidiasis. It occurs most commonly in infants but may affect any age group. It is characterized by dry, painful, white plaques covering the tongue, hard palate, and buccal mucosa. These lesions may be scraped off of the raw underlying mucosa. Invasive oropharyngeal or esophageal candidiasis is known to occur in children with diabetes or immunosuppression. Fungal smears may demonstrate hyphae, but fungal culture is needed for a definitive diagnosis. A cutaneous candidiasis is less common and manifests as sore throat, burning of the mouth, and foul taste. Erythematous, ulcerated mucosa is the characteristic appearance. Angular chelitis, painful fissures at the oral commissure, may also be due to candida overgrowth. In children, a search for an underlying condition must be undertaken along with treatment of the acute fungal infection. Most can be treated with a topical antifungal agent, although recurrent infections may require intravenous antifungal therapy. Other fungal agents that can involve the oral cavity include histoplasmosis and mucormycosis, which typically affect the hard palate.
Odontogenic infections are common in children and may lead to abscess formation or Ludwig's angina, a potentially life-threatening floor of mouth cellulitis. This process is more commonly seen in adults with poor dentition than in children who have shorter deciduous dental roots. Anaerobic bacteria must be considered present in the odontogenic infection, and these often have B-lactamase resistance. Recent studies demonstrate that high doses of amoxicillin-clavulanate may overcome this resistance if penicillins are to be used. A recent study showed that greater than 50% of deep neck infections in adults were found to have an odontogenic source, with Streptococcus viridans and Klebsiella pneumoniae as the two most common pathogens. In children, the odontogenic source of deep neck infection is second in likelihood to an oropharyngeal source. Antibiotic therapy, absence drainage when present, and definitive treatment of the source of infection are crucial to patient care. In cases of Ludwig's angina, airway stability is the initial concern, and tracheostomy may be required. Deep neck infections are discussed in Chapter 65, "Deep Head and Neck Space Infections."

Oral manifestations of human immunodeficiency virus (HIV) infection occur in 30 to 80% of the infected population. The most common sites of involvement are the palate, tongue, lips, buccal mucosa, and gingiva. In children, the most common signs of HIV infection are oral candidiasis, diffuse parotitis, and oral ulcers. Other oral pathology that may suggest underlying HIV infection includes xerostomia, recurrent herpetic or aphthous ulcers, angular chelitis, hairy leukoplakia, gingivitis and periodontitis, and papillomas. Oral hairy leukoplakia presents as an asymptomatic, corrugated lesion along the lateral margin of the tongue, caused by the Epstein-Barr virus. Kaposi sarcoma presents in the oral cavity as a pigmented macule, nodule, or hemorrhagic lesion. It may darken with age, ulcerate, necrose, or become lobulated.

**INFLAMMATORY AND SYSTEMIC DISEASES**

Lesions of the oral cavity and oropharynx are often presenting signs of an underlying systemic disorder. These lesions are easily accessible, and many times are diagnostic. Systemic inflammatory diseases most commonly affect adults but may occur in children and adolescents; lasting sequelae may result from a delay in diagnosis.

Kawasaki disease, or mucocutaneous lymph node syndrome, is an acute onset, idiopathic, multisystem vasculitis. It occurs in children under 5 years of age, with a peak incidence in 1- to 2-year-olds. It is characterized by several days of high fever, conjunctivitis, rash, erythema and edema of the extremities, cervical lymphadenopathy, and multiple oropharyngeal signs. These include strawberry tongue, fissured lips, mucosal erythema, and necrotic pharyngitis. Up to 20% of untreated children will develop cardiac complications, with coronary artery aneurysm being the most dangerous. Kawasaki disease is the most common cause of acquired cardiac disease in children under 5 years of age. Treatment consists of intravenous gammaglobulin and aspirin.

Wegener granulomatosis commonly affects the oral cavity although it is more commonly seen in the nasal cavity and subglottic sites in teenagers. Gingival hyperplasia is common, but painful mucosal ulcerations surrounded by an erythematous margin may also be present. Behçet syndrome is a systemic inflammatory disorder characterized by recurrent oral and genital ulcers which resemble aphthous ulcers. Ocular inflammation, such as uveitis or iridocyclitis, aids in diagnosis. Corticosteroids, chlorambucil and acyclovir have been used for treatment. Reiter syndrome classically presents as urethritis, uveitis, conjunctivitis, and arthritis in young men. Superficial, erythematous oral ulcers with a white rim are associated with this syndrome. Sjogren syndrome is a collagen vascular disease that causes xerostomia, keratoconjunctivitis, and arthritis. Lateral biopsy confirms the diagnosis by demonstrating a lymphocytic infiltrate in the minor salivary glands. Approximately 25% of patients with systemic lupus erythematosus will have oral cavity manifestations including xerostomia, petechiae, hemorrhagic bullae, and white mucosal keratoses.

Primary macroglossia may occur in hypothyroidism, acromegaly, and Beckwith-Wiedemann syndrome. Secondary macroglossia may occur in angioneurotic edema, amylloïdosis, glycerogen storage diseases, neurofibromatosis, actinomycosis, syphilis, tuberculosis, and in neoplastic processes. Macroglossia occurs in 15 to 20% of patients with amylloïdosis and can grow to massive proportions. Amyloidosis may also occur as nodules or polyoid lesions and can be located anywhere in the larynx or trachea. Burning mouth syndrome is a local neuropathy of the tip and lateral aspects of a normal appearing tongue. This disorder of peri- and postmenopausal women is treated with amitryptiline and clonazepam. Geographic tongue is an idiopathic benign migratory glossitis resulting from a loss of filiform papillae. In this process, there are central, red, atrophic lesions on the dorsum of the tongue with a margin of desquamating epithelium. Lesions may occur on the buccal mucosa, as well. This chronic condition may persist for years and does not require treatment. Fissured tongue is similar in that multiple lesions occur on the dorsum of the tongue and treatment is not necessary. However, these fissures may become irritated with food particles, bacteria, or fungi. Fissured tongue has been associated with Down syndrome and Melherson-Rosenthal syndrome, a recurrent process of facial nerve palsy and facial edema. Hairy tongue is a benign disorder characterized by hyperplasty of the filiform papillae, which may then become colonized with pigmented bacteria. Poor hygiene, tobacco use, oral antibiotics, and radiation therapy are predisposing factors.

Aphthous stomatitis and recurrent aphthous ulcers are the most common condition affecting the oral cavity. Recent studies have demonstrated an alteration in cellular immune response as a predisposing factor. In the pediatric population, this disease occurs in older children and adolescents, with a gender predilection for females. There is a 48-hour prodrome of dysesthesia and erythema of the oral mucosa prior to appearance of an ulcer. There are three categories of aphthous ulcers. Minor aphthous ulcers account for approximately 80%; these are shallow, painful ulcers of the oral mucosa covered by a gray membrane and surrounded by an erythematous rim. These ulcers typically affect the buccal mucosa, lips, and tongue. They resolve spontaneously in approximately 2 weeks and may recur regularly in intervals. Major aphthous ulcers are characterized by painful ulcerations greater than 0.6 cm in size. These may occur on the soft palate, floor of mouth, and peritonsillar mucosa. Major ulcers may persist for up to 6 weeks and may also recur in regular intervals. Less common are herpetiform ulcers, crops of multiple painful, pinpoint lesions. These may coalesce into large, irregular ulcerations anywhere in the oral cavity. Treatment for all forms is symptomatic, with topical anesthetics or corticosteroids providing some degree of pain relief. In severe cases, intraleisional or systemic corticosteroids and acyclovir may be of some benefit.

Lichen planus is a common immune-mediated, inflammatory disorder of the epithelial surface of the skin and mucous membrane. It may occur in children and adolescents, although it is considered a disease of adulthood. The disease process is a cell-mediated immune response that may be a part of a systemic disease. Lichen planus of the oral cavity is found on the tongue, buccal mucosa, and gingival margin. The reticular type is more common and appears as isolated or coalescent white papules or lines known as Wickham striae. This can be symmetric and is usually asymptomatic. An erosive type contains an ulcerative center with lines or papules at the periphery and may undergo malignant transformation. Biopsy of the periphery of a lesion provides a diagnosis. Symptomatic lesions may be treated with topical, injectable, or systemic corticosteroids.

The autoimmune disorders pemphigus vulgaris, pemphigoid, and cicatricial pemphigoid similarly affect adults more than children. These conditions may be distinguished by their clinical, histologic, and immune characteristics. All demonstrate a loss of cohesion among epidermal cells that results in accumulation of intradermal fluid and blisters. In pemphigus vulgaris, this loss of cohesion occurs in the epidermal layer, and in pemphigoid occurs at the basement membrane. Nikolsky sign, a loss of epidermis by rubbing skin or mucous membrane, occurs in pemphigus vulgaris. Most cases of pemphigus vulgaris in children begin in the oral cavity. Vesicles and bullae form and rupture, leaving painful ulcerations similar to erythema multiforme. Oral lesions in pemphigoid occur in approximately 40% of patients.

Erythema multiforme is an acute inflammatory disorder of the skin and mucous membranes.
that is associated with infections, autoimmune disease, stress, and certain antibiotics. It affects males more than females and occurs mostly in the second and third decades of life. Two forms exist. Erythema multiforme minor is a self-limited disease of minimal skin and mucosal injury, lasting 2 to 3 weeks. Erythema multiforme major, known as Stevens-Johnson syndrome, consists of hemorrhagic skin and mucosal lesions. Target lesions consisting of a central bulla and surrounding erythema usually begin on the palms and soles. They typically merge and spread symmetrically. Oral lesions involve the lips, tongue, and floor of mouth but are absent in 25%. Erythema multiforme major is also associated with systemic symptoms and purulent conjunctivitis. It is more commonly associated etiologically with drug ingestion and can lead to death from pulmonary involvement. Diagnosis is made clinically, and treatment involves discontinuation of the causative agent, systemic corticosteroids, antihistamines, and supportive and local care.

**THE NECK MASS**

Pediatric patients commonly present with a chief complaint of a new neck mass. Although malignancy is a concern in the pediatric population, infectious and inflammatory causes are much more likely. To date, there is not an established guideline for the diagnosis of a new pediatric neck mass. The differential diagnosis is quite different than that of the adult population, in which the rate of malignancy may be as high as 50%.

A differential diagnosis may be generated based upon the age of the patient, the history, and the location and physical features of the neck mass. Table 2 illustrates the most common causes based upon age of the patient. In children, the most common cause of neck masses is inflammatory lymph nodes from viral or bacterial infections. Congenital neck masses are also common. Primary malignancy, such as lymphoma and leukemia, may occur but are less common. In older children and young adults, congenital or developmental lesions and salivary gland lesions are more common. For adults over 40, primary or metastatic malignancy must be the first consideration, with inflammatory and systemic disease being of second importance.

Workup consists of a thorough history and physical examination. A rapidly enlarging mass suggests an inflammatory or malignant cause. Temporal association with head and neck infection indicates an infectious or inflammatory origin. Constitutional symptoms of fever, sweats, weight loss, and fatigue are indicative of a systemic process such as lymphoma or mycobacterial infection. Neck masses should be assessed for size, multiplicity, character, surrounding tissue changes, and the presence of bruits or thrills. Lymph nodes greater than 2 cm in a child are considered abnormal, especially if enlarging, and warrant further investigation. There is no standard guideline for diagnosis or workup of the neck mass. Imaging is often undertaken even when a diagnosis is suggested by history and physical examination to establish the anatomy of the lesion and assist in surgical planning. Ultrasound is frequently used initially to determine if the lesion is cystic and unilocular or multilocular. CT and MR imaging provides essential information on the location that allows optimal preoperative planning. If a malignancy is suspected, chest radiography is indicated. When a diagnosis cannot be established, excisional biopsy is preferred over needle aspiration to provide adequate tissue for thorough pathologic analysis.

Midline neck masses include reactive lymphadenopathy, ranulas, thyroglossal duct cysts, and epidermoid, dermoid, teratoid, and thymic cysts. The thyroglossal duct cyst is the most common congenital neck mass, accounting for 70% of congenital neck anomalies. Approximately 50% of patients present before 20 years of age, with a second group of patients presenting in young adulthood. Treatment is surgical. Lateral neck masses are most commonly reactive lymphadenopathy, branchial arch anomalies, lymphatic malformations, major salivary gland tumors, and rarely, external laryngoceles. Lymphoma may present as a lateral, firm, fixed, neck mass. Branchial cleft anomalies may manifest as any combination of sinuses tracts, fistulas, or cystic masses. Depending on the embryologic origin, these anomalies may present in the external auditory canal, the tonsillar fossa, periparotid area, or the anterior or posterior cervical triangles. Lymphatic malformations include lymphangiommas and cystic hygromas and may be either uni- or multilocular. Approximately, 75 to 80% of all cystic hygromas involve the neck and the lower portion of the face. Treatment historically has been surgical, but recent studies have demonstrated benefit with intralesional sclerotherapy in selected cases. A laryngoele or dilated laryngeal saccule may present as an external neck mass in approximately 25% of cases. Congenital anomalies are discussed further in Chapter 70, “Congenital Anomalies of the Head and Neck.” Discussion of diseases of the salivary glands is found in Chapter 100, “Salivary Glands.”

Ranulas may occur in all age groups and present as one of two distinct types. The simple ranula is a cystic lesion of the floor of mouth representing either mucocele formation from obstruction or a mucus extravasation pseudocyst of the sublingual gland. It appears as a clear blue, superficial, fluctuant, nontender cystic mass in the lateral part of the floor of the mouth. A small simple ranula may be asymptomatic, whereas larger ones can cause dysphagia or impairment of speech. Simple ranulas may be treated with marsupialization or excision of the sublingual gland. Recurrence rates are markedly improved when excision of the sublingual gland is performed. The plunging ranula is the less common of the two types, extending through the floor of the mouth into the submandibular space. It presents as a soft, painless, ballotable, submandibular mass which may or may not have an intraoral component. Surgical treatment of the plunging ranula includes sublingual gland excision and evacuation of the ranula. Intralesional sclerotherapy with a streptococcal preparation, OK-432, has shown promising short-term results although long-term outcomes are yet to be established.

**BENIGN LESIONS OF THE GINGIVA, MAXILLA, AND MANDIBLE**

Several benign lesions are found in the newborn. The congenital epulis presents as a pink, lobulated, pedunculated mass of the anterior aspect of the maxillary gingiva. Treatment is local excision. The melanotic ectodermal tumor of infancy is a firm, well-circumscribed, often pigmented, mass arising at the junction of the globular and maxillary processes in the first 6 months of life. It may be associated with nasal obstruction and facial swelling, and the patient is treated with complete excision. Epstein pearls are small keratinous cysts found on the palate or alveolus. These cysts are transient and exfoliate within a few weeks.

The torus palatinus and torus mandibularis are not congenital lesions but arise after puberty.
and cementoblastoma. There are a number of other rare odontogenic tumors, some of which are treated with wide excision of the lesion. There is a precancerous lesion; malignant transformation occurs in 2 to 6%, with an annual high incidence of less than 1%. Histologic examination should be completed, including a complete neural and vascular examination. Hematoma, Horner syndrome, and transient ischemic attacks are heralds of blunt ICA injury. One must remember that lucid intervals of up to 72 hours are common with blunt ICA injury, and delayed onset of progressive focal neurologic signs may arise after an initial normal examination. Soft tissue plain radiography is indicated in oropharyngeal injury.

Suspicion for carotid injury is raised with lateral oropharyngeal injury that penetrates muscle or a mechanism that provides sufficient compressive force without mucosal penetration. In children with a high suspicion of injury or non-compliant families, imaging is recommended. The gold standard has been angiography, but recent evidence shows that contrast-enhanced computed tomography may be sufficient. Computed tomography (CT) angiogram has been studied in the adult population and appears to provide a high sensitivity but mediocre specificity for carotid injury. Thus, it may be a viable option as an initial radiographic study, with angiography reserved for abnormal findings on CT. Magnetic resonance angiogram (MRA) has also been shown to provide excellent detection of carotid injury. A patient treatment protocol consisting of serial examination has been recommended in cases of an asymptomatic child greater than 1 year of age with reliable parents who live in close proximity to medical care. Treatment for traumatic oropharyngeal lacerations is summarized in Table 3. Interventional or conventional neurosurgical techniques have had mixed outcomes. Anticoagulation with aspirin, tissue-plasminogen activator, or heparin is controversial.

MISCELLANEOUS DISEASE OF THE ORAL CAVITY AND OROPHARYNX

Lukoplakia

The World Health Organization (WHO) defines oral leukoplakia as a predominantly white lesion of the oral mucosa that cannot be characterized as any other definable lesion. Leukoplakia may be idiopathic or associated with tobacco smoking. It is primarily a disease of the adult population, with a prevalence of 0.1 to 5%. It is less common in children but is often found in those with candidiasis or viral infections. Leukoplakia is considered a precancerous lesion; malignant transformation occurs in 2 to 6%, with an annual transformation rate of less than 1%. Histologic
features of keratosis, inflammation, and dysplasia are highly variable. Risk of malignancy increases in extremely adherent lesions with abundant keratosis. Small studies have shown that vitamin A, retinoids, and beta-carotene may completely resolve the oral lesions and that retinoic acid may prevent histological worsening. Routine follow-up and excision of the lesion in high-risk populations is recommended.17

Vitamin Deficiency
Iron deficiency is common in children, with oral manifestations consisting of burning tongue, mucosal pallor and atrophy, angular chelitis, and hyperkeratotic mucosal lesions. In adults, iron deficiency may be associated with esophageal ulcers and webs in Plummer-Vinson syndrome. Vitamin C deficiency, or scurvy, presents as swollen red gingiva which progresses to hemorrhagic ulcerative gingivitis. Other findings include oral petechiae, stomatitis, and hemorrhagic mucosal lesions. Riboflavin deficiency manifests as glossitis, gingivalabial pallor, angular cheilosis, and a burning sensation of the oral cavity. Folate and B12 deficiency both cause recurrent oral ulcers and painful atrophy of the tongue and oral mucosa. Niacin deficiency, or pellagra, causes painful erythema and edema of the oral mucosa and tongue, as well as angular chelitis and necrotizing ulcerative gingivitis. Examination findings may be mixed, as multiple deficiencies may occur simultaneously.

Elemental Heavy Metal Toxicity
It is quite common to have oral signs and symptoms of heavy metal toxicity, as many of these are often metabolized and secreted in saliva. Lead poisoning is considered the most important chronic environmental illness affecting children today. In the pediatric population, nearly every organ system is subject to lead toxicity. In children, lead sulfide precipitates or “lead lines” at the gingival margin are fairly specific for lead poisoning. Environmental mercury toxicity has become a major concern because of its industrial uses in fossil fuels and agriculture. It has been used historically in dental amalgams and many medical therapies. Recent widespread exposures have occurred in fish, grain, and beauty creams. Otolaryngic manifestations of toxicity include metallic taste, sialorrhea, and ashen-gray mucous membranes. Other elements known to cause similar discoloration of the tongue and oral mucosa include arsenic and bismuth.

Drooling
Sialorrhea is the inability to control oral secretions, usually due to dysfunction of the swallowing mechanism. Although most commonly due to chronic nervous system impairment, many chronic disease processes may lead to this entity. Drooling can lead to further medical ailments, such as impaired masticatory function, risk of aspiration, perioral infections, and loss of fluid, electrolytes, and proteins. Nonsurgical methods of treatment include oral motor therapy, behavioral modification, and oral appliances. When not contraindicated, medications including cholinergic muscarinic receptor antagonists, for example, atropine, scopolamine, or glycopyrronium bromide, appear to be effective in many cases. Radiotherapy is not recommended for children because of the risk of inducing malignancy, growth retardation, xerostomia, mucositis, radionecrosis; however, this may be a reasonable treatment modality in the elderly population. Surgical treatment includes parotid or submandibular duct relocation or ligation, sublingual duct ligation, submandibular or sublingual gland excision. Duct relocation may be effective in the initiation of the swallowing mechanism. Although most commonly due to dysfunction of the swallowing mechanism and has a role for certain patients. Bilateral sublingual and submandibular duct ligation has been effective in approximately 80% of cases. This may be done surgically or with a Nd:YAG laser. When injected in the salivary gland, botulinum toxin inhibits acetylcholine release in the cholinergic nerve endings at neurosecretory junctions. Percutaneous injection under ultrasound guidance into the parotid and submandibular glands provides a safe, minimally invasive alternative that provides effect for 6 weeks to 6 months.

REFERENCES
Deep head and neck space infections continue to occur and may involve resistant microorganisms despite the use of broad-spectrum antimicrobial agents. Easy access to imaging studies such as computed tomography (CT) scans has improved our diagnostic abilities in differentiation of cellulitis versus abscesses of the fascial spaces of the head and neck in children. In general, patients with cellulitis and small early, uncomplicated abscesses may be treated with intravenous antimicrobials whereas larger abscesses will require incision and drainage or in selected patients needle aspiration.

ETIOLOGY OF DEEP HEAD AND NECK SPACE INFECTIONS

Deep head and neck space infections generally follow the lymphatic drainage pathways. Paranasal and nasopharyngeal infections generally precede retropharyngeal space infection. Tonsillar infections precede peritonsillar and parapharyngeal space infections. Dental and gingival infections may be the source of mandibular, submandibular, masticator, parotid, parapharyngeal, and buccal space infections. A abscess of the root of the canine teeth may lead to canine space infection. Trauma to the pharynx may provide a portal of entry for infection of the retropharyngeal, parapharyngeal, or visceral spaces. Sialoadenitis may lead to infection in the parotid or submandibular spaces. Congenital anomalies such as branchial cleft remnants, lymphangiomas, or dermoid cysts may become infected and cause infection of adjacent spaces. Hematogenous Haemophilus influenzae infection in the past often led to buccal space infection, but this is now rare in the H influenzae type b immunization era.

It is of critical importance to determine the original site of infection that led to the development of a deep head and neck space infection and to treat the patient adequately for both processes. This may include procedures such as mastoidectomy, sinus surgery, removal of a salivary gland, or dental surgery. For example, mastoiditis may be complicated by bone erosion and abscess below the mastoid cortex and into the upper neck (Bezold abscess) and be the source of an associated parapharyngeal space abscess, (Figure 1). Both the mastoid and deep neck space infections must be surgically drained to adequately treat the child.

If deep neck space infection occurs repeatedly in the same anatomic site, the presence of a congenital anomaly such as a branchial cleft remnant should be considered. For example, a third branchial cleft sinus with an opening into the pyriform sinus may be the cause of recurrent infections in the neck (Figures 2 and 3). After incision and drainage and resolution of the infection, the branchial cleft anomaly should be completely excised for definitive cure.

BACTERIOLOGY AND ANTIMICROBIAL THERAPY FOR DEEP HEAD AND NECK SPACE INFECTIONS

Infections of the fascial spaces of the head and neck are often polymicrobial and include gram-positive and anaerobic microorganisms. Studies have also shown a considerable percentage of gram-negative microorganisms in deep head and neck space infections in the pediatric population. In view of the presence of gram-positive, gram-negative, and anaerobic microorganisms in these infections, ampicillin-sulbactam is a good choice. For patients allergic to penicillin, cefuroxime, or clindamycin plus an aminoglycoside are good alternatives. Additionally, methicillin-resistant Staphylococcus aureus has become more prevalent as a cause of these infections. If a child has a serious infection and has been exposed to methicillin-resistant Staphylococcus aureus or is very ill or toxic despite ampicillin-sulbactam, then vancomycin or linezolid may be considered. Eikenella corrodens infection may be associated with human bites. E. corrodens is resistant to clindamycin but sensitive to penicillin and cephalosporins.

If incision and drainage, needle aspiration or blood or wound cultures detect a specific microorganism, the antimicrobial therapy may be narrowed based on susceptibility studies. For deep head and neck space infections intravenous antimicrobial therapy is usually continued for approximately 5 days. Once a child has responded favorably to intravenous and/or...
surgical therapy, oral therapy may be continued for 7 to 10 days with amoxicillin-clavulanate, cefuroxime, cefdinir, or clindamycin.

**DIAGNOSTIC STUDIES**

Laboratory diagnostic studies include complete blood count with white blood cell differential, electrolytes, and urine specific gravity. Blood, throat, and wound cultures should be obtained when appropriate.

Radiographic studies include anteroposterior and lateral neck films. If the retropharyngeal soft tissues are wider than 7 mm or the retrotracheal soft tissues are wider than 13 mm, then infection in the retropharyngeal space is likely. However, unless the lateral neck film is taken with the neck in extension and during inspiration, there will be spurious thickening of the retropharyngeal tissues. Air in the retropharyngeal tissues usually indicates the presence of an abscess.

CT is an excellent diagnostic tool to differentiate deep neck space cellulitis versus abscesses. An abscess appears as a lesion with a contrast enhancement and ultrasonography may also be useful for selected patients to determine whether peritonsillar abscess versus cellulitis is present when the examination is limited by pain on opening the mouth or when the child fails to improve after an initial trial of antimicrobials. CT is not needed for the majority of patients, and the diagnosis can usually be made by clinical examination.

Peritonsillar cellulitis in an older child with adequate oral intake may be treated with oral antimicrobial agents such as those listed above whereas those with poor oral intake must be treated with intravenous antimicrobials.

When severe pain, fever, significant bulging of the peritonsillar area, pain on opening the mouth and displacement of the uvula are present, a peritonsillar abscess is likely. CT may be used in selected patients to determine whether peritonsillar abscess versus cellulitis is present when the examination is limited by pain on opening the mouth or when the child fails to improve after an initial trial of antimicrobials. CT is not needed for the majority of patients, and the diagnosis can usually be made by clinical examination.

Peritonsillar cellulitis usually responds to antimicrobial agents, however, peritonsillar abscess requires incision and drainage, tonsillectomy, or needle aspiration, in addition to antimicrobial therapy. The decision to perform incision and drainage, tonsillectomy, or needle aspiration is based on several factors. If a child with a peritonsillar abscess has had a history of prior peritonsillar abscess, numerous episodes of recurrent tonsilitis, or adenotonsillar hyperplasty with obstructive sleep apnea or if previous incision and drainage or needle aspiration were not effective, then tonsillectomy can be done immediately. Tonsillectomy performed at the time of peritonsillar abscess is called “Quinsy tonsillectomy,” or “tonsillectomy à chaud.” “Quinsy” is an obsolete term for peritonsillar abscess, and “tonsillectomy à chaud” is derived from the French for “hot tonsillectomy.”

Review of the literature shows that recurrent peritonsillar abscess occurs in approximately 17% and recurrent tonsillitis occurs in approximately 28% of patients with peritonsillar abscesses.11-16 Tonsillectomy is usually not performed for patients with a single episode of peritonsillar abscess. Some surgeons have anecdotally claimed that immediate tonsillectomy for peritonsillar abscess is associated with an increased risk of bleeding. However, pooled data from a total of 1,169 patients who underwent immediate tonsillectomy showed only a 3.5% incidence of excessive perioperative or delayed hemorrhage.11-13,17-19 Only one of these studies showed an increased rate of secondary hemorrhage (22%) following immediate tonsillectomy.19

Tonsillectomy may therefore be performed immediately for some patients, whereas in other patients a decision may be made to perform tonsillectomy after an interval of approximately 6 weeks (interval tonsillectomy). Immediate tonsillectomy would be considered if there is acute severe airway obstruction or if incision and drainage has failed. Immediate tonsillectomy has the advantages of having only one period of hospitalization and morbidity and decreasing overall time and expense. Interval tonsillectomy should be considered if the general condition of the child is poor or the child has a coagulopathy or has taken anticoagulants.

Needle aspiration has also been advocated for drainage of peritonsillar abscess but is less reliable than incision and drainage, or immediate tonsillectomy. Repeat needle aspiration may be required.20,21 Even when incision and drainage are performed for peritonsillar abscess, a needle aspiration is used to locate the abscess.

**Retropharyngeal Space Infection**

Retropharyngeal space infections are usually present with fever, dysphagia, irritability, muffled cry or speech, torticolis, and stridor. Drooling and stridor may be present in severe cases. The retropharyngeal space consists of bilateral spaces separated by a midline raphe which is clinically important because infection in this space usually causes unilateral pharyngeal bulging. Occasionally, swelling from a retropharyngeal space infection may displace the tonsil in an anterior direction that mimics peritonsillar infection. CT can usually determine the correct space of the infection.

Infections in the retropharyngeal space can be severe and can spread from the base of skull to the mediastinum since the fascial planes are potentially contiguous (Figure 4). Retropharyngeal

![Figure 4] Computed tomography scan showing a rim enhancing mediastinal abscess with a lucent center (center). This abscess resulted from an inferior extension of a retropharyngeal abscess.
space infections occur between the prevertebral and buccopharyngeal fascial layers. Although the origin of retropharyngeal space infections is usually the nose, paranasal sinuses, or pharynx; foreign body ingestion with pharyngeal trauma can also lead to infection in this space, and some authors recommend routine esophagoscopy to rule out a foreign body.

Retropharyngeal cellulitis is, of course, treated with intravenous antimicrobial agents. Retropharyngeal abscesses are usually treated with transoral incision and drainage plus intravenous antimicrobials. The abscess may first be located with a needle aspiration.

Prevertebral Space Infection
Prevertebral space infections usually arise from staphylococcal or tuberculous infections of the vertebral bodies. These infections occur between the vertebral bodies and the prevertebral fascia. In contrast to retropharyngeal space infections which are unilateral because of the attachment of the retropharyngeal midline raphe, prevertebral space infections cause a bulge in the midline. While retropharyngeal space abscesses are usually drained by transoral incision and drainage, prevertebral abscesses are drained externally. A prevertebral space abscess requires long-term drainage.

Parapharyngeal Space Infection
The parapharyngeal (lateral pharyngeal) space is shaped like an inverted pyramid and extends from the lateral part of the base of the skull to the hyoid bone. It is divided into prestyloid and poststyloid compartments. The styloid process and the attached fascia of the tensor veli palatini divide the parapharyngeal space into a prestyloid compartment that contains the internal maxillary artery, the maxillary nerve, and the tail of the parotid gland; and a poststyloid compartment that contains the carotid artery, internal jugular vein, cervical sympathetic chain, and cranial nerves IX, X, XI, and XII. Parapharyngeal space infections usually present with pain, fever, stiff neck, and occasionally pain on opening the mouth which is from involvement of the internal pterygoid muscle. Imaging studies are useful to differentiate abscess versus cellulitis. Similar to the other deep neck space infections, parapharyngeal space cellulitis may be treated with intravenous antimicrobials. Abscesses in this space are usually drained by the external surgical approach described below.

Submandibular Space Infection
The submandibular space is divided into supramylohyoid and inframylohyoid portions by the mylohyoid muscle. The supramylohyoid portion contains the sublingual glands and the submandibular gland ducts. The inframylohyoid portion contains the submandibular glands and the associated submandibular lymph nodes. These two portions of the submandibular space are in continuity at the posterior aspect of the mylohyoid muscle. As the duct of the submandibular gland passes posterior to the mylohyoid muscle, it also connects the supramylohyoid and inframylohyoid portions of the submandibular space. The capsule surrounding the submandibular gland creates the space of the submandibular gland, which is also a potential site of abscesses. Bound by the anterior bellies of the digastric muscles, the submental space contains lymph nodes and is a potential space for infection.

Visceral Space Infection
Containing the thyroid gland, trachea, and esophagus, the visceral space can be infected and result in quite serious laryngeal edema and airway obstruction. The retrovisceral compartment of the visceral space is in continuity with the retropharyngeal space. Early aggressive therapy is indicated to avoid airway obstruction.

OPEN SURGICAL APPROACH TO DEEP NECK SPACE INFECTIONS
The indications for the open external neck approach to deep neck space infections include larger abscess (>1 cm), multilocular abscesses, failure of needle aspiration, complications, no improvement following 24 to 72 hours of intravenous antimicrobials, and possibly when an unusual or resistant microorganism is suspected. This approach is useful for drainage of infections in the parapharyngeal, submandibular, visceral, retropharyngeal, and prevertebral spaces and the carotid sheath.

An incision is made approximately two fingerbreadths below the lower border of the mandible. The lower border of the submandibular gland is identified and retracted superiorly. If the infection is in the space of the submandibular gland, the fascial capsule of the gland is incised inferiorly and the fascial capsule is dissected superiorly and gently retracted superiorly along with the marginal mandibular branch of the facial nerve. Care should be taken to preserve this nerve and to avoid a crush injury to the nerve from using a retractor against the mandible.

Once the submandibular area has been addressed, the dissection continues deeply to identify the carotid sheath. Once the carotid sheath has been identified, if an abscess is present in the sheath it should be opened and drained. An abscess in the jugular vein may be drained by this approach, and the vein may also be ligated superior and inferior to the abscess. The carotid sheath is an excellent landmark and pathway for further dissection to other deep neck spaces such as the parapharyngeal, retropharyngeal, and visceral spaces. Blunt finger dissection is an excellent and safe method to drain these spaces. Once the abscess cavity or cavities have been entered, blunt finger dissection is also used to break up loculations and to make separate abscess cavities into contiguous cavities when feasible. Iodoform gauze packing is placed into the deep aspect of the wound and brought out through the skin incision. The skin incision is only partially closed to allow drainage and removal of the packing. The packing is slowly advanced out of the wound in daily increments over 3 to 4 days.

AIRWAY MANAGEMENT FOR DEEP NECK SPACE INFECTIONS IN CHILDREN
If deep neck space infection results in partial airway compromise in a child, early establishment of an artificial airway is strongly advised before the airway obstruction results in an acute emergency. Elective establishment of an airway with a bronchoscope, endotracheal tube, nasopharyngeal airway, or tracheostomy is strongly advised prior to the need for emergent intervention which has a higher risk of complications. The artificial airway should be established in the operating room where equipment, good lighting, suction, and the most experienced airway personnel are available.

In small children, surgical manipulation and drainage of an abscess may result in edema and airway compromise. In such children, planning to leave the endotracheal tube in place until edema resolves following drainage of the deep neck space abscess should be considered. A plan to leave the endotracheal tube in place following drainage of a deep neck space abscess should be discussed with the parents prior to the operation to avoid parental anxiety.

Ludwig Angina
Ludwig angina is a severe and potentially lethal variant of submandibular space infection. It is a rapidly progressive, bilateral cellulitis of the supramylohyoid and inframylohyoid portions of the submandibular space. With Ludwig angina, there is “woody induration” of the floor of the mouth. Ludwig angina is by definition a bilateral cellulitis of the submandibular space, and an abscess may or may not be present.

Pain on opening the mouth occurs as the infection and inflammation spread to the internal pterygoid muscle in the parapharyngeal space. Laryngeal edema also occurs as the infection progresses. Thus the combination of edema of the floor of the mouth, elevation of the tongue, pain on opening the mouth, and laryngeal edema contribute to significant airway obstruction (Figure 5). All but the occasional, earliest, mildest cases of Ludwig angina should have an artificial airway established rapidly before the child progresses to complete airway obstruction. A rare, early, mild case, with minimal edema can be treated expectantly in the intensive care unit, without an artificial airway, with intravenous antimicrobials alone.

Although an abscess may not be present, Ludwig angina is the exceptional deep head and neck space infection in which incision and drainage is recommended even in the absence of an abscess. After the airway has been established by endotracheal intubation or tracheostomy, a horizontal
incision is made in the submental area and the fascial layers and muscles that are encountered are separated in the midline. Lateral dissection is also undertaken between the muscle layers to drain any abscesses that may or may not be present. The wound is packed with iodopyracet gauze which is advanced out over several days. The artificial airway is removed when the edema and infection have resolved.

OTHER HEAD AND NECK SPACE INFECTIONS

Masticator Space Infection

The masticator space is a potential space created by the splitting of the superficial layer of the deep cervical fascia around the masseter, internal pterygoid, and temporalis muscles. This space contains the ramus of the mandible and the temporalis muscle. The superior portion of the space is known as the temporalis portion of the masticator space. Abscesses may occur medial or lateral to the temporal muscle. Drainage of the lateral portion is accomplished by hairline incisions that extend through the temporalis fascia. When abscess occurs deep to the temporalis muscle in the infratemporal fossa, the incision must also extend through the temporalis muscle.

When infection occurs in the inferior portion of the masticator space, it may occur in a medial or lateral position. Infection in the lateral portion will involve the masseter muscle, and incision and drainage will require preservation of the facial nerve and its branches prior to detaching the fascia from the mandible. Infection in the medial compartment will involve the internal pterygoid muscle. Infections in the medial portion of the masticator space may be drained via intraoral incision. Infections in the masticator space often arise from extension of dental infection.

Parotid Space Infections

The parotid space is created by the splitting of the superficial layer of the deep cervical fascia around the parotid gland. Infections in this space usually arise from sialoadenitis. Even when an abscess is present, fluctuance is usually not palpated, since the fascial capsule is so dense and thick. Imaging studies such as computed tomography are needed to demonstrate an abscess.

Superficial abscesses in the parotid space may be drained by small superficial skin incisions in the direction of the facial nerve branches with gentle deep blunt dissection. Deep abscesses in the parotid space may only be drained after facial nerve identification and preservation.

Mandibular Space Infection

The superficial layer of deep cervical fascia splits to surround the mandible and thus forms the mandibular space. Infection in this space usually arises from dental infection. Intraoral pain and swelling are noted, and the abscess may be drained by intraoral incision.

Buccal Space Infection

Buccal space infection usually arises from dental infection. Infection in this space can also arise from hematogenous spread of Haemophilus influenzae, but this is now rare in the immunization era. Cheek swelling and pain on opening the mouth are present. The abscess may be drained via skin incisions in the direction of the facial nerve branches with gentle deep blunt dissection. Buccal space abscesses may also be drained via intraoral incision.

Canine Space Infection

Canine space infections are a result of root abscesses of the upper canines. Toothache commonly precedes the facial swelling that occurs lateral to the nares. The abscess may drain spontaneously near the medial canthus. It is important not to mistake canine space infection for dacryocystitis. This abscess may be drained by incision in the labial sulcus with superior elevation of the facial soft tissues. The canine root abscess must also be addressed by the dentist.

TREATMENT OPTIONS: ANTIMICROBIALS ALONE, INCISION AND DRAINAGE OR NEEDLE ASPIRATION

For patients with deep head and neck space infections that are mild with cellulitis and/or complications, antimicrobial therapy is indicated. If there is no improvement after 48 to 72 hours, repeat imaging studies and open surgical therapy should be considered. In seriously ill children without abscess who do not respond rapidly to standard antimicrobial therapy, the presence of resistant microorganisms such as methicillin-resistant Staphylococcus aureus should be considered and vancomycin should be added to the therapy. Seriously ill children with large and multilocular abscesses or those with complications or Ludwig angina should be treated with aggressive incision and drainage. Needle aspiration may be useful for drainage of small unilocular abscesses.22,23 Ultrasound or CT are useful to locate the abscess and guide needle aspiration.

Some authors have recommended treatment of patients with small (≤1 cm) uncomplicated abscesses with intravenous antimicrobials alone with good success.24,25 However, this approach should not be used if the abscess lies in a critical location such as immediately adjacent to the great vessels. In such patients the abscess may erode into the great vessels with catastrophic consequences; and, therefore, aggressive incision and drainage is recommended.

COMPLICATIONS

Complications associated with deep neck space infections are an indication for incision and drainage. The complications are listed in Table 2. The complication of internal jugular vein thrombosis deserves special discussion. Patients with deep head and neck space infections that spike fevers repeatedly in the so-called “picket fence” pattern may have internal jugular vein thrombosis which is releasing septic emboli. CT angiography and magnetic resonance angiography are excellent diagnostic studies for internal jugular vein thrombosis. Traditional angiography is also useful but is associated with increased risk of complications. Treatment of internal jugular vein thrombosis includes aggressive incision and drainage of the abscess. In addition, if the septic emboli continue, the internal jugular vein may be ligated or excised. Postoperative anticoagulation may help decrease the chances of propagation of the emboli.

CONCLUSIONS

Although deep head and neck space infections continue to be serious, with appropriate use of diagnostic tests, antimicrobial agents, surgical drainage, or needle aspiration, complications can be avoided and favorable outcomes can be achieved.

Sleep Apnea in Children

Nira A. Goldstein, MD

Pediatric sleep-disordered breathing (SDB) is viewed as a continuum of severity from partial obstruction of the upper airway producing snoring, to increased upper airway resistance to continuous episodes of complete upper airway obstruction or obstructive sleep apnea (OSA). Although the prevalence of primary snoring is 12%, the prevalence of OSA is 1 to 3%. SDB is an important cause of morbidity in children and may lead to growth failure, neurocognitive and behavioral abnormalities, cor pulmonale, and rarely death. Early recognition and treatment are important to prevent or treat these disorders.

HISTORICAL PERSPECTIVE

The earliest description of pediatric OSA is found in a novel by Charles Dickens, The Posthumous Papers of the Pickwick Club, which was published in 1837. Dickens described an obese, red-faced, hypersomnolent boy named Joe. In the medical literature, William Osler gave an extremely accurate description of pediatric OSA in his textbook in 1892. "At night the child's sleep is greatly disturbed; the respirations are loud and snorting, and there are sometimes prolonged pauses, followed by deep, noisy inspirations." He also coined the term "pickwickian" to describe morbidly obese, hypersomnolent patients. In 1956, Spector and Bautista associated pediatric respiratory distress with tonsillitis and adenoiditis. In 1965, both Noonan and Menashe described reversible cor pulmonale in children with adenotonsillar hypertrophy. Guillemainault and colleagues first described the clinical features of pediatric OSA in 1976. Since then, additional case series and cohort studies have drastically increased our knowledge regarding the potential morbidities of SDB and potential therapies, although much is still unknown.

DEFINITIONS

Classically childhood OSA has been defined as partial or complete upper airway obstruction during sleep, usually associated with sleep disruption, hypoxemia, hypercapnia, or daytime symptoms (Figure 1). The diagnosis of OSA has been based on threshold criteria on the overnight polysomnogram (PSG) such as apnea index or degree of oxygen desaturation. Children who snored but did not meet the threshold criteria for OSA were considered to be primary snorers (see Figure 1B), a condition which was believed to be clinically insignificant. In recent years, upper airway resistance syndrome (UARS) has identified children with elevated upper airway resistance characterized by snoring, labored breathing, and paradoxical breathing without classic apnea or hypopnea (see Figure 1C). These children exhibit similar clinical features to children with classic OSA and improve after treatment.

ETIOLOGY AND PATHOGENESIS

Pediatric OSA is caused by fixed and dynamic narrowing of the airway which may occur at several sites. Most commonly, enlarged tonsils and adenoids are the source of nasopharyngeal and oropharyngeal narrowing. The tissues of Waldeyer ring (tonsils, adenoid, and lingual tonsil) progressively enlarge between ages 2 and 8 years and are largest in relation to the airway between 3 and 6 years of age. Craniofacial abnormalities such as micrognathia or maxillary hypoplasia can narrow the upper airway. Lower airway abnormalities such as laryngomalacia can also impact airway patency. Rapid air movement through a narrowed airway from any of these conditions induces further upper airway collapse and obstruction. The pharyngeal muscle hypotonia and muscle incoordination found in children with neuromuscular conditions and cerebral palsy produce dynamic airway narrowing.

Given the multiple predisposing factors for pediatric SDB, no single factor accounts for all cases (Figure 2). Large tonsils and adenoid alone do not cause SDB. Numerous studies have been unable to find a relationship between tonsil and adenoid size and the development of OSA. Children with OSA do not exhibit obstruction when awake underscoring sleep-related dynamic airway collapse. Also, there have been reports of successful treatment by adenotonsillectomy in childhood with recurrence of SDB in the teenage years. The current view is that children with OSA have an underlying abnormality of upper airway motor control or tone which when combined with enlarged tonsils and adenoids results in dynamic airway obstruction during sleep.

The mechanisms underlying the development of the neurocognitive and behavioral deficits found in pediatric SDB are unknown. Proposed mechanisms include sleep disruption, sleep fragmentation, intermittent hypoxia, alterations in brain neurochemistry, brain inflammation, hormonal changes, changes in cerebral bloodflow, or altered cerebral perfusion pressure. Additional research is critically important in this area. Other consequences of pediatric SDB, including pulmonary hypertension (cor pulmonale), hypertension, and growth impairment, are likely caused in part by the effects of intermittent hypoxia during sleep. Hypoxemia or sleep fragmentation...
may affect brain neurochemistry and growth hormone secretion. Increased work of breathing with fewer calories available for growth may lead to failure to thrive. Large swings in intrathoracic pressure may affect cardiac afterload directly. The etiology of enuresis is unclear but may be secondary to increased urine production due to OSA, abnormal secretion of antidiuretic hormone (ADH), or merely reflect increased awakenings and arousals.

There is mounting evidence that there is a familial predisposition to the development of OSA as genetic-epidemiologic surveys of families of index patients with OSA have demonstrated a higher prevalence of SDB in family members as compared to the general population. Genes associated with obesity, craniofacial structure, and muscle development of the upper airway soft tissues are likely involved in the development of OSA, but further work is needed to identify specific loci.

EPIDEMIOLOGY

The prevalence of snoring and pediatric OSA have been estimated from community-based cross sectional surveys of parental reports of snoring and difficulty breathing during sleep. The prevalence of snoring ranged from 2.4 to 12% while the prevalence of SDB ranged from 0.69 to 4%. The peak incidence of pediatric OSA is between 2 and 6 years of age when the tonsils and adenoids are largest in relation to the size of the underlying airway. A second peak occurs between 12% while the prevalence of SDB ranged from 0.69 to 4%. The peak incidence of pediatric OSA is between 2 and 6 years of age when the tonsils and adenoids are largest in relation to the size of the underlying airway. A second peak occurs approximately 2 to 3 years of age during adolescence with the development of the adult body habitus and craniofacial structure. Most studies do not report gender differences. African American children have been reported to be at increased risk (3.5 times) for developing OSA and to be at increased risk (3.5 times) for developing OSA.

CLINICAL FEATURES

Nighttime Symptoms

Snoring is the most common symptom of SDB, and OSA is extremely unusual in children who do not snore (Table 1). Other nighttime symptoms include apnic pauses, snoring, gasping, restless sleep, frequent arousals, frequent awakenings, sleep with the neck hyperextended, unusual sleeping positions, for example, sitting, propped up on pillows, fetal position, diaphoresis, enuresis, and other parasomnias. A resuscitative snore often follows the apnic episodes. Occasionally stridor is found. Children may exhibit paradoxical inward rib cage motion while cyanosis is rarely observed. In children, OSA occurs mainly in rapid eye movement (REM) sleep, therefore symptoms may be absent for a significant portion of the night.

Daytime Symptoms

Hypertrophy of the tissues of Waldeyer ring may lead to daytime obstructive symptoms including mouthbreathing, hyponasality, chronic rhinorhea, nasal obstruction, and dysphagia (Table 1). A history of any of these symptoms should lead to an investigation of nighttime symptoms including snoring and possible apnea. During an acute upper respiratory infection, there may be enlargement of the lymphoid tissues of Waldeyer ring resulting in snoring and nighttime breathing difficulties. These symptoms may be temporary and resolve once the infection subsides but may signal the onset of chronic upper airway obstruction.

Failure to thrive has been reported to occur in approximately 10% of children and 42 to 56% of infants with OSA. There have been several reports documenting improvement in growth for children with failure to thrive and OSA after adenotonsillectomy. Pulmonary hypertension is a rare complication of OSA. Goldstein and colleagues, in two prospective studies evaluating the clinical diagnosis of SDB performed echocardiograms on all study participants. Pulmonary hypertension was found in 0/30 (0%) and 1/56 (2%) of patients and resolved in the one patient after adenotonsillectomy. Miman and colleagues identified 17 children with obstructive symptoms and adenotonsilar hypertrophy who had mild pulmonary hypertension by echocardiography. The pulmonary hypertension resolved in all patients after surgery. In the studies by Goldstein and colleagues, systemic hypertension was also found in 5/30 (16.7%) and 8/59 (20%) of patients. It resolved in all patients after adenotonsillectomy.

While daytime sleepiness is extremely common in adults with OSA, it is an uncommon finding in children. Behavioral and neurocognitive difficulties have been found in 8.5 to 63% of children with SDB. Children with primary snoring but otherwise normal sleep study indices have also been shown to have lower scores on measures of behavior and cognition using a battery of neurocognitive tests as compared to control children, although the mean scores for both groups were still in the normal range. Studies using standardized behavioral and neurocognitive assessments have documented significant improvements in test scores after adenotonsillectomy in children with SDB, suggesting that neurocognitive deficits are potentially reversible.

Poor academic performance has also been found in several studies of children with SDB. Only one study has evaluated improvement in academic performance after adenotonsillectomy. Gozal evaluated 297 first grade children in the lowest tenth percentile of their class by overnight pulse oximetry and transcutaneous CO2 measurement. Fifty-four children demonstrated sleep-associated gas exchange abnormalities and 24 of these children underwent adenotonsillectomy. The mean grades of the children who underwent surgery increased significantly during the following academic year as compared to the children whose parents refused surgery. There was no academic improvement in the children with primary snoring and the children without SDB. These findings also suggest that the neurocognitive difficulties found in children with SDB are reversible with treatment. To further evaluate the long-term impact of SDB in early childhood, Gozal and Pope mailed questionnaires to the parents of seventh and eighth graders whose school performance was in the top 25% of the class or the bottom 25% of the class, and who were matched for age, gender, race, school, and street of residence. Snoring in early childhood was significantly more common in the low performance group than the high performance group, but there was no significant difference in current snoring. Significantly, more low performance children had a history of adenotonsillectomy.

tissue adjacent to the pharynx as well as compres-
the upper airway by the deposition of adipose
children is 25 to 40%. Obesity predisposes children
SDB, most children with SDB are not obese.
Obesity predisposing children to sleep apnea is provided in Table 2.10

Obesity
Although obesity is a risk factor for pediatric
SDB, most children with SDB are not obese. However, the prevalence of SDB in obese
children is 25 to 40%. Obesity predisposes children to SDB by decreasing the cross-sectional area of the upper airway by the deposition of adipose tissue adjacent to the pharynx as well as compression from subcutaneous fat deposits in the neck. Individual symptoms and PSG abnormalities do not correlate with the degree of obesity. Soul-tan and colleagues found that 10 of 17 children who were obese or morbidly obese with OSA had substantial weight gain after adenotonsillectomy.11 Therefore treatment of the SDB will not help with weight reduction in obese children and might exacerbate the obesity. Diet, exercise, and behavior therapy are needed in addition to surgical therapy.

Down Syndrome
The anatomic and physiologic factors that predispose children with Down syndrome to OSA include midfacial and maxillary hypoplasia, macroglossia, a narrow nasopharynx, a shortened palate, generalized hypotonia, and a tendency to obesity. Shott and colleagues found the incidence of OSA to be 57% in a 5-year longitudinal study of 56 children with Down syndrome.12 Of the children with abnormal sleep studies, 77% of the parents reported no sleep problems in their children. Since many of the manifestations of SDB including daytime sleepiness, behavioral problems, developmental delay, and pulmonary hypertension are also common in children with Down syndrome, there is often a delay in diagnosis.

Although adenotonsillectomy is usually the first-line treatment of SDB in children with Down syndrome, persistent significant PSG abnormalities have been reported in up to 60% of children. Additional therapies may include nasal continuous positive airway pressure (CPAP), uvulopalatopharyngoplasty (UPPP), tongue reduction, maxillomandibuloadvancement, or tracheostomy. The efficacy of these surgical procedures in this patient population is unknown.

Craniofacial Syndromes
The prevalence of SDB in children with craniofacial syndromes is estimated to be 40 to 50%. Anomalies that predispose these children to OSA include midfacial and mandibular hypoplasia, increased nasal resistance, macroglossia, soft palate abnormalities, hypotonia, abnormal neural control of the airway, and structural defects. OSA has been found in children with Pierre Robin sequence, Treacher Collins syndrome, Apert syndrome, Pfeiffer syndrome, Larsen syndrome, Crouzon syndrome, Stickler syndrome, Goldenhar syndrome, velocardiofacial syndrome, and fragile X syndrome. Infants with Pierre Robin sequence (micrognathia, glossopisis, and cleft palate) may present with severe upper airway obstruction, although appropriate management may prevent many of the complications. With growth of the mandible, the upper airway obstruction improves with age. PSG is important for the diagnosis of SDB in children with craniofacial abnormalities and to evaluate the children’s response to therapy. Therapy includes adenotonsillectomy, UPPP, maxillary and mandibular advancement, mandibular distraction osteogenesis, nasal CPAP, and tracheostomy.

Achondroplasia
Achondroplasia is an autosomal dominant syndrome which is the most common form of dwarfism. Midfacial hypoplasia, dysplasia of the basiocciput, foramen magnum stenosis with compression of the cervical spinal cord, and thoracic cage restriction predispose these children to OSA. Surgical management may involve adenotonsillectomy, ventriculoperitoneal shunt, and foramen magnum decompression. PSG and neurological and respiratory assessments are important in the workup of these patients.

Mucopolysaccharide Storage Diseases
The mucopolysaccharidoses are genetic disorders in which enzyme deficiencies lead to defective degradation of lysosomal glycosaminoglycans with accumulation of mucopolysaccharides in the soft tissues of the body, including the respiratory tract. The type of mucopolysaccharidosis is determined by the particular enzyme deficiency. Examples are Hurler and Scheie syndromes (α-L-iduronidase deficiency), Hunter syndrome (iduronate sulfatase deficiency), and Sly syndrome (β-glucuronidase deficiency). In addition to hypotrophy of the tonsils, adenoid, tongue, and oropharyngeal mucosa, deposits in the tracheobronchial tree often lead to chronic pulmonary disease. These children often develop scoliosis, spinal problems, and hepatosplenomegaly. OSA may be severe and a cause of death. Treatment options include adenotonsillectomy, nasal CPAP, and tracheostomy. These patients present complex airway management, and even tracheostomy may not insure control of the airway.

Neuromuscular Disease and Cerebral Palsy
Children with neuromuscular disease are a heterogeneous group and include children with neuropathies, congenital myopathies, muscular dystrophies, myotonias, and myasthenia gravis. These children have a loss of respiratory muscle function and a drop in central respiratory drive leading to both obstructive and central apnea. The symptoms of SDB may be underestimated as they may be difficult to distinguish from the underlying disease. Treatment options include adenotonsillectomy, UPPP, tracheostomy, or CPAP. Children with cerebral palsy have poor neuromuscular control, increased oropharyngeal secretions, seizures, and gastroesophageal reflux disease (GERD) which may predispose them to SDB. Adenotonsillar hypertrophy along with decreased pharyngeal tone contribute to upper airway collapse. Treatment options include adenotonsillectomy, UPPP, tongue hyoid advancement, mandibular advancement, tongue reduction, CPAP, and tracheostomy.

Miscellaneous Conditions
Children with Arnold-Chiari malformation present with central and obstructive apnea as a result of brainstem compression (see the central apnea discussion below). Treatment involves decompression of the malformation. Children with sickle cell disease are at risk for the development of SDB, and SDB may be a predisposing factor for the occurrence of cerebrovascular accidents. Adenotonsillectomy has been shown to be successful in the resolution of symptoms and improvement in alveolar hyperventilation. Children with Prader-Willi syndrome have severe infantile hypotonia, feeding difficulties, developmental delay, craniofacial abnormalities, and obesity which all contribute to the development of SDB. Early treatment of SDB may delay the development of cor pulmonale, a common cause of death in these children. Iatrogenic causes of SDB are possible, most commonly from velopharyngeal flap surgery.

Adapted from reference 10.
PHYSICAL EXAMINATION

The child’s general appearance should be assessed with measurement of height, weight, and blood pressure. The craniofacial structure should be assessed for midfacial hypoplasia, retrognathia, micrognathia, and adenoid facies (open mouth, long face, mandibular hypoplasia). The presence of mouthbreathing, stertor, and hyponasality should be assessed. The nose should be examined for the presence of structural abnormalities. The oropharyngeal examination should evaluate tonsil size, tongue size, position of the palate, dentition, and the presence of any structural abnormalities. The neck should be examined for any neck masses. The adenoid may be evaluated by flexible fiberoptic nasopharyngoscopy or by the use of a small rigid telescope. If laryngeal abnormalities are suspected, flexible fiberoptic laryngoscopy may also be performed. The chest should be examined for the presence of a pectus excavatum. Neurologic function and development should be assessed.

DIAGNOSTIC STUDIES

Ancillary Studies

A lateral neck X-ray may be obtained to assess adenoid size. Cephalometric studies and upper airway fluoroscopy may be useful in children with craniofacial abnormalities but are not routinely used for otherwise healthy children. An electrocardiogram, echocardiogram, and chest radiographic may be obtained in children with severe OSA or children with signs of congestive heart failure to evaluate for pulmonary hypertension.

A home audiotape recording of the child’s breathing during sleep has a reported sensitivity of 71 to 88% and a specificity of 52 to 72% in predicting a positive result on PSG in otherwise healthy children. A home videotape recording has been shown to have a sensitivity of 94% and specificity of 68% in predicting a positive PSG. Although not specific enough to distinguish children with positive and negative sleep studies, these tapes are convenient, inexpensive methods to confirm the parents’ description of the child’s nighttime breathing difficulties and are useful in the clinical setting.

Pulse oximetry is not useful as a screening tool because of its low sensitivity but may prove useful if positive in a snoring child in whom there is a high index of suspicion for OSA. Nap polysomnograms also exhibit poor sensitivity and are only useful if they are positive. The difficulty with nap studies is that children over 4 years of age rarely nap, and REM sleep may be missed on a nap study. A mbulatory, unattended PSG performed in the child’s home may have a role in the diagnosis of SDB although end tidal CO2, EEG, and upper airway resistance are usually not measured.

Polysomnography

The PSG consists of electroencephalography and electromyography for sleep staging, chest and abdominal motion by strain gauges or respiratory inductive plethysmography, electrocardiography, pulse oximetry, nasal and oral airflow, and end-tidal or transcutaneous CO2. UARS is best detected by esophageal pressure monitoring, but this is not routine in most centers. Ideally, pediatric sleep studies should be performed in a pediatric sleep laboratory with a technical staff trained to work with children.

Obstructive apnea or the cessation of airflow with continued respiratory effort is defined as lasting at least 10 seconds in adults (Figure 3). Since children have faster respiratory rates than adults, the duration of an obstructive apnea in a child is two times the typical breath interval. An obstructive hypopnea is the partial cessation of airflow with continued respiratory effort, although there is no uniform definition of hypopnea in children among sleep laboratories. A central apnea is the cessation of airflow due to lack of respiratory effort (see Figure 3). Sleep study findings are commonly reported as the apnea-hypopnea index (AHI) or the number of apneas plus hypopneas per hour of sleep or the respiratory disturbance index (RDI) or the number of all respiratory events including respiratory arousals per hour of sleep.

The PSG criteria commonly used to diagnose OSA in a child are presented in Table 3. Marcus performed sleep studies on 50 normal children and found the average apnea index (AI) to be 0.1 ± 0.5 events per hour, minimal O2 saturation was 96 ± 2% and average maximal desaturation was 4 ± 2%. She concluded that apnea more frequent than one time per hour was abnormal. Obstructive hypventilation can be identified when the end tidal CO2 pressure is equal to or greater than 50 mmHg for more than 10% of the total sleep time. A wake esophageal pressure is usually between -10 and -5 cm of water, and UARS is diagnosed on the PSG when a repetitive breathing pattern with increasingly negative esophageal pressure culminating in an arousal is found. In the absence of esophageal pressure monitoring, some pediatric centers, based on experience, will consider a study suggestive of UARS if the thresholds for nocturnal awakenings (<1/hr), arousal index (<10/hr), or sleep efficiency (>80%) are exceeded.

Limitations of Polysomnography. Standards for positive PSG in children have been based on studies of their normative values. However, few studies have documented the relationship between PSG abnormalities and daytime sleepiness, impaired neurocognitive function, behavioral abnormalities, or other adverse outcomes of pediatric SDB. It is unclear whether children with mild PSG abnormalities, although outside of the normative range, require therapy. PSG focuses heavily on breathing with minimal measures of sleep quality. Normative data are limited to classically OSA and are not available for UARS.

It is controversial whether an otherwise healthy child needs a PSG prior to adenotonsillectomy. Reports have documented the inaccuracy of predicting which children with histories and physical examinations suggestive of OSA will have positive PSG. In seven trials, the accuracy of clinical evaluation of OSA was poor, ranging from 30 to 85%. On the basis of the published studies and because only 20 to 30% of snoring children have positive PSG, the American Thoracic Society Consensus Committee recommended PSG be obtained before adenotonsillectomy to differentiate primary snoring from OSA. Although the published studies suggest that clinical evaluation is inaccurate in diagnosing OSA in children, most of the studies used adult criteria for interpretation of the sleep studies, which are now recognized to be inappropriate for children. In addition, none of the studies considered the diagnosis of UARS in the evaluations. Weatherly and colleagues found that the accuracy of clinical assessment increased as the PSG criteria for a positive study became less stringent. In a prospective, randomized, controlled trial of children with a positive clinical assessment for OSA but negative PSG, children who underwent adenotonsillectomy had significant improvement in clinical assessment scores compared to children who did not undergo surgery at 6-month follow-up. In addition, recent research has suggested that primary snoring in children may not be benign.

PSG has been most useful to confirm the diagnosis of OSA and document its severity in the following situations: children who are younger than 2 years; high-risk patients for which surgery is contraindicated; children with craniofacial abnormalities, morbid obesity, or cerebral palsy; when

there is a discrepancy between the history and physical examination; and children who remain symptomatic after adenotonsillectomy. PSG is also a prerequisite to treatment with nasal CPAP or bilevel positive airway pressure (BiPAP) in high risk children or surgical failures.

**NATURAL HISTORY**

Little is known about the natural history of untreated SDB. As children with OSA and clinically significant SDB are routinely treated, there are no studies evaluating long-term effects or possible resolution of SDB. Two studies have evaluated children with untreated primary snoring and found that only 8 to 10% progressed to mild OSA at 1- to 3-year follow-up. Although infantile and childhood OSA may predispose individuals to adult OSA because of anatomical and familial factors, there is no current evidence that adults with OSA had SDB during infancy and childhood.

**TREATMENT**

**Medical**

Topical nasal corticosteroids have been studied to determine their ability to improve nasal airflow and improve SDB. Brouillette and colleagues performed a randomized, triple-blind, placebo-controlled trial of 6 weeks of nasal fluticasone propionate in 25 children with SDB. There was a significant reduction in the mixed/obstructive apnea/hypopnea index in the study patients from $10.7 \pm 2.6$ to $5.8 \pm 2.2$ as compared to the placebo group, although there was no significant change in symptom score and tonsil and adenoid size between groups. Although the study demonstrated a moderate reduction in the AHI, an index of 5.8 is still abnormal and the patients continued to have episodes of desaturation. In addition, patients with severe OSA, 4+ tonsils, and craniofacial conditions and infants were excluded. The study also did not address the duration of therapy, so it is unclear whether the topical nasal corticosteroids must be continued for a continued response.

Al-Ghamdi and colleagues performed an open-label pilot study of 5 days of oral prednisone on nine children with OSA. There was no improvement in symptomatology, sleep study indices, or tonsil and adenoid size. There have been two studies evaluating oral antibiotics. Sclafani and colleagues performed a prospective, randomized, double blinded, placebo-controlled trial of 30 days of amoxicillin/clavulanate potassium in 168 children with obstructive symptoms. Sleep studies were not performed. Treatment with the antibiotic significantly reduced the need for adenotonsillectomy at 1-month follow-up as compared to placebo (37.5% vs 62.7%). By 24 months, most of the children in both groups had undergone adenotonsillectomy (83.3% of the study group versus 98.0% of the placebo group). Don and colleagues performed a randomized, double-blinded, placebo-controlled trial of 30 days of azithromycin in 22 children with OSA documented by PSG. There were no significant differences in sleep study indices, tonsil size, or symptoms in the azithromycin group as compared to the placebo group. These preliminary studies suggest that the above therapies are not indicated for children with severe OSA but may have a role in the treatment of milder SDB or for temporary relief of symptoms.

Nasal CPAP or BiPAP is used in children with predisposing factors for OSA including craniofacial anomalies, neuromuscular weakness, or obesity in whom adenotonsillectomy is ineffective or not indicated and for children with idiopathic OSA after adenotonsillectomy. Studies have reported efficacies of 86 to 100% in normalizing PSG indices with long-term compliance rates of 80%. Supplemental oxygen has been used as a temporary measure to improve oxygenation in children with OSA, although end tidal $CO_2$ must be monitored as alveolar hypoventilation can occur. It is not recommended as the sole treatment modality for OSA. Weight loss is important in obese children to improve SDB and to reduce the risk for additional comorbidities related to obesity.

Children with a constricted maxillary arch and associated narrowing of the nasal airway may benefit from rapid maxillary expansion. An orthodontic appliance is fixed to anchor teeth and rapidly expanded over 3 weeks followed by a stabilization period of 6 to 12 months. Studies in selected children demonstrate improvements in SDB. It should be considered in older children who have failed other treatments.

**Tonsillectomy and Adenoidectomy**

The first-line therapy for the treatment of OSA or significant SDB in otherwise healthy children is adenotonsillectomy. It may also be the first line treatment in complex patients if the tonsils and adenoids are enlarged. Review of the published literature evaluating the success of adenotonsillectomy in otherwise healthy children reveals prospective observational, uncontrolled studies, and retrospective case series. Due to ethical concerns, there are no randomized, controlled trials comparing adenotonsillectomy to no treatment. Most studies report a success rate for resolution of PSG abnormalities of 75 to 100%. A meta-analysis by Lippton and Gozal reported a success rate of 80%. Studies evaluating clinical outcomes of obstructive symptoms after adenotonsillectomy report higher cure rates in the range of 90 to 100%, highlighting the need for further evaluation of the validity of PSG abnormalities in predicting future morbidity.

The postoperative pain associated with adenotonsillectomy as well as the small risk of postoperative hemorrhage has led the development of a number of different surgical techniques. A devicoidectomy may be performed using curettes, electrocautery, or the microdebrider. The classic technique of tonsillectomy was the “cold-dissection” in which the tonsil was grasped, the anterior tonsilar pillar incised, and the capsule dissected off the pharyngeal constrictors using blunt and sharp dissection. Hemostasis was obtained by suture ligation or electrocautery. Monopolar electrocautery has become the most popular technique of tonsil dissection in the past quarter century as it affords greater hemostasis during the dissection. It may be associated with increased postoperative pain and longer healing times.

Newer techniques include bipolar cautery, harmonic scalpel, plasma excision (coblation), powered intracapsular tonsillectomy (PIT), and radiofrequency volume reduction. Bipolar cautery allows precise coagulation with less tissue injury and may be performed using a small bipolar bayonet forceps with the operating room microscope or bipolar electrosurgical scissors. The harmonic scalpel uses ultrasonic vibration to transfer mechanical energy sufficient to break hydrogen bonds. Its vibrating titanium blades cut at a frequency of 55.5 kHz, generating minimal heat and tissue damage. Coblation uses current that is conducted through normal saline fluid or gel. The radiofrequency energy excites the saline solution creating a field of active protons that break molecular bonds between tissues. There is potentially reduced thermal injury and postoperative pain because of the lower temperatures produced. Preliminary studies comparing the harmonic scalpel and coblation with the traditional techniques have not demonstrated a clear advantage in terms of postoperative pain and reduction of postoperative hemorrhage rates, but additional studies are needed.

PIT using the microdebrider allows removal of the bulk of the tonsil with preservation of the tonsillar capsule to act as a “biologic dressing” over the pharyngeal constrictors muscles. Due to decreased thermal injury to the tonsillar fossa musculature, there is potentially reduced postoperative pain and hemorrhage. However, there is potential regrowth and infection of the remaining tonsil tissue. Retrospective studies comparing PIT with monopolar electrocautery tonsillectomy have revealed significantly less postoperative pain, use of analgesics, and a quicker return to normal diet in the PIT group. The largest of the studies was able to show a significant reduction in delayed postoperative bleeding and readmission for dehydration in patients who had PIT; these patients had a low rate of tonsil regrowth (0.46%, 95% CI 0.009 to 0.9%). Two recent prospective studies comparing PIT with monopolar electrocautery tonsillectomy show more modest benefits, and there were no differences in groups with respect to postoperative complications. Although the technique appears promising, more data are needed regarding its effectiveness and potential for recurrence of SDB secondary to tonsil regrowth.

Radiofrequency tonsil reduction involves inserting a temperature-controlled radiofrequency probe directly into the tonsillar tissue. The probe generates a current that creates a region of tissue destruction which contracts over time, reducing
tonsil volume. In adults, the procedure may be performed in the office under local anesthesia. Because of their inability to cooperate and the need for concomitant adenoidectomy, children still require a general anesthetic. Preliminary results are promising but larger studies are still needed.

Children with OSA are at risk for postoperative respiratory complications. Although the risk of postoperative respiratory complications in the general pediatric population ranges from 0 to 1.3%, rates of 16 to 27% have been reported in children with OSA.24 Risk factors are age under three, pulmonary hypertension or other cardiac abnormalities, craniofacial syndromes, failure to thrive, hyponatremia, acute airway obstruction, morbid obesity, and severe sleep study indices. These high-risk children require inpatient monitoring of their cardiopulmonary status after adenotonsillectomy. Narcotic analgesics should be used judiciously. These children may require oxygen therapy, corticosteroids, a nasopharyngeal airway, CPAP or BiPAP, or endotracheal intubation if respiratory compromise develops. Postoperative pulmonary edema is a rare complication that may occur after the relief of chronic upper airway obstruction. Treatment includes oxygen therapy, positive end-expiratory pressure (PEEP), restriction of intravenous fluids, diuretics, and possibly corticosteroids.

After tonsillectomy, children experience throat pain that lasts 1 to 2 weeks, referred otalgia from the pharyngeal surgical site, and halitosis. Nausea and vomiting may develop from the anesthetic agents, the swallowing of bloody secretions, or adverse reactions to narcotic analgesics. Some children after adenoidectomy will develop neck pain especially with extension and neck stiffness secondary to prevertebral inflammation. If the neck pain persists longer than two weeks, C1–C2 subluxation should be suspected. A soft diet is recommended for 10 to 14 days with a gradual return to normal activities. A cetaminophen should be used liberally. A cetaminophen with codeine may also be used but with discretion in high-risk patients. Nonsteroidal anti-inflammatory agents are avoided due to the increased risk of postoperative hemorrhage. Postoperative antibiotics are usually prescribed because of their beneficial effects on pain, fever, and halitosis. Perioperative corticosteroid administration has been shown to reduce vomiting and pain in the first 24 hours.

Dehydration is a complication of adenotonsillectomy that may require refeeding for intravenous hydration and pain management. Rehydration should be performed with isotonic solutions in appropriate volumes. Hyponatremia has been reported as a potential lethal complication after tonsillectomy caused by inappropriate administration of hypotonic solutions in children with intravascular depletion. In the surgical patient, free water is retained because there is an increase in antidiuretic hormone (ADH) secretion in response to decreased circulating blood volume. Administration of hypotonic solutions maintains these elevated ADH levels leading to the retention of free water with a resultant decrease in serum sodium and serum osmolality.

Postoperative hemorrhage is the most common severe complication of tonsillectomy, occurring in 2 to 4% of patients. Primary bleeding occurs within the first 24 hours and is considered to be related to surgical technique while delayed bleeding occurs within the first 10 days (most commonly on the sixth or seventh day) and is attributed to the slough of eschar. Bleeding may stop spontaneously, but children with significant bleeding should be admitted and observed. Attempts may be made to control bleeding in the emergency room, but many children require control in the operating room. A clot in the tonsillar fossa indicates recent bleeding and must be removed to determine if the bleeding has stopped. Repeated bleeding may indicate injury to a large vessel with pseudoaneurysm formation. Angiography and selective embolization may be required to diagnose and treat this rare complication.

Preoperative coagulation studies are not performed routinely before adenotonsillectomy as they have limited predictive value and are not cost-effective. However, children with a history of abnormal bleeding or children with a family history of bleeding or coagulation disorders do warrant a preoperative workup. Children with sickle cell disease are at increased risk for complications after adenotonsillectomy. Protocols have been developed which include aggressive hydration and preoperative transfusions to reduce the percentage of hemoglobin S to less than 30 to 40%. Children with type 1 von Willebrand disease are successfully managed with preoperative administration of desmopressin acetate (DDAVP). Children with sickle cell disease, hemophilia, and other coagulopathies should be managed in conjunction with a pediatric hematologist.

Other Surgical Modalities

Surgical modalities other than adenotonsillectomy are considered for children who are not improved with it and children with other comorbid conditions. PSG is mandatory in this group of children to confirm the diagnosis and document the severity of SDB. The other surgical procedures for OSA are presented in Chapter 86, “Sleep Medicine and Surgery.” Most studies on surgical modalities other than adenotonsillectomy have evaluated children with comorbid conditions. Four studies have evaluated UPPP in neurologically impaired patients. Success rates measured by clinical or PSG criteria ranged from 80 to 87%.25 UPPP may be considered in children or adolescents with continued palatal obstruction after adenotonsillectomy. Concerns about midface growth have limited the use of septoplasty in the preadolescent, but it may be considered in older children with continued nasal obstruction. Although temperature-controlled radiofrequency reduction has been used for reduction of the inferior turbinates, soft palate, and base of tongue in adults, little has been published regarding its use in children.

Mandibular distraction osteogenesis has been described in children with micrognathia and respiratory distress from Pierre Robin sequence, Treacher Collins syndrome, Nager syndrome, and hemifacial microsomia. The procedure has been used successfully to prevent tracheostomy in affected infants, treat OSA in older children without tracheostomy, and allow decannulation. In the largest of the published series, 7 of 8 (88%) infants avoided tracheostomy and 5 of 6 (83%) older micrognathic children were cured of OSA, but only 2 of 12 (17%) children with tracheostomies and complex congenital syndromes were successfully decannulated.26

Cohen and Burstein have published several case series describing their use of skeletal expansion combined with soft-tissue reduction in their children with craniofacial syndromes or cerebral palsy and refractory OSA.23 In addition to adenotonsillectomy and UPPP, soft-tissue procedures included septoplasty and turbinectomy, tongue reduction, and tongue hyoid suspension. Skeletal expansion procedures included mandibular advancement, costochondral grafts, mandibular distraction, temporomandibular joint arthroplasty, and LeFort procedures. Tracheostomy was avoided in 90% of their patients, whereas 80% of their patients with tracheostomies were successfully decannulated. Supplemental oxygen therapy or CPAP was still required by 8% of the patients. Mandibular osteotomy with genioglossus advancement, hyoid myotomy with suspension, and maxillary-mandibular advancement may also be considered in otherwise healthy children who do not improve with adenotonsillectomy if the facial skeleton and dentition are mature, although there are few studies addressing these procedures in this group of children. Tracheostomy is thought to be curative in children with refractory OSA and should be considered if the RDI is greater than 60 and oxygen desaturation is less than 70% if CPAP is not tolerated.

Central Apnea

Central apnea is abnormal if it lasts 20 seconds or longer or is of any duration but associated with 4% oxygen desaturation or bradycardia. Three or more events per hour are considered abnormal. Periodic breathing describes an alternating pattern of respirations followed by a central respiratory pause. Periodic breathing is commonly found in healthy neonates but should be considered abnormal in infants and children if it accounts for more than 5% of total sleep time. Diagnosis of central apnea and periodic breathing may be difficult as these children may appear perfectly healthy when awake. Premature infants may exhibit these breathing patterns in the neonatal intensive care unit or may be admitted after an acute life-threatening event. Older children may have daytime sleepiness, restless sleep, and...
cyanosis during sleep but usually not snoring. A PSG is required for diagnosis.

The differential diagnosis of central apnea and periodic breathing is large, and the workup should be tailored to the likely cause (Table 4).28 Apnea of prematurity occurs in 84% of infants less than 1,000 g and 25% of infants less than 2,500 g and is commonly a pattern of mixed central and obstructive apnea. The most common cause is respiratory control immaturity, but central nervous system abnormalities, bacterial or viral infection, anemia, hypoglycemia, electrolyte imbalance, and sedating medications are also causative. The role of GERD is controversial. While chemical irritation of the larynx by a reflux episode may activate the laryngeal reflex and cause apnea, a clear causal relationship between GERD and apnea of prematurity has not been determined. Treatment options include CPAP, high-flow nasal cannula therapy, and methylxanthes such as theophylline and caffeine.

Congenital central hyperventilation syndrome (CCHS or Ondine curse) is an extremely rare entity in which affected children demonstrate severe hyperventilation particularly during sleep because they lack the normal ventilatory responses to hypercarbia and hypoxia. These children usually present shortly after birth with cyanosis upon falling asleep. CCHS is a diagnosis of exclusion as primary neuromuscular, cardiac, pulmonary, and metabolic diseases must be excluded. Most children will require placement of a tracheostomy and mechanical ventilation for treatment. Diaphragm pacing via phrenic nerve stimulation or BiPAP is another alternative. Approximately 15 to 20% of these children will present with Hirschsprung disease, but other autonomic nervous system abnormalities are common.

Disruption of the normal anatomical relationships within the brainstem can result in respiratory control abnormalities. This can occur in brainstem tumors or Chiari malformations. In Type I Chiari malformation (CM-I), there is herniation of the cerebellar tonsils through the foramen magnum often with an associated syrinx. CM-I usually presents in older children and adults. CM-I may be asymptomatic, but patients may present with occipital headaches, a wide variety of neurologic symptoms, and central apnea. In Chiari malformation Type II (CM-II), there is caudal displacement of the cerebellar vermis and brainstem. There is always an associated myelomeningocele and hydrocephalus is common. CM-II is usually diagnosed shortly after birth. Infants may present with prolonged expiration apnea and cyanosis that can lead to bradycardia and death. Stridor may be indicative of vocal cord paralysis and can manifest as obstructive apnea. Children with suspected Chiari malformations require magnetic resonance imaging of the posterior fossa, brainstem, and spine and should be referred to a neurologist or neurosurgeon for management. Patients with CM-II and hydrocephalus require immediate shunting followed by decompression surgery. A symptomatic patient with CM-I may be observed, but patients with apnea, syncope, vocal cord paralysis, and aspiration and those who fail medical management require decompression. Success rates for CM-I approach 80 to 90%, but the outcomes for CM-II are not as good, with up to 15% dying by age three and one-third having continued central nervous system deficits.

Aaron Sulman, MD

The development of image-guidance and robotic surgical systems has facilitated the expansion of minimally invasive approaches to complex surgical head and neck problems. In addition, the development of surgical simulators allows for alternative methods to develop surgical skills. This chapter reviews the roles of these technologies in otolaryngology head and neck surgery.

IMAGE-GUIDANCE SYSTEMS

Image-guidance systems were initially developed for neurosurgical and neurosurgical procedures using a stereotactic frame that required fixation of the patient’s head. They have been subsequently adapted for use in endoscopic sinus surgery. These systems assist the surgeon with intraoperative stereotactic anatomic localization through the use of computerized tracking devices. The tracking devices can localize the position of endoscopic instruments within the sinonasal cavity and depict them on a real-time video display of the preoperative computed tomography (CT) scan using the digital data set of the imaging study.

At this time, there are four types of technology that allow intraoperative image guidance: electromechanical, electromagnetic, optical, and sonic. For practical purposes, electromagnetic and optical systems are the most useful for computer-guided endoscopic surgery (CGES). The sonic system is not widely available in the United States. An example of the electromechanical system was introduced by ISG Technologies (Mississauga, Ontario, Canada) and uses a mechanical arm (“wand”) for anatomic localization. Anon and colleagues reviewed their experience with this system in 70 patients. No complications were reported; and, anecdotally, the authors felt the system was useful in revision surgery, massive disease, frontal recess or sphenoid surgery, and the presence of anatomic variants. However, this system requires preoperative placement of fiducial markers, re-registration with intraoperative head movement, and a mechanical arm. While these more complex systems are necessary for use with neurologic skull base surgery applications, the electromagnetic and optical systems are currently the most commonly used for paranasal sinus surgery.

There is only one electromagnetic system, represented by the InstaTrak (General Electric Medical Systems, Milwaukee, WI). This system relies on a radio frequency transmitter mounted to a patient headset and an electromagnetic sensor incorporated into a handpiece. The InstaTrak is a frameless, wandless system that uses preoperative CT images for triplanar real-time intraoperative localization of curved and straight surgical aspirators. The headset contains seven fiducial markers. Disadvantages of this system include the need to wear a headpiece during the preoperative CT scan and interference from metallic objects near the surgical field. Neumann and colleagues reported their experience using the electromagnetic InstaTrak system in 109 patients, 76 of whom had undergone previous surgery. The estimated accuracy was <3 mm in 106 (97.2%) patients and in no patients did unacceptable intraoperative drift occur. Setup of the InstaTrak system, including headset placement, draping, calibration, and verification took less than 5 minutes in all cases. Orbital fat exposure occurred in two patients and was the only reported intraoperative complication. Two patients developed cerebrospinal fluid (CSF) leaks, but these were anticipated given the underlying pathology (osteoma and meningioma). Postoperative complications included persistent synchiae in four patients and epistaxis in one patient. These authors concluded that the technology was useful for all patients undergoing revision sinus surgery, patients with skull base defects or paranasal sinus neoplasms, and patients undergoing primary surgery with extensive disease.

The optical-based image-guidance system utilizes an infrared camera to monitor instrument and head position. Light emitting diodes (LEDs) are mounted on the surgical instrument and the headset worn by the patient, which are tracked by an infrared camera. The tracking data are processed by an optical digitizer which displays the instrument location on reformatted and triplanar CT images. Several authors have evaluated the utility of this stereotactic system in neurologic skull base surgery and in endoscopic sinus surgery. Metson and colleagues reviewed 754 consecutive patients undergoing CGES by 34 physicians using the LandmarX system (Xomed, Inc., Jacksonville, FL). This is a frameless, frameless system that does not require fiducial or head placement for the preoperative CT scan. The mean accuracy of anatomical localization at the beginning of surgery was 1.69 ± 0.38 mm when five anatomical fiducials were used in the registration process. The use of the image-guidance system was estimated to increase operating room time by 15 to 30 minutes for the first five cases each surgeon performed. With experience, surgeons required only 5 to 15 minutes setup time. There were no intraoperative complications although there were three patients experienced epistaxis that occurred within one week after the operation. The epistaxis was not thought to be related to CGES. The mean follow-up was 15 months. A questionnaire was also completed by the surgeons who used the system. The most common situation in which CGES was utilized was after revision sinus surgery. The major reported disadvantage was increased operating room time (71%), and the major advantage was an increased level of confidence during surgery (85%). The overall use of this system was rated either “easy” (31.8%) or “very easy” (50%) by the surgeons. In addition, most surgeons (92%) anticipated continued use at the same or increased frequency. The authors conclude that optical-based CGES can be successfully integrated into a busy operating room environment used by multiple sinus surgeons. In addition, when properly used, it may extend the limits of safe and effective sinus surgery, especially in patients with distorted landmarks.

Computer-Guided Endoscopic Sinus Surgery: Indications

Endoscopic sinus surgery is a viable option for the management of medically refractory sinonasal inflammatory disease, neoplasms, and skull
base defects. However, frequently, the anatomy has been distorted by previous surgery or the disease process. In addition, bleeding in severe sinonasal inflammation or some neoplasms, bleeding can obscure the surgeon’s visualization. This can make thorough removal of diseased tissue difficult and potentially hazardous. Given the close proximity of vital structures including the intracranial contents and orbit, even minimal intraoperative disorientation can result in serious complications. In an attempt to improve the safety and efficacy of the endoscopic approach to sinonasal disease, image-guidance systems have been developed. Several authors have reviewed their experience with the different types of image-guidance systems; however, it is still unclear from the current published literature if computer-guided endoscopic sinonasal surgery (CGESS) accomplishes these goals.

The ideal image-guidance system allows for correlation of the patient’s anatomy with the CT image to 2 mm or less. Additionally, intraoperative head movement should not affect the accuracy of the system. Other favorable characteristics include a frameless, wandless system, ease of setup and use, and lack of need for skin fiducial placement. There are several drawbacks to using the skin fiducial method, including the need for placement of the fiducials and the CT scan the day before the operation. In addition, the fiducials may fall off or move after the patient is anesthetized and the facial musculature relaxes.

Metson and colleagues reviewed their experience with both optical- and electromagnetic-based systems in 79 patients. Both systems provided an accuracy of <2 mm at the start of the operation. However, by the completion of the operation, accuracy had deteriorated by an average of 0.89 mm due to anatomical drift. Even at this accuracy level the authors thought both systems were useful. This is because, when properly used, image-guidance systems should be used to identify larger and not to distinguish margins of safety at a millimeter level. Disadvantages of the system include increased operating room time and expense. CGESS increased the mean total operating room time by 17.4 minutes. However, the actual operating time was not prolonged since the time required to set up, calibrate, and register the system was carried out before the start of the operation. In addition, the time represented a mean, and once operating room personnel became familiar with the system this value was reduced to less than 10 minutes. With regard to expense, the authors calculated that use of CGESS increased total charges by $496 per operation due to the increased operating room time. Because of the increased time and expense associated with CGESS, the authors do not recommend it for routine head and neck cases.

Current indications for image-guided sinus surgery (IGSS) are as follows:

1. Revision sinus surgery.
2. Distorted sinus anatomy of developmental, postoperative, or traumatic origin.
3. Extensive sinonasal polyposis.
4. Pathology involving the frontal, posterior ethmoid, or sphenoid sinuses.
5. Disease abutting the skull base, orbit, optic nerve, or carotid artery.
6. CSF rhinorrhea or conditions where there is a skull-base defect.
7. Benign and malignant sinonasal neoplasms.

Several articles have been published since the introduction of the technology in the 1990s; however, to date, there is limited evidence that the intraoperative use of IGSS reduces complications and/or improves clinical outcomes. Recently, a systematic review of the evidence-based literature was performed to address these issues. The authors concluded that randomized clinical trials of IGSS are not practical, ethical, or feasible and that clinical experience, expert opinion, and case series support the current indications for IGSS. In addition, studies designed to draw conclusions regarding the role of IGSS in decreasing major complications are not possible.

At the Medical College of Wisconsin, an optical-based, computerized image-guidance system (Stealth with LandmarX software) is set up, calibrated, and registered as follows. The patient undergoes a preoperative image-guided CT scan without fiducials. During the induction of anesthesia, the system is set up and the CT data are loaded onto the computer. Once the patient is asleep, topical decongestants are placed in the sinonasal cavity. While waiting for decongestion to occur, the image-guided headset is placed. The patient is subsequently prepped and draped. The endoscopes and instrumentation is set up and local anesthetic (1% lidocaine, 1:100,000 epinephrine) is injected into the side to be operated on first. While allowing vasoconstriction to occur, the registration is carried out using the tracer contour technique which takes less than a minute.

Once accurate registration is obtained (<2 mm), CGESS commences. In most cases, this takes less than 2 minutes to accomplish, and we still wait another 3 to 5 minutes for vasoconstriction. Thus, although it could be argued that this process adds to operating room time, it is substantially less than 5 minutes of net additional time.

We have found the system to be most useful in cases requiring frontal sinus ventilation, revision surgery, repair of skull base defects, and resection of sinonasal neoplasms. The instrumentation, which can currently be integrated, is particularly useful in the endoscopic approach to the frontal sinus. CGESS should be viewed as a means to help identify spaces within the sinonasal cavity, not to measure millimeter increments (Figures 1 and 2). In addition, it is not a replacement for sound surgical technique, anatomic knowledge, and experience.

**Surgical Simulators**

Simulation is becoming accepted in the surgical community as an alternative in surgical skill training. In large part, this trend evolved due to the large number of medical errors identified in the Institute of Medicine’s report entitled To Err Is Human: Building a Safer Health System. This publication estimated that between 44,000 and 98,000 patients die as a result of medical errors annually. One of the mechanisms cited by the authors to reduce medical errors is to incorporate simulation into surgical training.

In addition to “learning by doing,” cadaveric and live animal dissections and procedures have been historically utilized to facilitate surgical development; however, limitations on the availability of these resources (as well as cost) limit these as long-term solutions. In addition, they may not represent the best models for many types of human surgery and techniques. Computer simulation has been used successfully in other fields for pilot and astronaut training, in military exercises, and for nuclear power plant operations training. Although the initial costs may be larger, the long-term costs may be less than those associated with the more traditional training methods noted above. Advantages of simulation include the reality that there is no risk to patients, it is always available, tasks can be practiced repeatedly without concern for materials or cost, and the potential for objective monitoring of surgeon proficiency and progress exists.

Endoscopic sinus surgery has become the treatment of choice for those patients who fail medical therapy for chronic rhinosinusitis. While conceptually quite simple, performing endoscopic sinus surgery safely and effectively is quite challenging. Successful completion of endoscopic sinus procedures depends on a detailed knowledge of the relevant anatomy, as well as the ability to effectively manipulate the endoscope and instruments within the tight confines of the nose and paranasal sinuses. Furthermore, the close proximity of several vital structures including the brain, orbit, and internal carotid artery adds to the difficulty. These procedures require coordination of the endoscopes with the surgical instruments in a three-dimensional (3-D) space which requires the development of complex ambidextrous perceptual, visuospatial, and psychomotor skills for which virtual reality simulators are gaining acceptance as means of training. This skill set is quite different than that needed to perform open surgical procedures.

The endoscopic sinus surgery simulator (ES3) was developed by Lockheed Martin Corporation and has been investigated as an adjunctive training tool in otolaryngology residency programs. Glaser and colleagues demonstrated that the ES3 provided medical students with significant subjective training benefits as well as objectively measured performance benefits. Thus, they concluded that the ES3 holds much promise as a training tool in the development of endoscopic sinus surgery skills. Further development
of ES3s will hopefully decrease the initial costs as well as enhance the virtual reality experience necessary to develop endoscopic sinus surgery skills.

Simulators have also been developed for use in temporal bone dissection and airway management. A virtual temporal bone dissection environment has been developed utilizing high-resolution, multimodal, and multiscale data sets. These data sets are then used to create visual, haptic, and auditory interfaces. This system allows the development of an environment in which temporal bone surgery can be learned in a way similar to that experienced with cadaver material. Eventually such technology may be available over the Internet. Simulators have also been developed as an assessment tool for resident airway management skills. Utilizing manikins, the residents were asked to manage two pediatric airway emergency cases. The authors conclude that medical simulation is useful for assessing individuals’ technical skills, that is, intubation, as well as related knowledge base.

ROBOTIC SURGERY

A robot can be defined as “a mechanical device that is controlled using a computer system.” Over the past decade, robotic surgery had transitioned from science fiction to common practice. Recently, systems have been developed for use with laparoscopic, open, and percutaneous surgical procedures. This type of device overcomes limitations that occur with a human assistant such as fatigue, tremor, and miscommunication between the surgeon and assistant. In addition, robotic systems add precision and help to improve visualization. Finally, robotics allows for telesurgery, in which a surgeon can operate at a location remote from the patient.

There are multiple types of robotic systems which will be described. With continued engineering advancements, the devices continue to evolve, with different ones designed to achieve a variety of surgical goals. Some are intended for an assistant’s role, some are designed to perform a procedure autonomously, and some are designed to be a conduit between the surgeon and the patient.

Although many robotic devices exist with a variety of intended applications, they can be separated into two general categories: offline and online systems. Offline robots are programmed to perform an entire procedure without using direct human interaction. This includes an orthopedic device, RoboDoc (Integrated Surgical Systems, Davis, CA), which once calibrated, performs bone drilling necessary for insertion of knee and hip replacements. This has been shown to drill more accurately than manual drilling. A newer offline system is MrBot, a device created for transperineal MRI-guided placement of radioactive seeds for prostate brachytherapy (Johns Hopkins University, Baltimore, MD). A newer offline system is a device

Figure 1 Patient with history of extensive endoscopic sinus surgery with resection of the middle turbinate and subsequent stenosis of right frontal sinus outflow tract. Note how image guidance is utilized to confirm the surgeon’s location with regard to the skull base, orbit, and frontal sinus outflow. The image-guidance findings must be correlated with all available anatomic landmarks.

Figure 2 Same patient shown in Figure 1 after endoscopic frontal sinusotomy (Draf Type IIb) is completed. Note location of probe and correlation with anatomic landmarks.
called the PAKY-RCM (Percutaneous Access to Kidney-Remote Center of Motion) (Johns Hopkins University, Baltimore, MD) for obtaining intrarenal access for percutaneous stone treatment. A radiotherapeutic device being used with increasing prevalence is the Cyberknife (Sunnyvale CA), which allows a robotic arm to deliver radiation from a linear accelerator to a specific lesion in the body from numerous different vectors based upon image guidance.19,21 With each of these described systems, the robot is calibrated with coordinates, usually employing image guidance. Once calibrated, the robotic system performs an autonomous task which is monitored by the surgeon and can be halted if there is concern of an untoward event.20

Online systems differ in that the surgeon has complete control over the device at all times.1 One such device that has been in use for the past decade is the AESOP, an acronym for Automated Endoscopic System for Optimal Positioning (Computer Motion, Goleta, CA).16 This is a remote robotic device which holds the camera during laparoscopic procedures. It can be manipulated by voice-activation, a foot pedal, or a handheld joystick. In the absence of surgeon commands, this device remains in a static position.

Recently, more complex online systems have been utilized with increasing frequency. These are “master/slave” telemanipulator systems. This consists of a “master” surgeon console where the operating surgeon sits and uses hand, foot, or voice controls to manipulate surgical instruments.22 The slave is the apparatus docked to the patient. This portion consists of robotic arms that contain and manipulate surgical instruments and an endoscopic camera. Hand controls are present at the master console and are used to manipulate the instruments using remotes.

Two systems have been developed to accomplish this and both have received FDA approval for general surgical applications.22,24 These systems, Zeus and da Vinci, were developed by separate companies which have since merged. Production of the Zeus system has been discontinued in favor of the da Vinci robot although existing machines are still in use. With Zeus (Computer Motion, Goleta, CA), the slave device consists of two robotic arms manipulated by the hand controls, containing the surgical instruments. The third arm is an AESOP device which controls the camera. Three-dimensional visualization is possible when polarizing glasses are used. All three of the arms are attached to the patient’s bed; and, therefore, when the position of the bed is altered, all robotic arms remain in a constant location relative to the patient.
