Notice: The authors and publisher have made every effort to ensure that the patient care recommended herein, including choice of drugs and drug dosages, is in accord with the accepted standard and practice at the time of publication. However, since research and regulation constantly change clinical standards, the reader is urged to check the product information sheet included in the package of each drug, which includes recommended doses, warnings, and contraindications. This is particularly important with new or infrequently used drugs. Any treatment regimen, particularly one involving medication, involves inherent risk that must be weighed on a case-by-case basis against the benefits anticipated. The reader is cautioned that the purpose of this book is to inform and enlighten; the information contained herein is not intended as, and should not be employed as, a substitute for individual diagnosis and treatment.

It has been a great pleasure to be associated with John Jacob Ballenger in the production of several recent editions of this book and to work with Phillip Ashley Wackym in the development and execution of this centennial edition of Ballenger’s Otorhinolaryngology Head and Neck Surgery. The central focus of the 17th Edition is the important role molecular medicine is playing in understanding the pathogenesis of disease and patient diagnosis and therapy in the first decade of the 21st century. The selection of the sectional editors and the senior authors for each chapter was based on their contribution of new knowledge to the subject matter of their sections and chapters through highly regarded research and their intellectual leadership of the specialty, thereby assuring that their contributions to this book are truly authoritative. The editorial aim was to encompass the important information in all of the specialties relating to disorders of hearing, balance, smell, taste, voice, speech and language that are the principal responsibilities of the 21st century otorhinolaryngologist head and neck surgeon and to organize and edit it into a comprehensive compendium with an absolute minimum of redundancy. In the last ten years, there has been a great deal of international cooperation in understanding and categorization of major disease entities and developing consensus on patient management based on these concepts; the fruits of these labors are to be found in the various sections of the book. The book is designed to satisfy the informational needs of developing specialists and specialists wanting to maintain their competence with a reader friendly source of contemporary knowledge. The extraordinary currency of this work is largely due to the short time between composition and printing which is a tribute to the publisher, Brian C. Decker, and his gifted staff. My gratitude goes foremost to Ashley Wackym for his leadership, creativity, brilliant intellect and just plain hard work but in full measure to the sectional editors, authors and illustrators who have made this centennial edition one that will give the reader information, pleasure and inspiration.

James B. Snow, Jr., M.D.
July 2008
FOREWORD

One hundred years ago William Lincoln Ballenger at the University of Illinois College of Physicians and Surgeons wrote the great American classic, Diseases of the Nose, Throat and Ear. The 17th Edition embraces a tradition, which embodies clear and concise writing with complementary full color illustrative material. As the original author expressed in his Preface for the First Edition, the current editors have endeavored to include material that one would find in a “textbook and an atlas.”

The editors have expanded this edition into 101 chapters, which offer a comprehensive compilation of the specialty of otorhinolaryngology head and neck surgery. The editors chose authors who are experts in their respective fields who have offered reliable and authoritative treatises of their subjects. Care was taken to present the scientific underpinnings of each discipline, which provide the basis for diagnosis and treatment. The authors have endeavored to include the evidence that underlies management of the disorders.

The addition of color plates throughout the chapters has added an important new dimension to this book distinguishing it in the field. The use of color not only conveys additional information rarely seen in a text of this magnitude but also enhances the appearance of the book. The illustration of surgical concepts and procedures in color carries on Ballenger’s original idea of adding an “atlas” to the text.

The six sections of this book cover the field of Otorhinolaryngology Head and Neck Surgery with thoroughness that includes not only the breadth of the specialty but the depth of knowledge in each of the disciplines. As it has for the last 100 years, this book provides a valuable foundation for the library of all otorhinolaryngologists head and neck surgeons.

Richard A. Chole, M.D., Ph.D.
July 2008
INTRODUCTION

One hundred years. An interval that is longer than the vast majority of us will live. After I was asked to serve as an editor of the seventeenth edition of Ballenger’s Otorhinolaryngology Head and Neck Surgery, with Dr. James B. Snow, Jr., I searched for and acquired a copy of the first edition of William Lincoln Ballenger’s Diseases of the Nose, Throat and Ear Medical and Surgical, which was published in 1908. I read portions of the original book and spent much time thinking about our field, our progress and our future opportunities.

It was an opportune time to do so. I was mid-career, approaching my fiftieth birthday and preparing to enter my second decade as a department chairman. My mentors and role models helped shape the person I am today; but, when Jim Snow asked me to work with him to develop the current edition, I was in the right time in my life and career to be able to try to synthesize what was needed for current and future students, young otorhinolaryngologists-head and surgeons and experienced surgeons who wanted to update their base of knowledge. Jim was the perfect person to lead me through this phase of my development. He is amazingly bright, organized, thoughtful and willing to be introspective. He has served as a brutally honest critic, enthusiastic supporter and father figure for me. Jim has taken my critical and analytical skills honed by Paul Ward, Brian McCabe, Bruce Gantz and Vicente Honrubia to another level, for which I will forever be grateful. We established a comfortable relationship in which each person could say exactly what was on his mind and then be confident that we would each incorporate the other’s view point in improving the book—that goal was always foremost in our minds. Jim was generous in seeking my vision, perspective and judgment. He treated me as an equal, thereby facilitating our work, and I now understand how this contributed to making this book exceptional. During the course of the development of this book, it was also a traumatic and difficult personal journey for Jim. His wife of 53 years, Sallie Lee Ricker Snow, valiantly fought and gracefully succumbed to cancer. Sallie was exceptionally kind and thoughtful and engaged in our community. She completed Jim as a person, and her loss saddened all of us who knew her.

Looking at the first edition was amazing. What were our predecessors thinking? What clinical challenges were the greatest for them and how could they advance and develop the field? What was the world like a century ago? The 1908 Nobel Prize in Physiology or Medicine was given to Ilya Ilyich Mechnikov of Russia and Paul Ehrlich of Germany in recognition of their work on immunity. Other notable events that year include: the first time the ball signifying the New Year was dropped in Times Square, New York; General Baden-Powell founded the Boy Scouts; Denmark, Germany, England, France, the Netherlands and Sweden signed the North Sea Accord; Mother’s Day was celebrated for the first time; the Lusitania crossed the Atlantic in a record four days and 15 hours; Robert E. Peary sailed from New York on his expedition to the North Pole; Bulgaria declared independence from the Ottoman Empire; Henry Ford introduced the Model T automobile; Albert Einstein presented his quantum theory of light; and, at age three, Hsuan-T’ung (Henry Pu-Yi) became the last Emperor of China. Clearly much has changed in our world. It is also true that much has changed between the first and seventeenth editions of this book.

Although a tremendous amount of work was completed during the two years that I spent with Jim in designing and editing this book, I am proud to have played a role in this centennial edition of Ballenger’s Otorhinolaryngology Head and Neck Surgery. I hope that all those using the printed book and its online version will benefit from its organization and content; and, more importantly, I hope that a multitude of patients will benefit from the information contained in this edition.

P. Ashley Wackym, M.D.
July 2008
DEDICATION

This centennial edition is dedicated to Sallie Lee Ricker Snow, wife, mother, artist, friend and colleague, whose keen intellect and faithful companionship served as the inspiration for this and several recent editions.

James B. Snow, Jr., M.D.

This work is dedicated to my wife Jeremy and my son Ashton from whom I have stolen innumerable hours in pursuit of the highest standard of academic otorhinolaryngology-head and neck surgery, and Paul Ward—the teacher who has influenced me the most.

P. Ashley Wackym, M.D.

CONTRIBUTORS

Arman Abdalkhani, MD
Resident
Department of Otolaryngology–Head and Neck Surgery
Stanford University School of Medicine
Stanford, California
*Embryology, Anatomy and Physiology of the Nose and Paranasal Sinuses*

Sumit K. Agrawal, MD
Fellow (Otology/Neurotology)
Stanford University School of Medicine
Stanford, California
*Vestibular Schwannomas and Other Skull Base Neoplasms*

Ian J. Alexander, MD
Fellow
Cosmetics Program
Facial Plastic Surgery and Otolaryngology
Geisinger Medical Center
Danville, Pennsylvania
*Wound Healing and Flap Physiology*

George Alexiades, MD
Associate Adjunct Professor
Department of Otolaryngology–Head and Neck Surgery
New York Eye and Ear Infirmary
New York, New York
*Microtia, Canal Atresia and Middle Ear Anomalies*

John W. Alldredge, MD
Resident
Department of Otolaryngology–Head and Neck Surgery
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
*Endoscopic Surgery of the Skull Base, Orbits and Benign Sinonasal Neoplasms*

Kenneth W. Altman, MD, PhD
Associate Professor
Department of Otolaryngology
Mount Sinai School of Medicine
New York, NY
*Laryngopharyngeal Reflux and Laryngeal Infections and Manifestations of Systemic Diseases*

Bryan T. Ambro, MD, MS
Assistant Professor
Division of Facial Plastic and Reconstructive Surgery
Department of Otolaryngology–Head and Neck Surgery
University of Maryland Medical Center
Baltimore, Maryland
*Rejuvenation of the Lower Face and Neck*

Manali Amin, MD
Associate in Otolaryngology
Department of Otolaryngology
Children’s Hospital of Boston
Boston, Massachusetts
*Anatomy and Physiology of the Oral Cavity*

Raghu S. Athré, MD
Resident
Department of Otolaryngology–Head and Neck Surgery
University of Texas Southwestern Medical Center at Dallas
Dallas, Texas
*Cellular Biology of the Immune System*

Nafi Aygun, MD
Assistant Professor
Division of Neuroradiology
Department of Radiology
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Imaging of the Nasal Cavities, Paranasal Sinuses, Nasopharynx, Orbits, Infratemporal Fossa, Pterygomaxillary Fissure and Base of Skull*
Contributors

Karen Jo Doyle, MD, PhD
Professor in Residence
Department of Otolaryngology–Head and Neck Surgery
University of California Davis
Sacramento, California
*Idiopathic Sudden Sensorineural Hearing Loss*

Ward R. Drennan, PhD
Postdoctoral Fellow
Auditory Prosthesis Perception and Psychophysics Laboratories
Kresge Hearing Research Institute
University of Michigan School of Medicine
Ann Arbor, Michigan
*Cochlear Implant Coding Strategies and Device Programming*

Marc G. Dubin, MD, FACS
Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Revision Paranasal Sinus Surgery and Surgery of the Frontal Sinus*

Garth D. Ehrlich, PhD
Professor of Microbiology, Immunology and Otolaryngology
Professor and Vice Chairman, Human Genetics
Drexel University College of Medicine
Executive Director
Center for Genomic Sciences
Allegheny-Singer Research Institute
Pittsburgh, Pennsylvania
*Biofilms and Their Role in Ear and Respiratory Infection*

Marc D. Eisen, MD, PhD
Assistant Clinical Professor
Division of Otolaryngology
Department of Surgery
University of Connecticut School of Medicine
Farmington, Connecticut
*Central Auditory Processing and Functional Neuroimaging*

Mark R. Elstad, MD
Professor
Department of Internal Medicine
University of Utah School of Medicine
Salt Lake City, Utah
*Bronchology*

Jose N. Fayad, MD
Associate
House Clinic
House Ear Institute
Los Angeles, California
*Microtia, Canal Atresia and Middle Ear Anomalies*

Adam E. Flanders, MD
Consultant/Neuroradiology
Professor of Rehabilitation Medicine
Division of Neuroradiology/ENT
Department of Radiology
Thomas Jefferson University Medical College
Philadelphia, Pennsylvania
*Imaging of the Oral Cavity, Pharynx, Salivary Glands and Neck*

David R. Friedland, MD, PhD
Associate Professor and Chief
Division of Otology and Neuro-Otologic Skull Base Surgery
Department of Otolaryngology and Communication Sciences
Medical College of Wisconsin
Milwaukee, Wisconsin
*Cranial and Intracranial Complications of Acute and Chronic Otitis Media Menière Disease, Vestibular Neuritis, Benign Paroxysmal Positional Vertigo, Superior Semicircular Canal Dehiscence and Vestibular Migraine Perilymphatic Fistulae*

Rick A. Friedman, MD, PhD
Neurootologist, House Ear Clinic
Chief, Section on Hereditary Disorders of the Ear
House Ear Institute
Los Angeles, California
*Hereditary Hearing Impairment Molecular Biology of Hearing and Balance*

Headache and Facial Pain
The temporal bone (TB) is a complex portion of the skull base that contains the labyrinth with its nerve supply (cranial nerve VIII) and also other cranial nerves such as the facial, trigeminal, vagus, glosso-pharyngeal, spinal accessory, and hypoglossal nerves. A thorough knowledge of the gross and microscopic anatomy of the TB and the physiology of the labyrinthine sense organs is essential for the specialist who strives for accuracy in diagnosis and precision in surgery of the TB. This knowledge is gained first from dissection of cadaveric whole TB specimens but is greatly enhanced by study of prepared histologic sections from normal and pathologic TB.

OSTEOLOGY

Four major components of the TB contribute to the skull base: the squamous, tympanic, mastoid, and petrous.

The *squamous* portion of the TB provides attachment for the temporalis muscle, which is bounded inferiorly by the temporal line (Figure 1). The temporal line provides an external landmark for the floor of the middle cranial fossa. The zygomatic process projects forward from the lower portion of this bone, and together they form the anterior border of the mandibular fossa, which receives the condyle of the mandible.

The *tympanic* portion of the TB is an incomplete cylindrical portion of the TB that, together with the squamosal portion, forms the medial part of the external auditory canal. This portion of the external auditory canal is 2 cm in length by 1 cm in diameter. Its anterior boundary is the posterior limit of the mandibular fossa; medially, its border is the tympanic membrane. The posterior part fuses with the mastoid component of the TB at the tympanomastoid suture. Failure in development of this part of the TB is responsible for congenital aural atresia, a form of conductive hearing loss correctable by surgery.

The major portion of the TB formed by the *mastoid* portion attributes its large size to extensive pneumatization. The mastoid process projects posteriorly and inferiorly behind the external auditory meatus and serves as the attachment for the sternocleidomastoid muscle. A deep groove in its inferior aspect houses the posterior belly of the digastric muscle, which is innervated by the facial nerve. The superior surface of the mastoid compartment is formed by a thin plate of bone known as the tegmen mastoidea. Posteriorly, it forms the anterior plate of the posterior cranial fossa and is indented by a groove for the sigmoid sinus. The superior and inferior petrosal sinuses travel medially along the superior and inferior aspects of this part of the TB.

The *petrous* portion of the TB forms its medial part inferior to the middle cranial fossa; posteriorly, it forms the anterior surface of the posterior cranial fossa (Figure 2). The superior surface of the petrous bone is highlighted by the prominence of the superior semicircular canal, a landmark in surgery within the middle cranial fossa. Anterior to this portion of the petrous bone is the hiatus for the greater superficial petrosal nerve, which joins with the geniculate ganglion of the facial nerve. In some temporal bones, this hiatus is enlarged, and the geniculate ganglion may be exposed in the middle cranial fossa. Anterior and medial to this region is a concave area for the semilunar ganglion of the trigeminal nerve. On the posterior surface of the petrous bone are several important landmarks. The most obvious aperture is the...
internal auditory meatus (canal) that transmits the seventh and eighth cranial nerves as well as the labyrinthine artery or loop of the anterior inferior cerebellar artery (Figure 3). The lateral end (fundus) of the internal auditory canal (IAC) is divided horizontally by the falciform crest. The superior compartment contains the facial nerve anteriorly and the superior division of the vestibular nerve posteriorly (Figure 4). The inferior compartment transmits the cochlear nerve anteriorly and the inferior division of the vestibular nerve posteriorly. The endolymphatic sac may be found in a depression covered by a bony shelf (operculum) anterior to the sigmoid groove. It narrows down into the vestibular aqueduct as the intraosseous endolymphatic sac. The depression for the semilunar ganglion and the fifth cranial nerve on the anterior surface of the petrous bone also carries the sixth cranial nerve through a dural canal referred to as Dorello’s canal. These two nerves may be involved in inflammatory or neoplastic processes that occupy the petrous apex (PA) and are responsible for the clinical syndrome known as Gradenigo syndrome (fifth cranial nerve pain, diplopia from lateral rectus muscle palsy, and otorrhea).

**AUDITORY SYSTEM**

**External Ear**

The external or outer ear is that portion of the ear that is lateral to the tympanic membrane (Figure 5). It consists of the external auditory canal as well as the auricle and cartilaginous portion of the ear.

The auricle is a semicircular plate of elastic cartilage characterized by a number of ridges or grooves. The major ridges of the auricle are the helix and antihelix, the tragus and antitragus, which surround the concha, which is the scaphoid depression posterior to the external auditory meatus. The cartilage of the external auditory meatus is continuous with that of the outer portion of the ear canal and auricle.

The external auditory canal is made up of a cartilaginous extension of the auricle in its outer half and the mastoid and tympanic portion of the TB in its medial half. It is bounded medially by the tympanic membrane and is lined with skin that is thin with little subcutaneous tissue medially but laterally contains numerous hair follicles and ceruminous and sebaceous glands. The bony external auditory canal averages 3.5 cm in length, with a diameter of 1 cm. The tympanic membrane is composed of three layers: the outer squamous epithelial layer, the medial mucosal layer facing the middle ear, and the fibrous layer or tunica propria, forming the substance of the tympanic membrane. The fibrous layer gives the tympanic membrane its shape and consistency. Radial fibers of the tunica propria insert into the manubrium, circumferential fibers providing strength without interfering with vibration, whereas tangential fibers reinforce the architecture of the tympanic membrane. These physical characteristics are important for the vibratory characteristics necessary for sound transmission.

The tympanic membrane is identified by a prominent landmark, the manubrium of the
brane configurations that obscure the round window niche; U = umbo.

Figure 6 Photograph of a normal left tympanic membrane. I = long process of incus; M = malleus; R = round window niche; U = umbo.

malleus, which is limited superiorly by its lateral or short process and inferiorly by a rounded end referred to as the umbo (Figure 6). The umbo forms the deep apex of the conical shape formed by the tympanic membrane. The tympanic membrane is incomplete superiorly, where it lacks a fibrous layer in the portion superior to the short process of the manubrium. Since it lacks a fibrous layer, this portion is called the pars flaccida (Shrapnell’s membrane). The major or inferior portion of the tympanic membrane is referred to as the pars tensa.

Middle Ear

The space between the tympanic membrane and the bony capsule of the labyrinth in the petrous portion of the TB contains the ossicular chain with its associated muscles, the aperture of the eustachian tube, and the vascular system. The tympanic cavity is divided into the epitympanic, mesotympanic, and hypotympanic regions. The hypotympanic portion is that portion of the middle ear that lies inferior to the aperture of the eustachian tube and the round window niche (RWN). This portion of the middle ear contains various bony trabeculae and the bony covering of the jugular bulb. This bony surface may be dehiscent, exposing the jugular bulb in the hypotympanic region. Inferiorly, a small channel (the inferior tympanic canaliculus) transmits Jacobson nerve (a branch of cranial nerve IX).

The mesotympanic portion of the middle ear is limited superiorly by the horizontal portion of the facial canal and inferiorly by the RWN. This region contains the oval and round windows, the stapes bone, the stapedius muscle posteriorly, and the canal for the tensor tympani muscle anteriorly. The oval window is kidney bean shaped with a convex superior rim and a concave inferior rim. In the oval window, the footplate of the stapes bone is held in place by the annular ligament. The RWN forms a deep recess often covered with various mucous membrane configurations that obscure the round window membrane (RWM). The RWM is a fibrous membrane covered with a layer of mucosa that is roughly kidney bean shaped, with a major component anterior and inferior and a minor component located posteriorly and horizontally in the RWN. Posteriorly, in the mesotympanicum there are two bony recesses of clinical importance. The recess lateral to the vertical segment of the facial canal is called the facial recess. The space medial to the facial canal is called the sinus tympani (Figure 7). These two recesses are important clinically as they frequently harbor chronic middle ear infection and must be controlled in surgery. The facial recess also provides access to the middle ear space and RWN in those procedures in which the ear canal wall is preserved (ie, intact canal wall mastoidectomy, cochlear implantation). A bony projection from the facial canal (pyramidal eminence) contains the tendon of the stapedius muscle before its insertion into the neck of the stapes bone. The most anterior portion of the middle ear space is called the protympanum and is bordered superiorly by the orifice of the eustachian tube and anteriorly by the canal for the internal carotid artery (see Figure 7).

The epitympanum is the portion of the middle ear that is limited superiorly by the bony roof of the middle ear called the tegmen tympani. This bony landmark is continuous posteriorly as the tegmen mastoidea. The medial wall of the epitympanum is formed by the bony prominence of the lateral and superior semicircular canal ampullae as well as the epitympanic portion of the facial (fallopian) canal. The head and neck of the malleus and its articulation with the body and short process and a portion of the long process of the incus occupy most of the space in the epitympanum. These two ossicular masses are held in place by ligaments anteriorly and posteriorly to provide an axis of rotation for the ossicular chain (Figure 8). The epitympanic space communicates posteriorly through a narrow opening called the aditus ad antrum to the central mastoid tract of the mastoid cavity.

Anteriorly, the epitympanum is separated at the cochleariform process from an anterior epitympanic cell of variable size by a bony and mucous membrane barrier, which may completely or incompletely separate the two compartments. This anterior epitympanic space is formed by pneumatization from the protympanum (see Figure 8). The anterior epitympanic space is also important surgically as it may contain inflammatory tissue (ie, cholesteatoma) that has extended from the protympanum.

Auditory Ossicles. Sound pressure energy is transmitted from the tympanic membrane across the middle ear space by the ossicular chain composed of the malleus, incus, and stapes (Figure 9). The head of the malleus and body of the incus function as a unit suspended by ligaments in the epitympanum. The tip of the long process of the incus articulates at a right angle with the head of the stapes so that the sound energy transmission initiated by medial displacement of the tympanic membrane is carried by the parallel displacement of the elongate processes of the malleus and incus to the head, crura, and footplate of the stapes (see Figure 9). Since the surface area of the tympanic membrane is larger than that of the stapes footplate by a ratio of 25 to 1, the sound pressure density in the oval window and the inner ear fluids is similarly increased. Maintaining this ratio by various reconstructive methods constitutes an important principle in middle ear surgery. The stapes therefore acts in a piston-like fashion in the oval window. The stapes bone is shaped like a stirrup with a head, neck, and footplate or base. The crura are bowed, the posterior one more so than the anterior, and fused with the footplate, which is formed from both otic capsule and periosteal bone. These auditory ossicles are controlled to some degree by two middle ear muscles, the tensor tympani and the stapedius. The tensor tympani muscle is housed in a bony semicircular in the anterior mesotympanic

Figure 7 This axial computed tomographic scan of the temporal bone illustrates a normal mastoid cell system (MA), the horizontal segment of the internal carotid artery (ICA), the jugular bulb (JB), the sigmoid sinus (SS), and a nonpneumatized petrous apex (PA). C = basal turn of the cochlea; FN = facial nerve; T = sinus tympani.

Figure 8 This horizontal cut through a celloidin-embedded temporal bone illustrates the relationship of the facial nerve (FN) to the superior division of the vestibular nerve (VN) in the internal auditory canal. The axis of rotation of the head of the malleus (M) and body of the incus (I) with their ligamentous attachments in the epitympanum is shown. AE = anterior epitympanic space ventilated into the protympanum (*); LC = lateral semicircular canal crista and ampulla; PC = posterior semicircular canal; C = endosteum of the cochlea (basal turn); TT = tensor tympani tendon; G = geniculate ganglion.
just superior to the orifice of the eustachian tube (Figure 10). The muscle converges posteriorly into a tendinous segment that is anchored at the cochleariform process and turns abruptly laterally to insert on the neck of the malleus. The tensor tympani is innervated by a branch of the fifth cranial nerve. Its motoneurons are located centrally in the parvocellular division of the trigeminal motor nucleus, and its action causes the drumhead to be pulled medially, thus raising the resonant frequency of the sound conduction system.

The stapedius muscle arises within either its own or the falloplian canal and is accompanied by the motor portion of the facial nerve. It converges superiorly and anteriorly to form the stapedius tendon, which emerges through the pyramidal eminence to insert at the neck of the stapes. The stapedius muscle is innervated by a branch of the seventh nerve, and its motoneurons are located in the brainstem in the interface between the facial nucleus and the lateral superior olivary nucleus. Contraction of the stapedius muscle displaces the stapes posteriorly and attenuates sound transmitted by the ossicular chain. Since reflex contraction of the stapedius muscle is activated by sound, it is regarded as a protective mechanism for the cochlea.

Eustachian Tube. The eustachian tube is an essential communication between the nasopharynx and the middle ear (Figure 11). It is responsible for pneumatization of the middle ear and the mastoid and for maintaining normal pressure between the middle ear and the atmosphere. It represents the pharyngeal extension of the first branchial arch and extends from the lateral wall of the nasopharynx.

The skeleton of the medial three-fourths of the eustachian tube is cartilage that is surrounded by soft tissue, adipose tissue, and respiratory epithelium. The cartilage of the eustachian tube, which is hook shaped on cross-section, is stabilized and displaced by contraction of the tensor veli palatini and levator veli palatini muscles on swallowing or yawning. The eustachian tube is thereby opened, allowing for pressure equalization. The lining epithelium of the cartilaginous portion is similar to that of the pharynx with pseudostratified columnar cell epithelium and many mucus glands. Posterior to the union of the cartilaginous and osseous portion of the eustachian tube where the isthmus is located, the mucosa undergoes transition to cuboidal or low columnar cell epithelium similar to the tympanic cavity epithelium. Neoplastic compression of the eustachian tube lumen near its pharyngeal orifice (Rosenmüller fossa) will cause fluid to fill the middle ear space (serous otitis media), usually in an adult patient (see Figure 11). Investigation of this occult region by endoscopy, radiologic imaging, and biopsy is necessary in such instances.

In some patients fullness in the ear, autophony without hearing loss and a normal eardrum may be produced by an overly patent eustachian tube. Such patency of the eustachian tube may be caused by a decrease in the fat cells surrounding its cartilaginous segment associated with weight loss.

Nerve Supply of the External and Middle Ear. The auricle and the external auditory canal receive the sensory nerve branches from the fifth nerve via the auriculotemporal nerve and the greater and lesser auricular nerves. Branches from the glossopharyngeal and vagus nerves also contribute to this innervation. The branch of the vagus nerve is referred to as Arnold nerve, which travels in the posterior part of the ear canal in the posterior part of the tympanomastoid suture. When this nerve is stimulated, it produces a cough reflex as when the external auditory canal is being cleaned with an instrument. It may also participate in heralding a neoplastic or infectious process in distant regions of the aerodigestive tract also innervated by the vagus nerve (ie, larynx, hypopharynx) when pain is referred to the ear.

The main innervation to the middle ear space is through the tympanic plexus and Jacobson nerve, which receives a major contribution from the glossopharyngeal nerve through the inferior tympanic canaliculus. This nerve travels in a bony sulcus or canal over the promontory along with the inferior tympanic artery anterior to the oval window and finally anteriorly to become the lesser superficial petrosal nerve. This nerve ultimately carries the fibers of the preganglionic neurons of the ninth nerve to the otic ganglion, where they synapse with postganglionic neurons and are carried over the auriculotemporal nerve to the parotid gland. The glossopharyngeal nerve provides sensory innervation to the...
norrhea8 offers timely diagnosis and treatment for
partment in adult life (Figure 12). Their clinical
where they may enlarge with time into arachnoid
sinuses. Aberrant arachnoid villi in the middle or
of cerebrospinal fluid (CSF) into the dural venous
arachnoid villi whose function is the circulation
may become important in adult life. Such are the
near pneumatized portions of the TB where they
recesses of the mastoid compartment and particu-
to know as a guide in tracing infection into deep
may considerably and are important for the surgeon
to know as a guide in tracing infection into deep
cesses of the mastoid compartment and particu-
larly the PA.
Normal structures may be aberrantly located
near pneumatized portions of the TB where they
may become important in adult life. Such are the
arachnoid villi whose function is the circulation
of cerebrospinal fluid (CSF) into the dural venous
sinuses. Aberrant arachnoid villi in the middle or
posterior cranial fossa may be located adjacent to
the bone of pneumatized areas of the skull base
where they may enlarge with time into arachnoid
granulations which erode into the mastoid com-
partment in adult life (Figure 12). Their clinical
presentation as spontaneous CSF otorrhea or rhi-
norrea8 offers timely diagnosis and treatment for
the astute clinician (Figure 13). The prevention of
intracranial morbidity (meningitis, brain abscess)
from acute infection in these bony cavities is the
goal of early recognition.
Cell tracts arising from the middle ear space
are also important for the surgeon. These cell
tracts, particularly those that may lead to air cell
development in the PA, are those that course
inferior to the labyrinth or those that extend
around the canal of the internal carotid artery
(see Figure 14). Extensive pneumatization in
the development of the PA may create air cells
that can become isolated when the cell tract is
obliterated by bone or fibrous tissue leading to
the formation of cholesterol cysts over a period
of many years. Over time, these cysts erode the
pharyngeal tonsillar fossa and may be responsi-
ble for referred otalgia from neoplasms in
this organ. Such referred ear pain is commonly
encountered after tonsillectomy. Sympathetic
fibers from the carotid plexus also contribute to
the tympanic plexus. The chorda tympani nerve,
which is a sensory branch of the facial nerve, will
be discussed in the section “Facial Nerve.”

**Mastoid Compartment.** The air cell system
of the mastoid bone represents an extension of
the air compartment in the middle ear from the first
pharyngeal pouch. This process occurs in de-
velopment of the TB and may result in a variable
degree of pneumatization in the mastoid com-
partment (see Figure 7). Recurrent infection in
the middle ear and mastoid has been identified
as a factor that may limit the extent of pneu-
matization of the mastoid air cell system, whereas
absence of such infection may favor full develop-
ment of the air cell system. The air cells in the
mastoid compartment extend from the aditus ad
antrum in the epitympanum to the central mas-
toid tract (antrum) from which further extension
in several directions may occur.7 The posterior
superior cell tract extends medially at the level
of the superior semicircular canal toward the PA,
and the posterior medial cell tract extends toward
the PA at the level of the posterior semicircular
canal. The supralabyrinthine cell system extends
medially superior to the labyrinth, whereas the
retrofacial cell system extends posteriorly and
inferiorly along the bony ear canal to pneuma-
tize the mastoid tip. These cell tracts may vary
considerably and are important for the surgeon
to know as a guide in tracing infection into deep
cesses of the mastoid compartment and particu-
larly the PA.

**Figure 13** This coronal CT demonstrates fi-
ltering of a mastoid compartment (*) with CSF from a middle fossa
arachnoid granulation (arrow).

**Figure 14** Axial CT in a patient with an expanding cho-
lesterol cyst in the petrous apex (*) while the contralateral
temporal bone illustrates pneumatization of the apex region
(arrow) which leads to cyst formation. C = mastoid compartment; J = jugular foramen.
magnetic resonance imaging) is especially sensi-
tive to the identification of pathology in the PA.
Since the composition of the PA can include air
cells (see Figure 14), bone marrow (Figure 7),
the internal carotid artery (Figure 7), and the car-
tilage of the foramen lacerum, the list of lesions
that occur here is lengthy. Cholesterol cysts and
genital cholesteatomas are the most common;
however, infection, bone marrow neoplasms,
cartilage tumors, metastatic malignancies, neu-ogenic tumors, and aneurysms of the internal
carotid artery have been reported. Clinical signs
of a progressive lesion in the PA relate to nearby
structures: eustachian tube obstruction, facial pain
or anesthesia, and lateral rectus muscle palsy.

**Inner Ear**
The petrous portion of the TB houses the laby-
rinth with its attendant sensory structures respon-
sible for auditory and balance function. Within
the bony labyrinth is contained the membranous
labyrinth, which represents a continuous series
of epithelial-lined tubes and spaces of the inner
ear containing endolymph and the sense organs
of hearing and balance. The membranous laby-
rinth can be divided into three regions that are
interconnected: the pars superior or the vestibular
labyrinth with the exception of the saccule, the
pars inferior (cochlea and the saccule), and the
dehydraulic duct and sac. All the sense organs
of the labyrinth have in common that they con-
tain hair cells with rigid cilia and are innervated
by afferent and efferent neurons.10,11 Displace-
ment of the cilia of the hair cells is responsible
for opening potassium and calcium channels that
initiate the electrical potential within the hair cell
that is then leaked into the afferent neuron and
carried to the brainstem.

**Cochlea.** The cochlear duct, the auditory por-
tion of the labyrinth, extends approximately 35
mm.12 The cochlear duct and associated sensory
and supportive structures assume a form of a
spiral similar to a snail shell of 2.5 to 2.75 turns
(see Figure 15). This allows the long cochl ear duct
to be contained in a small space. A cross-section
of a cochlear turn (Figure 16) demonstrates the
essential structures in this sense organ. The scala
media or cochlear duct containing endolymph is triangular in shape in cross-section. The basilar membrane forms the horizontal limb of the triangle, Reissner membrane, the superior limb, and the stria vascularis with spiral ligament on the vertical side. The cochlear duct is filled with a fluid referred to as endolymph, whereas the fluid in the scala vestibuli and scala tympani is perilymph. Perilymph of the two scalae communicates through the helicotrema at the apex of the cochlea (Figure 17). All the structures of the cochlear duct and, particularly, the basilar membrane have a morphologic gradient whereby the width of the basilar membrane is narrowest at the basal end and widest at the apex. The spiral ligament and epithelial elements in the organ of Corti also have a morphologic gradient from base to apex (see Figure 15). This morphologic gradient, to a large degree, determines the location of maximal stimulation of the basilar membrane and inner hair cells by a given tone or frequency that is introduced to the inner ear. In this way, high frequencies are located at the base and low frequencies at the apex, with the frequency scale laid out in an orderly fashion over the remainder of the basilar membrane. The cochlear duct ends in a blind pouch (cecum) that is located near the RWM.

Perilymph of the scala vestibuli fills the vestibule under the stapes footplate. This perilymphatic compartment extends up the scala vestibuli of the cochlea and communicates with the perilymph in the scala tympani, which extends down the cochlea to terminate at the RWM. The perilymphatic compartment also communicates with the subarachnoid space through the periotic duct by way of the cochlear aqueduct that is filled with a trabecular meshwork of connective tissue capable of allowing some exchange of CSF and perilymph. However, perilymph is primarily formed by filtration from the vascular network in the spiral ligament.

The organ of Corti is a complex sense organ that contains inner and outer hair cells and supporting cells resting on the basilar membrane, with the ciliated ends of the hair cells protruding into or near a covering structure, the tectorial membrane (Figure 18). The apical portions of the hair cells are anchored in the cuticular plate, with the stereocilia (usually 100 to 150 per cell) protruding through the cuticular plate. The stereocilia of the outer hair cells make contact with the tectorial membrane, whereas the stereocilia of the inner hair cells lie free in the endolymphatic space inferior to the tectorial membrane. There are a single row of inner hair cells and three to five rows of outer hair cells. These cells differ morphologically in that the inner hair cells are more flask-shaped and tightly surrounded by supporting cells and have stereocilia that are arranged in a linear fashion, whereas the outer hair cells are columnar and incompletely surrounded by phalangeal or supporting cells lying free in the perilymph of the organ of Corti. The stereocilia of the outer hair cells form an inverted "W," and a basal body representing a rudimentary kinocilium is located on the spiral ligament side of the ciliary tuft. The inner hair cells are supported by interphalangeal cells, whereas the outer hair cells are supported by Deiters cells inferiorly and laterally by Hensen cells. The tectorial membrane is anchored medially at the limbus and attached to the Hensen cells laterally by a fibrous net. The basilar membrane and tectorial membrane are displaced vertically by the traveling wave created by sound energy delivered to the oval window. Since the fulcrum of these two structures is separate, they will slide horizontally when stimulated, resulting in a shearing action between the tectorial membrane and the cuticular plate. The resultant displacement of stereocilia initiates an electrical event in the hair cell. The organ of Corti contains approximately 15,500 hair cells, with about 3,500 of them being inner hair cells and 12,000 being outer hair cells. These hair cells are innervated by afferent and efferent neurons in a complex but orderly manner. The afferent neurons to the auditory sense organ are bipolar neurons referred to as spiral ganglion cells that are located in Rosenthal canal of the bony modiolus. Approximately 30,000 spiral ganglion cells innervate the human organ of Corti. The spiral ganglion takes the form of clusters of ganglion cells throughout the extent of the length of the cochlea. Ninety to 95% of the spiral ganglion neurons are type I neurons, which are large and myelinated and project a single dendrite directly to an inner hair cell. Approximately 10 to 20 type I spiral ganglion cells innervate one inner hair cell (Figure 19). These form the major

**Figure 19** Schematic of the organ of Corti summarizing the efferent (dark) and afferent clear innervation termination. I = type I spiral ganglion cell afferents; II = type II spiral ganglia cell afferents.
afferent input from stimulation of the organ of Corti. Type I ganglion cells degenerate readily following injury to the dendrite. The remaining 5% of afferent neurons in the spiral ganglion are type II ganglion cells, which are smaller and unmyelinated and have very thin distal processes. The dendrites of these type II neurons cross the tunnel space along its floor enveloped by pillar cell processes and form spiral bundles between Deiters cells. These dendrites then course apically between Deiters cells to innervate several to many outer hair cells per type II dendrite. A type II ganglion survives following injury to its dendrite.

The axons of the spiral ganglion cells project to the cochlear nucleus complex, which has anteroventral and posterovernal divisions of the ventral cochlear nucleus and the dorsal cochlear nucleus. Each type I afferent neuron bifurcates and also sends a trifurcating branch to the dorsal cochlear nucleus in an orderly fashion according to frequency.12 Apical turn neurons terminate in the most medial portion of the nuclear complex, whereas the basal turn neurons terminate laterally. Remaining frequency projections are ordered between these two regions of the cochlear nucleus. The central termination of the type II ganglion cells is not known largely because the small caliber axons are difficult to trace for long distances.

This frequency organization of the auditory pathway characterizes the remainder of the afferent pathway from end organ to cortex. Another feature of the afferent auditory pathway is that the numbers of neurons involved at the various auditory pathway from one cochlea. Numerals indicate order of neuron units in the pathway. VCN = ventral cochlear nucleus; DCN = dorsal cochlear nucleus; SO = lateral superior olivary nucleus; ASO = accessory superior olivary nucleus; IC = inferior colliculus; Retic. form. = reticular formation. (Reproduced with permission from reference 17.)

Figure 20 Diagram of the neuronal linkage that serves the afferent auditory pathway from one cochlea. Numerals indicate order of neuron units in the pathway. VCN = ventral cochlear nucleus; DCN = dorsal cochlear nucleus; SO = lateral superior olivary nucleus; ASO = accessory superior olivary nucleus; IC = inferior colliculus; Retic. form. = reticular formation. (Reproduced with permission from reference 17.)

Although there are 30,000 spiral ganglion cells in the monkey auditory nerve, 88,000 neurons are found in one cochlear nucleus in the primate. One superior olivary complex contains 34,000 neurons, whereas the nucleus of the lateral lemniscus has 38,000 neurons, and at the inferior colliculus level there are almost 400,000 neurons on each side and at the medial geniculate body 500,000 neurons. The auditory cortex has approximately 10 million neurons.

A brief description of the afferent auditory pathway follows (Figure 20).17 The cells of the dorsal cochlear nucleus project axons to the dorsal acoustic stria, which crosses the midline and ascends in the contralateral lateral lemniscus to terminate in the dorsal nucleus of the lateral lemniscus and the inferior colliculus, particularly its inferior half. The cell bodies of the ventral cochlear nucleus project axons to the ipsilateral accessory and main superior olivary nuclei and to the medial dendrites of the contralateral accessory olive. The neurons of the accessory olive have bipolar dendrites arranged horizontally. This arrangement is favorable to receive input from projections of both cochlear nuclei. As such, it is an important nuclear "way-station" for determining sound localization. Some fibers of the intermediate and ventral cochlear striae travel beyond the superior olivary complex and enter the contralateral lateral lemniscus to terminate in the inferior colliculus. The superior olivary complex is thought to function as both a relay station for the auditory pathway and as a reflex center. The best known reflex mediated through the superior olive is the stapedius reflex. Stapedius muscle motoneurons are located in the interface between the superior olivary and the facial nerve nuclei. The accessory superior olive projects bilaterally in the lateral lemnisci to terminate in the dorsal nuclei of the lateral lemniscus and the inferior colliculi. The lateral superior olive projects homolaterally in the lateral lemniscus to terminate in the dorsal nucleus of the lateral lemniscus and also in the inferior colliculus. No neurons from the superior olivary nuclei project beyond the inferior colliculus.

Projections from the inferior colliculus are primarily to the medial geniculate body. However, some projections to the medial geniculate body are received from the nuclei of the lateral lemniscus. All ascending neurons terminate in the medial geniculate body so that the final projection pathway to the auditory cortex, which is a major one, is from the medial geniculate body. Furthermore, the only commissural or interconnections between the two sides of the auditory pathway are at the superior olivary level, the level of the nuclei of the lateral lemniscus, and the inferior colliculus. No commissural projections are present superior to the inferior colliculus.

The ascending auditory pathway, although composed of four to five neurons in the linkage from end organ to auditory cortex and having an increasing volume of neural units active at each level, nevertheless is precisely organized according to the frequency scale and project bilaterally but predominantly in a contralateral pathway to the auditory cortex.

**Efferent Auditory Pathways.** Paralleling the afferent auditory pathway is a descending

**CHAPTER 1 / Anatomy of the Auditory and Vestibular Systems**

Figure 21 Diagram of the descending (efferent) auditory pathway. IC = inferior colliculus; DCN = dorsal cochlear nucleus; VCN = ventral cochlear nucleus; ASO = accessory superior olivary nucleus; SO = lateral superior olivary nucleus. (Reproduced with permission from reference 17.)

The next neuron in the descending chain is located in peripheral regions of the inferior colliculus and the nuclei of the lateral lemniscus. These projections terminate in brainstem neurons that give rise to efferent neurons projecting to divisions of the cochlear nucleus and to neurons that give rise to the third and final neuron in the descending auditory pathway, the olivocochlear bundle, which innervates the organ of Corti.18,19

The olivocochlear bundle has both an ipsilateral and a contralateral limb or component (Figure 22). The neurons, which number

**Figure 22 Drawing of the olivocochlear efferent pathway.** See text for a description. (From reference 19.)
approximately 1,000 to 3,000, arise from neurons located within and near the superior olivary complex. The contralateral limb of the olivocochlear bundle forms a major part of the efferent bundle, accounting for approximately three-fourths of the number of efferent neurons projecting to the organ of Corti in one ear. These axons arise from small neurons located near the accessory olivary nucleus, ascend in the brainstem, and cross the midline at the level of the facial genu below the floor of the fourth ventricle. They are joined by the smaller ipsilateral component, which arises from similar olivary and periolivary neurons of the ipsilateral superior olivary nucleus before joining the contralateral limb as it enters the vestibular nerve root. As it leaves the brainstem in the vestibular nerve, the bundle gives off collateral branches to the ventral cochlear nucleus and exits the vestibular nerve within the IAC just distal to the saccular ganglion. It then enters Rosenhthal canal, where it travels perpendicular to the spiral ganglion cells and their dendrites, forming the intraganglionic or juxtaganglionic spiral bundle. The fibers from the efferent bundle are given off regularly as they ascend the cochlea. These fibers penetrate the habenulae perforatae and are enclosed in a large calyx-type ending by one or two large-diameter afferent neurons (Figure 24). The type I hair cells are flask shaped and are contacted by bouton-shaped endings from both the afferent and efferent systems. These afferent neurons are myelinated but small compared with those that innervate type I hair cells. The crista is a ridge of neuroepithelial cells that traverse the ampullated end of each membranous semicircular duct. The ampulla contains the sense organ for the detection of angular acceleration and deceleration (see Figure 23). The hair cells in the crista ampullaris are arranged with the type I hair cells near the crest of the crista and type II hair cells near the slopes.10,26 It is noteworthy that the hair cells in cristae of the semicircular ducts are oriented in a single direction based on the alignment of their ciliary bundle.10,26 The ciliary bundle of each vestibular hair cell consists of 100 to 150 stereocilia and a single kinocilium, which is located to one side of the stereocilia (see Figure 25). In the case of the horizontal semicircular duct, the kinocilium of each hair cell is located on the utricular side of the crista. In the vertical cristae (of the superior and posterior semicircular ducts), the kinocilium are located toward the nonampullated ends or away from the utricle (Figure 26). Sitting on top of the crista and reaching to the roof of the ampullary wall, even attached to it, is a gelatinous partition called the cupula, composed of mucopolysaccharides possessing an equal density to the endolymph, which surrounds it (see Figure 23). It is the displacement of the cupula that initiates through the hair cells an action potential in the neurons contacting the hair cells.25,26 When the deflection of the cupula is toward the kinocilium, there is a depolarization of the hair cell neuron unit with an increase in the resting vestibular nerve action potential, whereas a deflection away from the kinocilium produces hyperpolarization or a decrease in the resting discharge of the vestibular neuron.10 The semicircular ducts in each labyrinth are oriented to each of three planes in space, with the lateral semicircular duct cristae recording angular acceleration in a horizontal plane, whereas the posterior and superior (vertical) semicircular duct cristae record movement in the two vertical planes of space. In man, when the head is in the upright erect position, the anterior aspect of the lateral semicircular canal angles 30° upward from the horizontal plane. To induce complementary input to the vestibular nuclei, the canals of each bony labyrinth are coplanar; in other words, the
posterior semicircular canal of one labyrinth is coplanar with the superior semicircular canal of the contralateral labyrinth. Because of the opposite polarization of hair cells in coplanar semicircular ducts (see Figure 26) following rotation in a given plane, one coplanar duct will be facilitated and its contralateral partner will be inhibited.27

Figure 26 Diagram summarizing the orientation of hair cells in the vestibular sense organs based on the location of the kinocilium in the ciliary bundle.

The maculae are flat sense organs that are divided approximately in half by a line called the striola. The striola divides the macula into two halves, in which the hair cell ciliary polarization is in opposite directions (see Figure 26). In the macula of the utricle, the hair cells are oriented toward the striola, whereas in the saccule, hair cells are oriented away from the striola. Since the maculae project centrally to the vestibulospinal pathways primarily, but to a lesser extent to the vestibulocochlear pathways, it is possible that the opposite polarization of regions in the maculae allows excitation and inhibition to antagonistic muscle groups. Type I hair cells seem to predominate near the striola, with type II hair cells furthermost from the striola. The cilia of the hair cells in the macular sense organs are covered by an otolithic membrane, gelatinous in makeup with otoconia composed of calcium carbonate crystals with a specific gravity of 2.71 embedded in the gelatinous blanket. The movement of the otocoonial membrane by gravitational forces or inertial forces displaces the hairs of the hair cells, thus bringing about activity in their afferent nerve input.

Figure 25 Diagram of the innervation pattern to the type I and type II vestibular hair cells.
aferents travel up the center of the ampullary nerve to innervate type I hair cells at the crests of the cristae,24,29 whereas the smaller fibers innervate the slopes and therefore surround the larger fibers in each ampullary nerve (see Figure 27). On the other hand, the distribution of the large and small afferents in the saccular and the utricular nerves is more dispersed since the division between the location of type I and type II hair cells in the maculae is not so clearly demarcated as in the cristae.

Central Vestibular Pathways

The division of duct afferents in the rostral one half to two-thirds of the vestibular nerve and utricular afferents in the caudal portion of the vestibular nerve is related to their termination in the major vestibular nuclei in the brainstem.29 The semicircular duct afferents after bifurcating send an ascending branch to the superior vestibular nucleus and a descending branch with many collaterals to the rostral portion of the medial vestibular nucleus, with some collaterals to the ventral division of the lateral vestibular nucleus (Figure 28). This projection is organized in the duct innervated by the inferior division terminates most medially in the superior nucleus and most ventrally in the medial nucleus, whereas the two semicircular duct cristae supplied by the superior division of the vestibular nerve terminate dorsolaterally in the superior nucleus and dorsally in the medial nucleus.29 Short collaterals from the incoming axons of semicircular duct afferents also terminate on the intravestibular nerve nucleus, a small nucleus within the vestibular nerve root. The afferents from the utricular and saccular maculae also bifurcate, with their ascending ramus terminating in the lateral and medial nuclei and the descending branch to the descending and group Y vestibular nuclei (Figures 29 and 30). The projection to the lateral nucleus is on neurons in the ventral division of the lateral vestibular nucleus and on large neurons in the rostral extension of the medial vestibular nucleus. The large neurons in the medial nucleus represent afferents to the abducens nucleus and to the subnucleus in the oculomotor nucleus, which innervates the medial rectus muscle. The latter projection pathway travels over the ascending tract of Deiters.3 The saccular afferents also send terminations to the group Y nucleus, a minor nucleus that is located between the restiform body and the dorsal acoustic stria and the lateral vestibular nucleus. The group Y nucleus’ major projection is to the contralateral group Y and superior nuclei.32

The oculomotor nucleus is the most complex nucleus serving extraculomotor function. The organization of the four subnuclear groups of motor neurons had evaded precise description by traditional neuroanatomical methods employing the retrograde neuronal reaction following axon transection. With the introduction of retrograde tracers of axon transport, the configuration of these four subnuclear cell groups in the oculomotor complex has been delineated (Figure 31).3

This description has aided our understanding of vestibulocuular projections. The projections of the major nuclei are responsible for the reflex connections of the duct and the macular afferents.3,34–36 Second-order pathways are activated by duct afferents that project from the superior and medial vestibular nuclei and course in a parallel fashion to terminate in
the trochlear and oculomotor nuclei with rostral terminations in the nucleus of Darkesewitch and the interstitial nucleus of Cajal (see Figure 28). These pathways travel in the medial longitudinal fasciculus (MLF), with the ipsilateral pathway from the superior nucleus being inhibitory and the contralaterally projecting pathway from the medial nucleus being excitatory. They are responsible for the conjugate eye displacement manifesting as nystagmus from canal stimulation or destruction. Neurons from the medial vestibular nucleus project bilaterally to the abducens nuclei.37 The ascending tract of Deiters projects to the abducens nuclei; VI

The major pathway is the lateral vestibulospinal tract (LVST), which arises from the large multipolar neurons in the lateral vestibular nucleus and to a lesser extent from the descending nucleus. This pathway is somatotopically organized so that the vestibulospinal projections to the cervical and upper thoracic regions arise from neurons in the anteroventral portion of the lateral vestibular nucleus, whereas the most caudal and sacral portions of the spinal cord are innervated by the multipolar neurons in the most dorsal and caudal portions of the lateral vestibular nucleus. Truncal and limb musculature of the intervening segments are organized in an orderly fashion between these extremes. This pathway provides excitatory tone to extensor muscles of the limbs. The medial vestibulospinal tracts (MVSTs) travel down the MLF and are largely inhibitory, although some facilitatory connections are made from the descending vestibular nucleus.27 The projections through the MLF arise from the caudal portions of the medial and descending vestibular nuclei. Since they are largely inhibitory, they act synergistically with the innervation of neck and upper truncal muscles excited by the LVST. The MVSTs extend down to the upper cord levels but do not reach the thoracic, lumbar, and sacral region levels reached by the LVST.

Other pathways exist in the vestibular nuclei that are of importance. One such pathway is the commissural pathway that interconnects the vestibular nuclei (see Figure 28). The major intervestibular or commissural projections are between the superior, medial, and descending vestibular nuclei.32 A minor projection may exist between the lateral vestibular nuclei. As mentioned earlier, the group Y nucleus also forms a significant commissural projection to the contralateral group Y nucleus as well as the superior nucleus. The commissural pathways are largely inhibitory on second-order neurons activated by canal input. It is possible that they serve to potentiate the differential response arising from stimulation of coplanar canals. The commissural projections are important in the recovery of balance following ablation of one set of vestibular sense organs (labyrinthectomy). It has been demonstrated that the commissural pathways are largely responsible for providing the reactivation of input to the denervated side of the brainstem to approximate that in the intact half.39
The interaction of vestibular pathways with the cerebellum is emphasized by reference to certain areas of the cerebellum as the vestibulocerebellum (VC). These are the nodulus, uvula, flocculus, and ventral parafl occulus (see Figure 28). Other areas of the anterior and posterior lobes of the vermis are also included to a lesser extent. This association is based on the projection of the first- and second-order vestibular afferents to the cerebellum via the mossy fibers. All canal afferents continue through the superior nucleus after termination there, to converge and terminate on neurons in the VC. Second-order neurons in the superior, medial, lateral, and descending nuclei relay input from the utricular and saccular maculae to the same areas. There is also some relay of canal input to the vestibular nuclei on the cerebellum. The importance of such direct as well as relayed labyrinthine input to the cerebellum is not known but may have some bearing on different information coming in for modification of cerebellar output. For example, the relayed canal input may be modified by commissural inhibition before entering the cerebellum. Furthermore, other afferent input (spinal) may alter the labyrinthine (macular) input before relay to the cerebellum.

Input from the labyrinth and spinal cord, although important, is not the only source of input to the flocculus and nodulus, where overlap with labyrinth input occurs. Therefore, interaction between vestibular and visual signals in the VC has firm anatomic and physiologic support. These various inputs to the VC probably determine the pattern of output from these regions, which will impact on neurons in the vestibular nuclei.

In a reciprocal fashion, there are extensive projections to the vestibular nuclei from the cerebellar cortex and nuclei. The anterior and posterior parts of the vermis provide extensive projections to the lateral vestibular nucleus, particularly the dorsal half. The output of the VC is distributed throughout the vestibular nuclei, especially to those areas related to the cerebellar input. These cerebellar projections are entirely inhibitory since Purkinje cells are inhibitory neurons. However, not all cerebellar output is inhibitory. The fastigial nucleus (FN), which receives labyrinthine input, exerts an excitatory effect on the vestibular nuclei. The caudal part of the FN projects to parts of all of the contralateral vestibular nuclei, whereas the rostral region projects to the ipsilateral nuclei. The FN can be a link between the cerebellar cortex and the vestibular nuclei that provides an excitatory input on vestibular neurons.

**Efferent Vestibular Pathway**

An efferent vestibular pathway has also been demonstrated in lower and higher mammalian forms. This pathway originates from discrete populations of ipsilateral and contralateral neurons located lateral to the abducens nucleus and projects to each vestibular labyrinth (Figure 34). The unmyelinated axons converge with the olivocochlear bundle as the vestibular root is reached in the brainstem. They travel with the olivocochlear bundle efferents through the vestibular nerve to the point where the vestibular ganglia are reached. At this point, the vestibular efferents diverge from the parent efferent bundle to break up into fascicles and individual axons that then disperse throughout the ampullary and macular nerve branches. They branch and ramify richly along their course within the nerve trunks and after penetration of the basement membrane in the neuroepithelium of the vestibular sense organs. Here they represent fine fibers that form many bouton-like vesiculated endings in terminal type II hair cells and the calyces encapsulating type I hair cells (see Figure 25), as well as on the primary afferent dendrites innervating both type I and type II hair cells. These fibers are cholinergic, as are the olivocochlear efferents, and can be demonstrated selectively with acetylcholinesterase localization techniques. In addition, a wide array of efferent neuropeptides, which serve as neuromodulators, are expressed. Similarly there are a diverse group of muscarinic, nicotinic, and neuropeptide receptors expressed by hair cells and primary afferent neurons which receive the vestibular efferent input, thereby producing a wide array of neurophysiologic effects. The number of efferent neurons is relatively small compared with the number of afferent neurons in the vestibular nerve. In the cat, for the 8,000 afferent neurons, there are 200 to 300 efferent neurons that supply their branching an almost equal number of efferent terminals to the number of afferent terminals in the sense organs. Although the number of vestibular efferents in the human labyrinth has not been determined, it is presumed that the imbalance in number is similar to that in lower forms. The function of the efferent system to the vestibular sense organs is not known. Most experimental studies indicate an inhibitory effect on afferent vestibular activity. However, an excitatory effect has also been demonstrated in primates. It is possible that the efferent effect is to raise or lower the resting activity level in vestibular afferents, thereby modifying their operating range. Unlike the efferent auditory pathway, the vestibular efferent pathway is represented by small neurons located near the medial vestibular nucleus, where they can be contacted by first-order afferents. Thus, a two-neuron reflex arc exists to type I hair cell afferent terminals and type II hair cell soma.

**FLUIDS OF THE INNER EAR**

As mentioned earlier, there are two fluid compartments of the inner ear, the endolymp and the perilymph. Endolymph is a fluid that has a similar ionic composition to intracellular fluid and fills the membranous auditory and vestibular labyrinth. Endolymph is formed by secretory cells in the stria vascularis and by dark cells near
the ampullary ends of the semicircular ducts and the walls of the utricle. The endolymph is thought to be absorbed in the endolymphatic sac. Endolymph composition is characterized by a high potassium level and a low sodium level. The membranous labyrinth is suspended within the bony labyrinth by a fine trabecular network in a space that is filled with perilymph. Perilymph, in contradistinction to endolymph, has an ionic composition similar to extracellular fluid, with low potassium and high sodium levels. A comparison of the composition of the two fluids with that of serum and CSF is found in Table 1. This differential chemical makeup in the two fluid compartments is important to the establishment of a standing voltage surrounding the sense organs, which permits the generation of nerve impulse in the hair cell afferent neuron unit. Perilymph is secreted largely as the result of diffusion from the capillary network in the spiral ligament adjacent to the scala tympani with a smaller portion derived from CSF by way of the cochlear aqueduct.

**BLOOD VESSELS OF THE EAR**

Two major vessels have little or nothing to do with the vascular supply of the ear itself but are important in disorders and surgery of the TB. These are the sigmoid sinus and the internal carotid artery. The sigmoid sinus is a continuation of the lateral (transverse) sinus, which is formed by the superior sagittal sinus. It makes an indentation into the posterior fossa plate of the mastoid portion of the TB before taking an abrupt redundant turn on itself (jugular bulb) to exit through the jugular foramen accompanied by cranial nerves IX, X, and XI (see Figure 7). This structure is important as it may represent a lethal complication of bacterial mastoiditis (thrombophlebitis) when erosion of its bony covering occurs. The anatomy of the jugular bulb is particularly crucial to the diagnosis and surgical management of neoplasms, which originate in the bulb such as glomus jugulare tumors or schwannomas.

The internal carotid artery enters the TB just anterior to the jugular foramen and travels in a bony canal anterior to the middle ear through the tympanic canaliculus in the middle ear. The bony canal, anterior to the jugular foramen and travels in a lateral direction anterior to the jugular foramen and travels in a lateral direction, is as an important landmark in surgery of the PA and skull base. Rarely, an anomalous internal carotid artery may appear clinically to be a vascular neoplasm in the middle ear.

The circulatory networks of the external and middle ears and the inner ear are completely separate, with the one being supplied by the carotid system, whereas that of the labyrinth is derived from the vertebrobasilar system. The external carotid artery may appear clinically to be a vascular anomaly but is an important set of arterial branches from the external carotid system. The arterial branches to the middle ear space are the anterior tympanic branch from the internal maxillary artery, which enters through the petrotympanic fissure and travels along the eustachian tube and the semicanal for the tensor tympani. The middle meningeal artery gives off the superior tympanic branch that enters the middle ear through the petrosquamous fissure. The middle meningeal artery also gives off the superficial petrosal artery that travels with the greater superficial petrosal nerve and enters the facial canal at the hiatus. This vessel anastomoses with a branch of the posterior auricular artery, the stylomastoid artery, which enters the facial canal inferiorly through the stylomastoid foramen. A branch of the stylomastoid artery leaves the fallopian canal to travel through the canaliculus with the chorda tympani nerve to enter the middle ear. Finally, the inferior tympanic artery, a branch of the ascending pharyngeal artery, enters the middle ear through the tympanic canaliculus in the hypotympanum with the tympanic branch of the ninth nerve.

The vascular supply to the ossicles is derived from the anterior tympanic artery, the posterior tympanic artery, and branches from the plexus of vessels on the promontory. The most tenuous link in the ossicular chain as regards blood supply is the tip of the long process of the incus, which commonly undergoes necrosis secondary to conditions that compromise its blood supply.

### BLOOD SUPPLY TO THE INNER EAR

The blood supply to the inner ear is derived from the labyrinthine branch of the anterior inferior cerebellar artery off the basilar artery. Occasionally, the internal auditory artery has a direct origin from the basilar artery. This vessel represents an end artery as it receives no known anastomosing arterial vessels. The internal auditory artery as it enters the IAC divides into three branches. The first branch, the anterior vestibular artery, supplies the semicircular ducts, utricle, and saccule. The second branch, the vestibulocochlear artery, supplies the saccule, utricle, posterior duct, and basal turn of the cochlea. Its third and terminal branch is the cochlear artery, which enters the modiolus, where it gives off the spiral vessels that form external and internal radiating arterioles. The internal radiating arterioles descend to supply the limbus as well as the basilar membrane and organ of Corti. The external radiating arteriole courses through the interscalar septum to supply the vascular arcades and capillaries of the stria vascularis. This arteriole anastomoses with the venous supply near the spiral prominence, with the venous return being along the floor of the scala tympani, where the veins merge with the collecting venules from the spiral vein to form the posterior spiral vein. This posterior spiral vein, or inferior cochlear vein, then travels along the scala tympani to exit at the cochlear aqueduct through a separate channel and enters the inferior petrosal sinus. The remainder of the labyrinth is drained by a venous system, which parallels to some degree the arterial system. Therefore, an anterior vestibular vein and the posterior vestibular vein drain the posterior duct ampulla as well as the saccule and a portion of the utricle and superior duct ampulla. These merge to join the vein at the cochlear aqueduct. The venous return from the semicircular ducts and the body of the utricle converge to form the vein at the vestibular aqueduct, which travels as the vein of the paravestibular aqueduct. This vein travels along with the intracranial endolymphatic sac toward the extracranial endolymphatic sac. This venous system drains into the sigmoid sinus.

### FACIAL NERVE

The anatomy of the facial nerve and its branches are important in clinical practice not only because of the cosmetic effects of facial paralysis, whether it be by disease or surgical injury, but because the various components of facial nerve are important for the diagnosis and localization of lesions in the TB. The facial nerve has sensory function and autonomic afferent and efferent function, together with the motor function, for the facial musculature. The neuronal pathway from the motor cortex to the facial nucleus is either two or three neurons in a mono- or disynaptic pathway. The motor control of the facial muscles is located at the inferior end of the pre- sylvian gyrus. The area for facial musculature
innervation is located near the area of innervation of laryngeal muscles. Although a moderate corticobulbar projection exists, it is not the only pathway innervating the facial nucleus. Various extrapyramidal neurons located in the red nucleus as well as the periaqueductal gray nucleus also project to the facial nucleus. The projection to the facial nucleus is largely contralateral as are most corticobulbar projections, but there is bilateral innervation to the facial neurons supplying the frontalis muscle. The facial nerve consists of four major components: the motor component to the facial musculature, a sensory component to receptors in facial muscles as well as to the face, autonomic secretomotor and special sensory pathways. The motor component of the facial nerve is the largest component and provides innervation to the facial musculature. It has been demonstrated in the cat with retrograde neuronal tracers that the regional facial muscle groups are supplied by groups of neurons within the facial nerve nucleus in a medial and lateral arrangement. The number of facial motoneurons has been estimated at approximately 10,000 to 20,000. As axons leave the facial nucleus, they travel in a dorsal direction to loop around the abducens nucleus under the floor of the fourth ventricle and then curve in a ventrolateral direction passing between the lateral superior olivary nucleus and the descending trigeminal root to emerge from the brainstem ventral to the eighth nerve. The nerve is joined by the nervus intermedius and travels in the IAC in its anterior and superior compartment. In this portion of the IAC, it has an intimate anatomic relationship with the superior division of the vestibular nerve, and indeed the nervus intermedius may travel within the vestibular nerve for a part of its intracanalicular course. At the distal end of the IAC, the facial nerve diverges in an anterolateral direction to enter the labyrinthine segment of the fallopian canal (see Figures 4 and 8). At the geniculate ganglion, it makes an acute bend near the floor of the middle cranial fossa to continue within the bony canal in its tympanic segment. The course within the labyrinthine segment of the fallopian canal is associated with an extension of the subarachnoid space. This extension of the subarachnoid space is usually limited by the location of the geniculate ganglion but in a small portion of TBs may extend into the tympanic portion of the fallopian canal. The greater superficial petrosal nerve emerges from the geniculate ganglion at the facial hiatus (see Figure 4) and courses along the floor of the middle cranial fossa between layers of dura to reach the foramen lacerum, where it joins with the carotid sympathetic nerves to form the vidian nerve in the vidian canal. The tympanic portion of the facial nerve travels superior to the oval window in a postero-lateral direction to the level of the horizontal or lateral semicircular canal, where it makes a 90° turn in a ventral direction to continue as the mastoid portion of the facial nerve (Figure 35). After traveling the length of the vertical canal, the facial nerve emerges from the stylomastoid foramen to enter the parotid gland anterior to the mastoid tip. Before emerging from the stylomastoid foramen, the chorda tympani nerve is given off through a bony canal in a retrograde direction toward the middle ear, where it passes between the long process of the incus and the neck of the malleus to enter the epitympanum and leave the middle ear space before joining the lingual nerve. The facial nerve provides innervation to the posterior belly of the digastric muscle just external to the stylo-mastoid foramen and then emerges into the parotid gland, where it gives rise to four to five branches providing innervation to the facial musculature. Although the motoneurons in the facial nerve are spatially organized within the nucleus, the fibers to the peripheral facial muscle groups are interspersed throughout the course of the facial nerve but gather together again on exiting the TB to provide the four to five distal branches supplying the regional facial musculature.

**General Sensory Component**

An unknown number of sensory afferent neurons are intermixed with the motor axons in the facial nerve trunk. In an animal model (cat), approximately 15 to 20% of the nerve fibers in the medium to large fiber size persist even after total facial nerve transection in the cerebellopontine angle. It is not clear what peripheral receptors these afferents innervate. The possibilities are either spindles within the facial musculature or some sensory receptors in the skin, particularly the dermis.

**Autonomic Secretomotor Neurons**

Secretomotor or motor preganglionic neurons of the facial nerve are located in the superior salivary nucleus in the brainstem (Figure 36A). They travel in the nervus intermedius, with some traveling within the vestibular nerve trunk. Those traveling within the vestibular nerve leave in the vestibulofacial anastomosis in the distal part of the IAC to join the nervus intermedius as it travels with the facial nerve trunk in the mental canal. Some efferent preganglionic neurons pass through the geniculate ganglion to the foramen lacerum and the vidian canal. After leaving the vidian canal, they synapse with postganglionic neurons in the sphenopalatine ganglion that innervate the...
cance in harboring neurotropic viruses (herpes virinae), which gain entry through nerve endings in the oral cavity. After long latent periods, the viruses can be reactivated later in life to manifest as viral neuropathies (e.g., Bell palsy, recurrent vertigo).

Development of the Ear

Daniel I. Choo, MD
Gresham T. Richter, MD

The development of the ear has been an object of intense investigation for the past century. Housed within the temporal bone, the human ear is composed of 3 discreet but interdependent units: the external, middle, and inner ear. The function of these components is to conduct and translate sound efficiently into signals that can be interpreted by the brain. This process is highly dependent on the synergistic and complete development of each part. The external ear, composed of the pinna and external auditory canal (EAC), gathers and introduces sound to the eardrum, a thin elastic membrane connecting the external to the middle ear. The middle ear mechanically conducts and amplifies the sound to the inner ear through a lever system of 3 interconnected ossicles from lateral to medial: the malleus, incus, and stapes. An intimate connection between the malleus and tympanic membrane (TM) as well as the stapes and the oval window of the inner ear allows energy to be transmitted into a liquid medium. Waves within the inner ear, generated by movement of the stapes on the oval window, stimulate mechanoreceptors within the cochlea that are transduced into neural impulses.

The inner ear is derived from the otic vesicle, an invagination of ectoderm adjacent to the primitive hindbrain. The external and middle ear arise almost entirely from the first and second branchial arches (ie, pharyngeal) arches around the interposed first pharyngeal cleft and pouch. From these embryologic origins, development begins around 4 weeks of gestation and progresses via embryologic differentiation of embryologic soft tissues within the “pharyngeal apparatus.” Sequential levels (1 to 5) of the pharyngeal apparatus are subdivided into 3 components known as the branchial (pharyngeal) arches, pouches, and clefts. The arches are the fundamental constituent from which structures arise from embryonic mesoderm: the building blocks of muscle and vascular elements, and the neural crest cells, which are the source of skeletal and neural elements. Embryologic disruption of a branchial arch can lead to congenital head and neck anomalies, for example, branchial clefts, cysts, sinuses, or fistulae. The first and second branchial arches are referred to as the mandibular and hyoid arches, respectively. As their names imply, they also contribute significantly to bony and soft tissue skull base and maxillofacial growth. Thus, malformations of the auricle often accompany craniofacial anomalies. The most common examples include Treacher Collins syndrome, Goldenhar syndrome, Nager syndrome (acrofacial dysostosis), and Kabuki syndrome.

Auricular Development

During the fifth to sixth week of development, the early auricle arises from a series of paired mesenchymal condensations around the first pharyngeal cleft referred to as the 6 hillocks of His (auricular hillocks). Debate has ensued regarding the origin of each hillock as they soon lose their identity in early development. However, it is now generally accepted that the first 3 hillocks are thought to be second branchial arch derivatives that ultimately become the antitragus, antritragus, and lower helix and lobule. Figure 1 provides a schematic of the proposed auricular components from each hillock. Complex rearrangements and fusion of the hillocks camouflage the details of their individual contributions to the ear. Nonetheless, they become the cartilage and soft tissue of the external ear that is nearly fully developed by birth. Continued cartilage deposition and matrix formation occurs after birth to create a stronger and larger auricle. By 5 to 6 years root, and helical crus, respectively. The last 3 hillocks are thought to be second branchial arch derivatives that ultimately become the antitragus, antritragus, and lower helix and lobule. Figure 1 provides a schematic of the proposed auricular components from each hillock. Complex rearrangements and fusion of the hillocks camouflage the details of their individual contributions to the ear. Nonetheless, they become the cartilage and soft tissue of the external ear that is nearly fully developed by birth. Continued cartilage deposition and matrix formation occurs after birth to create a stronger and larger auricle. By 5 to 6 years
risk to future growth. A dult size is achieved by early adolescence.

Simultaneous development of mesenchymal precursors gives rise to the extrinsic (anterior, superior, and posterior) and intrinsic auricular muscles and blood supply. Sensory and motor branches of the fifth (arch I) and seventh (arch II) cranial nerves supply the external ear. While the muscles are controlled by the seventh cranial nerve (CNVII), the auricolotemporal nerve (CNV) and great auricular nerve (C2, C3) provide the majority of sensation to the tragus and the pinna. Sensory branches of the facial nerve (CNVII) and vagus (CNX) also provide sensation to the central and cranial portions of the external auditory canal, respectively.

The early embryonic pinna begins caudal to the growing mandible near the base of the neck. However, as synchronous first arch derivatives develop (mandible), the auricle is displaced more cephalad and posterior. By the end of the second trimester, the pinna will reach its adult location at the side of the head. It follows then that in syndromes with proposed arrested development of first and second branchial arch derivatives (eg, Treacher Collins syndrome, hemifacial microsomia, Nager syndrome, and Kleeblatts syndrome), the pinna is retroverted, malformed, and set in a lower and more anterior position than the normal adult configuration. These deformities are frequently accompanied with middle ear malformations as its components also arise from the first and second pharyngeal arches. The relationship between ear and facial development is thereby evident in innumerable syndromes and teratogenic anomalies. Disturbances in external ear growth can also hallmark associated corporal defects. Thus, clinically a newborn with low set or dysmorphic ears should be explored for potential malformations or syndromes involving the face, limb, eye, heart, spine, or kidneys (eg, CHARGE, VATER, VACTERL, Townes-Brocks, Wildervank, and branchio-oto-renal syndromes). Consultation with a genetics specialist is warranted as genetic numerators are frequently discovered in children with auricular malformations.

Failure of differentiation or fusion of the hillocks is thought to result in developmental malformations of the auricle including microtia, anotia, fistula, sinuses, and preauricular tags. Microtia occurs in approximately 0.03% of newborns and can be accompanied by canal stenosis, atresia, and ossicular abnormalities. Isolated cases are thought to arise sporadically, although autosomal recessive and autosomal dominant transmission patterns have been reported. Microtia is divided into 4 grades from a mild auricular deformity, with a small but recognizable pinna (grade I), to complete agenesis (anotia, grade IV). Grades II and III represent gradual reductions in pinna formation, from a rudimentary pinna found in grade II to complete loss of the pinna with only a malformed lobule (grade III) (Figure 2). Higher grade microtia are often associated with canal abnormalities. Eighty-five percent of microtia cases are unilateral, whereas bilaterality is more common in syndromic patients.

First branchial cleft anomalies are the result of early disruption of hillock fusion. They result in a duplicated EAC (type I) or persistent embryologic tract often communicating with the EAC (type II). These can present as periauricular swellings, tags, cysts, sinuses, or fistulae and consist of only ectodermal (as in type I anomalies) or ectodermal and mesodermal (type II) origin. Preauricular tags, the most common and benign ear deformity, are the result of supernumerary auricular hillock formation and can point to more serious anomalies of other parts of the body. Variations in the complex structure of the auricle can lead to minor malformations of the pinna or conchal bowl. The classic “lop” (prominent) and “cup” ear deformities are the result of exorbitant or disrupted cartilage formation of the helix and concha, respectively. Fetal alcohol syndrome, fetal positioning, teratogenic exposure (eg, thalidomide or isotretinoin), and maternal endocrinopathies have caused deformities of the external ear. Patients with Down syndrome frequently have hypoplastic and round ears. Regardless of cause, many auricular malformations and first cleft anomalies are surgically correctable problems.

**External Auditory Canal and Tympanic Membrane**

As the hillocks of His condense at around 6 weeks gestation, the first branchial cleft (groove), an ectoderm derivative nestled between the first two branchial arches, deepens to form the external auditory meatus (EAM). Simultaneously, the concha arises, in concert with the cartilaginous portion of the EAC, to create the cup and funnel form of the ear introitus. Invagination of the first branchial cleft is coordinated with development of the tympanic ring, a mesenchymal first arch derivative that develops...
as a discrete unit in approximately the ninth week of gestation. This ring forms the peripheral framework of the future TM and bony EAC but is incomplete with a defect superiorly corresponding to the future notch of Rivinus. Initially the tympanic ring develops along the superficial and lateral aspect of the temporal bone. The medial aspect of the first branchial cleft at this point becomes intimately attached to the ring’s circumference. During the ninth to sixteenth week of gestation, as the ring dives deeper anteriorly and medially within the temporal bone, so does the adherent first branchial cleft. A meatal plug, a solid core of epithelial cells, follows as the cleft extends inward from the introitus toward the developing tympanic cavity. Proliferation of the ectodermal cells contributes to the meatal plug and assists in the medial expansion of the EAC. Furrowing ceases as a sheet of ectoderm (epithelium) comes in close contact with the endoderm of the lateral end of the first pharyngeal pouch that is simultaneously creating the future tympanic cavity (ie, tubotympanic recess). A mesenchymal contribution from the first arch remains between these 2 layers (Figure 3). Ultimately, this component thins and differentiates to form the fibrous layer of the TM to include both outer radial and inner circular fibers. As the tympanic ring develops, it widens to consummate the future dimension and orientation of the bony EAC and TM. The intimate layers of the first branchial cleft and pouch with the intervening mesenchyme of the first branchial arch ultimately become the final squamous, fibrous, and mucosal components of the TM at birth, the only ear structure that retains all 3 germ cell layers.

Formation of the EAC, however, is not complete until resorption of the epidermal plug. This process begins at approximately 21 weeks of gestation with proposed apoptosis and gradual hollowing of the EAC until only the most medial cells remain to form the outer (lateral) layer of the future TM. The process is thought to end by 28 weeks of gestation with the new EAC between the mastoid and the condylar fossa of the mandible. After birth, the tympanic ring continues to grow with ossification and lateral expansion to become the bony EAC. Although smaller in the infant, final dimensions of the EAC should approximate 8 mm in diameter and 2.5 cm in length to create a total volume of approximately 2 cm³. Failure of resorption during the end of the second and beginning of the third trimesters can lead to a continuum of pathology from partial stenosis, membranous atresia, to complete bony atresia of the EAC.

Congenital aural atresia occurs in 1:10,000 to 1:20,000 live births and occurs more frequently as unilateral cases (3:1), on the right side, and in males. A medial bony meatal plate remains in aural atresia and is juxtaposed to the developing tympanic cavity and replaces the TM. A medial bony meatal plate remains in aural atresia and is juxtaposed to the developing tympanic cavity and replaces the TM. This contributes to a maximal conductive hearing loss found in these patients. The development of the manubrium malleus has also been shown to be intimately coordinated with the formation of the medial EAC; and, despite the degree of canal deformity, defects in canal resorption are accompanied by lateral malleal anomalies. A middle ear malformations also occur with complete aural atresia.

By birth, the TM is near adult size (9 mm in diameter); however, its position remains horizontal relative to the vertical axis of the adult TM. Distinction between the 2 components of the TM (pars flaccida and pars tensa) is also difficult in the newborn. Continued expansion and ossification of the tympanic ring during the first year postnatally leads to reorientation of the TM, formation of the lateral bony EAC, and closure of the tympanic cavity.

Figure 3 Drawing showing the development of the external auditory canal (EAC) and middle ear. Development of the external meatus, EAC, and middle ear space involves a complex process of ectodermal proliferation, cellular resorption, and coordinated maturation with the tubotympanic recess forming the tympanic membrane (TM) and middle ear cleft. The ectodermal cells at the dorsal end of the first branchial groove proliferate and expand medially. This solid core of ectodermal cells is referred to as the meatal plug (A). By the twenty-first week this meatal plug begins to hollow out, leaving the EAC lumen. Formation of the EAC is typically complete by the twenty-eighth week of gestation (B). Note that the medial-most ectoderm and endoderm of the tubotympanic recess interface in such a way that these two layers combine to form the TM (B). (Reference 2a.)
the notch of Rivinus with simultaneous clarification of the pars flaccida. In addition, expansion of the tympanic ring assists in closure of ventral embryologic tracts of the EAC and middle ear to the meninges (Hyrtil fissure) and parotid gland (foramen of Hilschke). Retention of these structures has been blamed for some intracranial (meningitis, epidural abscess) and extracranial (parotitis) complications of otitis media due to infectious spread.

EAC development occurs subsequent to auricular morphogenesis. Accordingly, it is possible to see isolated aural atresia or stenosis without concomitant auricular deformities. This result suggests incomplete dissolution of the epidermal plug near the twenty-first to twenty-eighth week of gestation. In contrast, it is quite unusual to find severe auricular malformations without associated middle ear or EAC abnormalities, since this suggests disrupted development early in gestation. In a child with microtia, temporal bone imaging is appropriate to identify potential middle ear or canal defects. Congenital cholesteatomas may be found in the middle ear of patients with aural atresia without clinically apparent disease.

Early discovery through imaging can prompt earlier surgical intervention and prevent potential adverse effects (see Chapter 62, “Microtia, Canal Atresia, and Middle Ear Anomalies”).

Genetic and Molecular Determinants

Multiple genetic and molecular factors are involved in external ear development. Many appear to be equally distributed within middle and inner ear anlagen and are involved in the coordinated development of these structures with the external ear. Significant overlap of molecular events in inner, middle, and external ear growth has made isolation and identification of the role of various factors difficult. Regardless, the genetic analysis of external ear malformations has blossomed from gene-targeting techniques and the identification of human syndromes affecting ear formation. The most notable is branchio-oto-renal (BOR) syndrome that consists, as the name implies, of simultaneous ear, craniofacial, and renal defects. Ear anomalies including supernumerary tags, periauricular fistulae, microtia, and atresia, as well as dysplastic middle ear development have been associated with these patients. Haploinsufficiency of the Eya1 gene causes BOR syndrome, and there are similar external ear anomalies identified in mice homozygous for Eya1 null mutation. Nonetheless, the role of Eya1 remains unclear. Its presence in early cartilaginous condensations suggests that this is a fundamental element in ear cartilage formation. Mutations of the ossicular chain found in Eya1 negative embryos also validate claims that ear cartilage growth (the embryonic source of early ossicular development) is dependent on this gene.

Similarly, thebmp5 gene, a member of the bone morphogenetic protein family, appears to be involved in late stages of pinna cartilage development. Specifically, positional cloning of thebmp5 gene has been performed; it has been shown to be mutated in a strain of mice with small pinna (short ear, se). Condensations of ear cartilage and the perichondrium of differentiating cartilage expressbmp5. Mesenchymal condensation of ear cartilage during late development is defective in strains with bmp5 mutant genes leading to foreshortened ears.

Extensive investigation into the Hoxa family of genes in external ear development has also been performed. In particular, mutants in Hoxa2 gene are associated with various anomalies of the external ear. The normal pinna does not form in the absence of Hoxa2 resulting in a microtic remnant. In addition, dose-dependent phenotypes have been created with differing levels of Hoxa2 expression. Although considered important in early developmental stages of the pinna, the direct impact of Hoxa2 on expression on external ear development remains unclear. Nonetheless, some studies suggest that its fundamental role is defining the future identity of the second arch hillocks.

As previously mentioned, the development of the EAC is regulated in part by the formation and migration of the tympanic ring. This process appears independent of the formation of the pinna. Embryos with mutations of genetic determinants of the EAC have no associated external ear deformities. Specifically, Goosecoid (Gsc) and Prxl mutant embryos display absent EAC in the context of normal pinna. These genes are known regulators of tympanic ring condensation and endochondral ossification conferring the importance of tympanic ring elements in EAC formation.

Molecules important in the formation of EAC include various secreted factors and their receptors that are simultaneously implicated in middle and inner ear development. Endothelin-1 and its converting enzyme along with fibroblast growth factor 8 (Fgf8) are the most notable products implicated in formation of the tympanic ring, neural cell migration, and epithelial-mesenchymal interactions involved in extralobar development. Future identification and investigation of specific gene products found in auricular and EAC malformations will improve our understanding of the complex and coordinated development of the ear from its branchial arches and cleft.

MIDDLE EAR

Acoustic waves are transmitted as vibrations of the TM at the medial aspect of the EAC. These vibrations are amplified through a lever system of the middle ear ossicles. In total, sound is amplified 22 times from the air to the inner ear as a result of the size differential of the TM to the oval window (17:1), and the shape of the ossicular chain (malleus handle is 1.3 times longer than the long arm of the incus), hence the overall mechanical advantage is $1.3 \times 17 = 22$. Disruption of middle ear mechanics can thereby cause major conductive hearing losses. Discontinuity of the chain alone can maximize conductive deficits to 50 to 60 dB and this emphasizes the importance of normal middle ear and ossicular development.

The middle ear is located medial to the EAC and is composed of the air-filled tympanic cavity, the 3 ossicles and their ligamentous attachments, the eustachian tube orifice, the oval and round windows, the facial nerve and its chorda tympani branch, and 2 muscles that help dampen the mobility of the ossicular chain (tensor tympani muscle and stapedius muscle). The compartment is lined with mucosa and contained by the temporal bone that includes the squamous (superior), petrous (medial), tympanic (lateral), and mastoid (posterior) segments. The roof of the tympanic cavity is called the tegmen tympani and is composed of squamous bone that separates the middle ear from the middle cranial fossa. The lateral aspect of the tympanic cavity consists of the TM and its surrounding tympanic ring. All temporal bone segments, except the mastoid, develop prenatally and synchronously with the middle ear. As the middle ear expands postnatally so does the mastoid which maintains connection to the middle ear by a posterior air-filled, mucosal-lined space known as the aditus ad antrum. Bone growth of the mastoid is nearly complete by 3 years of age, but pneumatization and expansion continue into early adult life. Ossification of the temporal bone also proceeds well after birth and includes the lateral tympanic ring (medial EAC), that is initially cartilaginous and flexible until approximately 1 year of age.

Middle ear formation begins as a lateral and superior expansion of the first pharyngeal pouch between the first and second pharyngeal arches. Initially, this creates an endoderm-lined space known as the tubotympanic recess (see Figure 3). At 4 weeks gestation, progressive superior and lateral advancement of the recess eventually engulfs surrounding and loosely organized mesenchyme. By 7 weeks, a fluid-filled tympanic cavity or nascent middle ear has been shaped. The distal end of the tubotympanic recess remains connected to the developing nasopharynx and becomes the eustachian tube anteriorly as the second pharyngeal arch mesenchyme constricts and delineates it from the expanding tympanic cavity. Simultaneous ingrowth of the first pharyngeal cleft (early EAM), lateral to the tubotympanic recess, allows early interface of the medial recess endoderm with the ectoderm of the EAC to mark the boundaries of the future TM.

Pre- and postnatal orientation of the eustachian tube is shown to be horizontal. Eustachian tube dysfunction and concomitant otitis media commonly affecting infants and young children have been attributed to the horizontal position of the early eustachian tube. This theoretically prevents appropriate drainage and ventilation of the middle ear. Fortunately, gradual growth of the skull base and midface accommodates lengthening (17 mm in the child to 35 mm in the adult) and displacement of the tube vertically (45° in adulthood). This is accompanied with a reduced incidence of otitis media in childhood.
Although the ossicular chain is absent within the early tympanic cavity, it is already in construction from neural crest cells within the mesenchyme of the first and second pharyngeal arches above and lateral to the growing recess (Figure 4). Specifically, around 5 to 6 weeks of gestation, the malleus head and neck along with the body and short process of the incus arise as a common ossicular mass from the first branchial (mandibular) arch. These first arch contributions are otherwise known as Meckel cartilage. At the same time, the stapes superstructure, malleal manubrium, and long process of the incus stem from Reichert cartilage, elements derived from the second branchial (hyoid) arch. In contrast, the stapedial footplate and annular ligament of the stapes at the oval window of the inner ear develop from the otic capsule and anlage of the inner ear. By the sixteenth week of gestation, the ossicles reach adult size.

The tensor tympani and stapedius muscles also develop from the mesenchyme from the first and second branchial arches. Accordingly, their innervation corresponds to the nerve of each respective arch. The mandibular branch of the trigeminal nerve (CNV) supplies the tensor tympani, a muscle that extends from its bony canal near the eustachian tube to the malleal manubrium and attenuates mobility of the chain when stimulated by loud sounds. Similarly, the facial nerve (CNVII) provides motor branches to the stapedius muscle, which is activated at high sound intensity and limits the amplitude of the stapes.

Stapes development involves an additional process of complex morphogenesis as it begins as a blastema near 4.5 weeks of gestation. The facial nerve divides the blastema into the stapes, interhyale, and laterohyale. The interhyale becomes the stapedial muscle and tendon, whereas the laterohyale becomes the posterior wall of the middle ear and a portion of the fallopian (facial nerve) canal. The stapes superstructure begins as a ring around the stapedial artery, a second arch derivative that ultimately regresses. Although rare, a persistent stapedial artery can result in significant and unexplained conductive hearing losses. By the tenth week of gestation, the stapes assumes its more typical stirrup-like shape as the footplate develops in conjunction with the otic capsule.

Each ossicle begins as a cartilaginous condensation of neural crest derivatives of their respective arches and, within 4 weeks of their onset, become models for the future chain. Ossification of the entire chain starts around the sixteenth week of gestation as it quickly reaches adult size. Stapes ossification is delayed until 19 weeks of gestation. Ossicular remodeling is an adaptive process and continues throughout gestation and shortly after birth for the malleus and incus. Stapes growth and ossification is thought to be complete by the third trimester and does not appear to undergo remodeling postnatally.

As the ossicular chain develops, expansion of the mesenchyme- and mucoid-filled tympanic cavity continues laterally and superiority. In the process, the pharyngeal endoderm divides into 4 sacs known as the saccus anticus, saccus posticus, saccus superior, and saccus medius. These sacs envelop the developing ossicular chain, pneumatize the middle ear, and become future spaces within the tympanic cavity. In the process, the middle ear ossicles, muscles, and ligaments and mastoid antrum become lined with endoderm (future cuboidal epithelium) derived from the first pharyngeal pouch. Simultaneously, blood supply is transmitted through numerous mucosal folds created at the junction of 2 sacs. Expansion of the tympanic cavity is nearly finished by approximately 30 weeks of gestation. Several mesenchymal elements differentiate into mucosal folds and permanent ligaments that suspend the ossicular chain. During the final (ninth) month of gestation, fine tuning of the tympanic cavity and its lining is complete. However, embryonic mesenchymal remnants and fluid can remain for several months after birth as they are slowly absorbed from the middle ear space. This can affect early chain mobility and be mistaken for otitis in the neonate. Theoretically, sufficient absorption shall have occurred by 2 months of age to allow for proper ossicular mobility.

Residual rests of epithelial cells within the tympanic cavity can give rise to an unusual but notable cause of hearing loss in the infant known as a congenital cholesteatoma. Retained amniotic epithelia, squamous differentiation of middle ear mucosal epithelium, or epithelial cells derived from the developing TM have been blamed for their occurrence. Despite the origin and in contrast to the acquired type, congenital cholesteatoma grow deep to the TM and most frequently in the anterior-superior quadrant. If untreated, these otherwise benign tumors can cause serious otic complications as a result of ossicular, labyrinthine, or fallopian canal bone destruction.

Further pneumatization of the epi tympanum, middle ear, antrum, and petrous bone occurs during the latter part of the third trimester and early postnatal life as these cavities enlarge without deposition of additional bony matrix. Epithelium simultaneously covers the growing spaces. Pneumatization of the middle ear is nearly complete by the first year of life. The middle ear and antrum are of adult size in the infant. However, continued postnatal pneumatization of the mastoid leads to further lateral and posterior expansion of this bone. The styloid process, lateral to its respective foramen, also develops postnatally. Together, the growth of these structures assists in the protection of the facial nerve as it exits the stylomastoid foramen. In a neonate and infant, the facial nerve is subject to injury as it projects more superficially and laterally from the temporal bone. Facial weakness from the use of obstetric forceps and mastoid surgery has been reported and should incite extreme care in this region when operating on an infant less than 1 year of age.

The facial nerve is an integral component of the developing middle ear. A rising from the facial nucleus, the nerve enters the internal auditory meatus, travels via the fallopian canal to the geniculate ganglion, and takes a sharp turn posteri orly to enter the tympanic cavity. It traverses the middle ear as the tympanic (ie, horizontal) segment and travels above the oval window (and then posteriorly to entrance the tympanic cavity). The chorda tympani nerve provides taste sensation to the anterior two-thirds of the tongue. In approximately 50% of cases, the bony canal of the tympanic segment of the facial nerve is congenitally dehiscent, a fact that has been attributed to facial nerve complications during middle ear surgery. An aberrant course of the facial nerve can also contribute to ossicular deformities and conductive hearing loss. For example, the facial nerve may override the oval window and lead to stapes malformations or discontinuity of the ossicular chain.

Although an overriding facial nerve is rare and can occur independent of other auricular...
anomalies, it is not an uncommon finding during the repair of aural atresia. Due to the disrupted development of the EAC, the mastoid segment of the temporal bone is juxtaposed to the glenoid fossa of the mandibular condyle in these patients. Disrupted ossicular development accompanies the external ear deformity. As a result, the facial nerve, unimpeded by the normal growth of the ossicular chain and EAC, diveres sooner and more anterior within the middle ear to emerge from the stylomastoid foramen. Here, it can override the stapes or simply prevent risk-free reconstruction of the ossicular chain. Jahrsdoerfer and others have thereby created radiographic criteria to determine which candidates for aural reconstruction will have the best possible hearing outcome.10 Those with an absent stapes, poorly aerated tympanic cavity or a significantly anomalous facial nerve at surgical risk within the space of the middle ear are considered poor candidates.

Anomalies of the middle ear often accompany those of the external ear. Naturally, syndromes affecting development of the first and second branchial arches have not only auricular and EAC deformities but impact the ossicular chain as they also arise from the same embryonic anlagen. The middle ear cleft is commonly hypoplastic in the BOR syndrome, as can be the middle ear ossicles.11 Crouzon disease is characterized by craniofacial abnormalities and hearing loss. The hearing loss is usually conductive owing to anomalies of the middle ear and atresia of the EAC. Other craniofacial disorders with hearing loss include Treacher Collins syndrome, Goldenhar syndrome and hemifacial microsomia, Nager syndrome, and Klippel-Feil syndrome. Early tests for conductive hearing losses are essential in these patients. Deformity of the malleus and incus, with coalescence into a common ossicular mass and adherence to an atretic bony membranous plate, is frequently found in these patients. Conductive hearing losses may be surgically correctable around 5 years of age when development of the mastoid and middle ear space is nearly complete. However, hearing losses should be addressed within 6 months of age using bone-conductive hearing devices to allow for appropriate auditory and speech development.

Intrinsic bone diseases can also influence development of the ossicular chain. Osteogenesis imperfecta is an autosomal dominant disorder with abnormal osteoblastic activity that can be accompanied by pathologic or iatrogenic fractures of the ossicles due to “weak” bones. Brittle bones also accompany osteopetrosis (Albers-Schoenber disease) due to failed resorption of calcified cartilage leading to ossicular fractures with mixed hearing losses. Patients with syndromes restricting skeletal growth, such as achondroplasia, an autosomal dominant condition, can also have absent, fused, or fore-shortened ossicular chains. Symphalangism syndrome, another autosomal dominant disorder, has aberrant bone fusion at interphalangeal joints and is associated with conductive hearing loss. The ear anomaly is attributable to the fixation of the stapes to the petrous part of the temporal bone. Congenital otosclerosis occurs as a result of disrupted mesenchyme development at the junction of the otic capsule with the middle ear leading to fixation of the stapes to the oval window and a 20 to 40 dB conductive hearing loss. Another conductive disorder with fixation of the stapes is due to mutations of the X-linked DFN3, M genes, POU3F4/BRN4.12 These disorders of middle ear morphogenesis along with their recently discovered aberrations in genetic and molecular factors are listed in Table 1.

### Genetic and Molecular Determinants

The middle ear develops from condensations of neural crest cells within the mesenchyme of the first and second branchial arches. Mesenchymal-epithelial interactions are thought to coordinate the complex structure of the ossicular chain. Significant overlap exists with growth of the external ear as the temporal ring, tympanic membrane, and manubrium of the malleus involve a common wall. This is evident when examining genes responsible for development of the branchial arches. Early molecular and genetic studies on the middle ear involved extrapolation from avian models to mammals since these were easily manipulated during embryogenesis. However, precise mutations in the murine model have recently and dramatically expanded our knowledge of genetic and molecular determinants of middle ear growth.13-15

Molecular signals involved in branchial arch development have been confirmed to play a role in middle ear growth. Specifically, endothelin-1, Fgf8, and retinoic acid (RA) are required for appropriate maturation of the ossicular chain.14 Targeted mutations in endothelin-1 and Fgf8 lead to profound underdevelopment to absence of first branchial arch derivatives, namely, the malleus and incus. The stapes is also affected during endothelin-1 mutations but does not seem to be impacted significantly by defects in Fgf8 production. On the other hand, RA appears to have an affinity for stapes development, a structure arising predominantly from the second branchial arch, while conferring minimal if no deficits on malleus and incus formation when mutated.14,15 Homeobox transcription factors also appear to function as regulators of middle ear development but with less direct impact on specific branchial arches. Predominant and extensively studied factors include Prxl, Goseocid (Gsc), Dlx1, and Dlx2. Prxl appears to help establish location, size, and fate of neural crest condensations of future skeletal elements of the ossicular chain. Mutations in the Prxl gene lead to egregious cartilaginous attachments from surrounding skeletal bone to the maldeveloped structures consistent with incus and stapes. Malleal growth is also affected by Prxl mutations but may be the result of a disturbance in the coordinated development and insertion of the manubrium into the tympanic ring during TM and EAC development since these structures are also affected by mutations in this gene. Gsc is thought to regulate expression of molecules important in recruiting mesenchymal cells into skeletal condensations within the middle ear.15 In contrast Dlx1 and

BO = branchio-oto; BOR = branchio-oto-renal; EAC = external auditory canal.
ear is unique in generating a neural ganglion that is derived from its own primordial otocyst by allowing cells to delaminate from the anteroventralotocyst which coalesce to form the statoacoustic ganglion. These neurons then develop dendrites and axons that connect the sensory epithelia in the ear to the second-order auditory neurons.

Concomitant with this neural differentiation, the otocyst proper undergoes a complex morphogenesis, such that the gross anatomy of the membranous labyrinth is nearly mature by the end of the eighth week of gestation (Figure 6).25 The first morphologic change in the otocyst is the outgrowth of the future endolymphatic duct and sac. This structure begins as a dorsal diverticulum that elongates and migrates medially. The remaining otocyst enlarges circumferentially and also elongates on a dorsal–ventral axis. From this time point onward, the inner ear can be divided morphologically, developmentally and, in terms of clinical relevance, into a superior and inferior region (ie, pars superior and pars inferior). The superior portion of the otocyst gives rise to the 3 semicircular ducts, their associated ampullae and the utricle. The inferior portion gives rise to the saccule and cochlea. The clinical significance of such delineation is that congenital malformation of the inner ear is often observed as defects of the pars inferior, that is, abnormalities of the cochlea and saccule.

The 3 semicircular ducts develop sequentially during the fifth week of gestation, starting with the superior duct and followed by the posterior and then lateral duct. The superior and posterior ducts differentiate from a vertical canal plate while the lateral duct differentiates from a lateral (horizontal) canal plate outgrowth. These plate-like outgrowths generate the mature semicircular ducts by fusing the central portions of each plate which then resorb, leaving behind a duct-like structure (see Figure 6). One end of the lateral and the common crus of the superior and posterior ducts open into the utricle while the other ends form a dilated structures (the ampullae) that house the actual sensory hair cell organs (the cristae ampullares) for each semicircular duct and open into the utricle. The 2 ampullae for the superior and lateral ducts form anteriorly near the junction of the ducts with the utricle, while the ampulla for the posterior duct is located at the posterior end of the duct (see Figure 6E).

The cochlea begins as an evagination from the ventral portion of the otocyst starting at around the fifth week of gestation. After extending ventrally, the cochlear duct begins coiling such that it has formed 1½ turns by the eighth week, 2 turns by the tenth week, and has completed the normal 2½ turns by 25 weeks of gestation.

The utricle and saccule start to form during the sixth week. As the cochlear duct extends, the opening between the saccule and cochlea becomes constricted and forms the narrow cochleosaccular duct. In the mature inner ear, two additional ducts are evident medially: the utricular and saccular ducts that connect to the endolymphatic duct (Figure 7).26

Development of the Sensory Organs

Six major sensory organs are present in the human inner ear. The organ of Corti is responsible for auditory function, while the remaining 5 other sensory organs are dedicated to vestibular function (the 3 cristae and the utricular and saccular maculae). The developmental origin of these sensory organs is unclear. Based on early studies of the chicken inner ear, it has been proposed that all sensory cells in the inner ear derive from a ventromedial region of the otic cup. Subsequent studies utilizing gene expression patterns as molecular markers for the developing sensory organs in the chicken and mouse have since revealed that expression of bmp4 (bone morphogenetic protein 4), Msx-1 (muscle segment homeobox 1), and Lfng (lunatic fringe) can mark several specific cell patches (as opposed to one) that ultimately differentiate into hair cell patches.27,28 Similarly, in X enops experiments, time-lapsed, fluorescent labeling of various regions of the primitive otocyst show that all quadrants of the otocyst can contribute to sensory hair cells.

Once the position and type of a sensory organ has been specified, morphologic differentiation follows, and the sensory epithelium can be identified by an increase in the thickness of the otic epithelium into a pseudostratified layer that later differentiates into sensory hair cells and...
supporting cells. The notch signaling pathway is used in a variety of tissues for generating cell type diversity and regulating differentiation during development. Genes in the notch signaling pathway have also been implicated in the determination of hair cells and supporting cells in the inner ear. Mutation or deletion of the genes in this pathway have also been implicated in the determination of hair cells and supporting cells in the cochlea. Mutation or deletion of genes in this pathway resulted in the absence or aberrant number of sensory hair cells in zebrafish and mice.

**Cristae Ampullares.** The sensory epithelium for the crista ampullaris elevates into a ridge-like fold where hair cells and supporting cells develop. Cells surrounding the sensory epithelium are secretory in function and are thought to generate the gelatinous cupula in which the stereocilia of the sensory hair cells are embedded. The mound-like elevation of the crista is evident by the eighth week of gestation, and the sensory structure is mature by the twenty-third week of gestation (see Figure 7).

**Maculae.** The maculae develop in a similar fashion as the cristae except the sensory epithelium is flat, and it is covered by an otolithic membrane that contains superficial calcareous deposits, the otoconia. The maculae appear to be fully differentiated between 14 and 16 weeks of gestation (see Figure 7).

**Organ of Corti.** The organ of Corti develops from the posterior wall of the cochlear duct. As the cochlear duct increases in length, the cross-sectional shape of the duct changes from round to oval to triangular (Figures 8). The posterior wall develops into the sensory tissue, the organ of Corti; the anterior wall forms part of Reissner membrane; and the lateral wall forms the stria vascularis. The organ of Corti starts to differentiate at the basal region of the cochlear duct around the seventh week of gestation, whereas the epithelium in the apical turn is undifferentiated and pseudostratified at this age. By the twenty-fifth week of gestation, the organ of Corti is fully differentiated.

**Development of the Statoacoustic Ganglion.** Based on animal studies, neurons of the statoacoustic ganglion are thought to originate from the otic epithelium, whereas glial cells in the ganglion are derived from the neural crest. Morphologic studies suggest that cells in the anteroventral lateral region of the otic cup/otocyst delaminate from the epithelium, migrate away from the otocyst, and undergo proliferation before aggregating to form the ganglion. In parallel with the growth of the otocyst, the statoacoustic ganglion forms a pars superior and a pars inferior at about the time when the membranous labyrinth is divided into a dorsal vestibular and a ventral cochlear region. The pars superior of the ganglion provides the peripheral neural connections to the superior and lateral cristae and the macula of the utricle. The pars inferior gives rise to a distinct vestibular portion that innervates the macula of the saccule and posterior crista and the spiral ganglion that innervates the organ of Corti.

Helix loop helix transcription factors, such as Neurogenin 1, have been implicated in the
formation of the statoacoustic ganglion. In mice with a deletion of Neurogenin 1, the statoacoustic ganglion fails to form.\textsuperscript{37} Growth factors such as fibroblast growth factor 3 are also important for the formation of the vestibular ganglion in the mouse.\textsuperscript{38} Once the neurons of the ganglion reach their final position and finish proliferation, they express high-affinity neurotrophin receptors and become dependent on neurotrophins secreted by the presumptive sensory organs in the membranous labyrinth. Mice with targeted deletion (knockout) of genes encoding brain-derived nerve growth factor or Neurotrophin 3 or their respective receptors had a loss of ganglionic neurons and innervations to the sensory organs.\textsuperscript{39} However, this trophic dependency of ganglionic neurons on their target tissues is not reciprocal. In the absence of afferent innervation, the differentiation of sensory hair cells appears unaffected, at least until birth.\textsuperscript{40,41}

**Bony Labyrinth Development.** Concurrent with the development of the otocyst, the mesenchymal cells surrounding the otic vesicle differentiate into a cartilaginous otic capsule by the eighth week of gestation. As the membranous labyrinth enlarges, vacuoles appear in areas surrounding the otic epithelium as a result of programmed cell death. These vacuoles soon coalesce to form the perilymphatic space that is filled with perilymph. In the cochlea, the perilymphatic space develops in 2 divisions; the scala tympani forms before the scala vestibuli (see Figure 8).

Ossification of the cartilaginous capsule to form the bony labyrinth does not occur until the membranous labyrinth has acquired its adult size. Bone formation starts around the fifteenth week of gestation and ends by the twenty-first week with a total of 14 ossification centers. The first ossification center appears at the base of the cochlea where ossification occurs more rapidly than in the semicircular canals. In the vestibular portions of the inner ear, the membranous labyrinth continues to grow until approximately the twenty-first week of gestation. But by the twenty-third week of gestation, all the ossification centers have fused thus limiting any further growth in the membranous or bony labyrinth.

**HUMAN EAR MALFORMATIONS AND MODELS OF MOLECULAR DEVELOPMENT.**

Many genes causing human deafness have been identified recently. In some cases, the functional deficit is the result of gross malformations of the external, middle, or inner ear or a combination of more than one of these components (Table 1). Examples of some of these syndromes are described in the molecular sections of the external and middle ears listed above and in the following paragraphs.

**Branchio-Oto-Renal and Branchio-Oto Syndromes**

The branchio-oto-renal (BOR) syndrome is an autosomal dominant disorder characterized by branchial arch anomalies (branchial cleft cysts and sinuses), ear malformations affecting the external, middle, and inner ear regions, and various renal anomalies ranging from undetectable (in the branchio-oto (BO) syndrome) to bilateral aplasia (in the branchio-oto-renal (BOR) syndrome) to bilateral aplasia.\textsuperscript{4} Hearing loss is the most common presenting symptom and occurs in 88% of patients with BOR syndrome.\textsuperscript{11,43}

The most common external ear anomalies are preauricular pits and skin tags, but microtia and aural atresia are also noted in patients with BOR syndrome. The middle ear cleft is commonly hypoplastic in patients with BOR syndrome, as can be the middle ear ossicles. In the inner ear, aplasia or hypoplasia of the cochlea has been reported as a BOR phenotype (Figure 9). The vestibular portions of the inner ear similarly show absent or malformed semicircular canals. Depending on the ear phenotype, hearing loss can be sensorineural, conductive, or mixed, as seen in approximately one-half of the patients with BOR syndrome.\textsuperscript{4}

The gene responsible for causing BOR and BO syndromes has been identified to be the human homolog of the Drosophila eyes absent (eya) gene.\textsuperscript{11,42} The spectrum of malformations seen in BOR syndrome suggests a defect in the EYA1 molecular pathway occurring sometime between the fourth and the tenth week of gestation. The types of DNA mutations identified in patients with BOR syndrome suggest that the developmental malformations result from reduced gene dosage.\textsuperscript{11}

Mice with eya1 also displayed similar severe external, middle, and inner ear defects suggesting that the functions of this protein in ear development are evolutionarily conserved.\textsuperscript{5} In mice, eya1 is specifically expressed in the early otocyst along the ventromedial wall and the adjacent statoacoustic ganglion.\textsuperscript{44} At later embryonic time points, EYA1 is expressed along the neuroepithelium that eventually gives rise to key cochlear structures, such as the inner and outer hair cells. In addition, EYA1 is also expressed in the external and middle ear primordia. These results suggest that the encoded protein of EYA1 plays a direct role in the formation of all three components of the ear in mice as well as in humans. Studies in Drosophila eye imaginal disks show that the Eya gene product is a transcriptional coactivator that acts as part of a complex with other transcription coactivators during eye morphogenesis.\textsuperscript{24}

**Pendred Syndrome**

Pendred syndrome is an autosomal recessive disorder classically characterized by deafness and goiter. The presence of goiter is usually variable in severity; however, most patients have a positive perchlorate discharge test indicative of a defective organification of iodine in the thyroid gland. The onset of deafness in the classically described syndrome is congenital, profound, and sensorineural in nature. Cochlear hypoplasia with poorly partitioned mid and apical turns, sometimes referred to as Mondini malformations, and enlarged vestibular aqueducts (EVAs) are often described in these patients.

The gene responsible for causing Pendred syndrome was identified using a positional cloning approach and was named PENDRIN.\textsuperscript{45,46} Functional studies in Xenopus oocytes show that the encoded protein functions as a chloride/iodide transporter.\textsuperscript{47} The clinical significance of this gene broadened when mutations in PENDRIN were also shown to cause autosomal recessive deafness that mapped to the locus of DFNB4, a recessive nonsyndromic form of deafness.\textsuperscript{48} Expression and gene-targeting studies in mice have provided insights into the etiology of this disorder. In mice, Pds is activated during embryonic development of the inner ear. Its expression is restricted to nonsensory regions of the inner ear including the endolymphatic duct and sac, nonsensory regions of the utricle and saccule, and the external sulcus region in the cochlea.\textsuperscript{49} Pendrin knockout mice are deaf and display variable defects of the vestibular structures.\textsuperscript{49} However, the cause of inner ear dysfunction in these mice most likely is not attributable to structural malformations as implied by the human disorder. The membranous

The external, middle, and inner ears are all potentially affected in branchio-oto-renal (BOR) syndrome. At the

labyrinth of the Ps knockout mice dilates during embryogenesis that is likely due to the disruption of normal endolymph homeostasis resulting from loss of the ion transport function of Ps. The sensory hair cells develop and appear normal at birth but degenerate later in life. This is thought to be due (again) to the loss of a normal inner ear fluid environment. It is likely that the etiology of human Pendred syndrome is similar to that of the Ps mutant mouse model, where the deficit lies in ionic imbalance of the endolymph rather than the structural malformation during development. The EVA associated with Pendred syndrome supports this hypothesis. Clinically, our knowledge base and understanding of the function of PENDRIN in the inner ear, the sequelae of loss of normal PENDRIN function, the mechanisms explaining associations of EVA and cochlear hypoplasia with PENDRIN mutations are steadily advancing. Mutant mice carrying mutations similar to those found in patients with Pendred syndrome will help to clarify this issue.

**Figure 9** The external, middle, and inner ears are all potentially affected in branchio-oto-renal (BOR) syndrome. At the external ear level, auricular malformations vary from mild hypoplasia to complete aplasia. (A) A rudimentary ear lobe is apparent even on this axial computed tomographic (CT) scan of the temporal bones in a child with BOR syndrome. Note also the failure of development of an external auditory canal (aural atresia) and the associated small middle ear cavity. (C and D) Demonstrate normative CT imaging data with middle and inner ear structures labeled as shown.

**X-Linked Deafness Locus 3**

X-linked DFN3 is caused by mutations in a member of the POU domain transcription factors, POU3F4/BRN4. In mice, Pou3f4 is important for the development of the ear. Transcription of this gene is activated in mice at the otocyst stage in the mesenchymal cells surrounding the otocyst. Pou3f4 knockout mice show a variety of deficits, including abnormal fibrocytes surrounding the cochlea, misshapen stapes, and shortened cochleae. The deficits caused by mutations of this gene in humans are usually conductive in nature and can be corrected by surgery.

**SUMMARY**

A tremendous number of advances have been made over the past several years in identifying developmental ear anomalies (hearing loss, malformations, etc.) and the molecular defects underlying those abnormalities. An in-depth review of the various genetic causes of hearing loss overlaps with this discussion and is presented in Chapter 26, “Hereditary Hearing Impairment.” However, it is worthwhile to point out that since many genetic causes of hearing loss present as congenital deafness, it is reasonable to speculate that the genetic mutations causing congenital hearing loss likely perturb the normal development of the inner ear in utero and are thus relevant to both abnormal and normal ear development. Through continued investigations into human manifestations (such as syndromic and nonsyndromic hearing loss), as well as continued research using animal models of human ear anomalies (eg, transgenic mouse models), marked advances in our understanding of human inner ear development will continue to emerge.

Molecular Biology of Hearing and Balance

Joni K. Doherty, MD, PhD
Rick A. Friedman, MD, PhD

Our working knowledge of the inner ear at the molecular level has been attained through analyses of mutations that result in hearing and balance dysfunction. Investigation of a particular mutation to determine its genomic location and gene product can provide vast information in terms of inner ear molecular mechanisms. Genetic mutations affecting the inner ear are being intensely studied in both humans and animal models, resulting in an exponential increase in our understanding of the molecular biology of the middle and inner ear.

MOLECULAR METHODOLOGY

Molecular biology has been used to address many basic science questions in otology. In many cases, the potential exists for such studies to influence clinical care, currently and in the future. An exhaustive discussion of molecular techniques is beyond the scope of this chapter, but a brief discussion follows. During the 1980s, advances in molecular genetic technology led to a rapidly progressive increase in the number of molecular markers that facilitate linkage analysis. These markers are polymorphisms, which are variations in the genetic code between individuals. They can be silent, in terms of encoding the protein sequence, depending on their location, that is, at the third position of a codon, or can result in amino acid substitution, which is sometimes inconsequential to protein function. Because differences in sequence can alter restriction enzyme cleavage sites, they can define genetic locations and have enabled scientists to identify the approximate location of inherited mutations.

The first requirement for linkage analysis is a large family with an inherited defect, such as hearing loss. The second requirement is to identify useful deoxyribonucleic acid (DNA) markers that differ in individuals with versus without the disease phenotype, in order to establish linkage. The Human Genome Project has facilitated identification of useful DNA markers that can be used in screening. Once the location is identified, DNA within that chromosomal location is cloned and functionally analyzed. Positional cloning refers to identifying a gene by its location first, and then determining its function by expression analyses.

Advancements in gene cloning techniques, such as use of the polymerase chain reaction (PCR) to amplify, that is, produce many copies, a gene of interest and incorporate DNA cleavage sites that facilitate cloning, have facilitated expression and functional analyses. The PCR can be combined with a reverse transcription reaction (RT-PCR) to target and amplify sequences that are expressed in a single cell, such as an inner hair cell. These single cells can be laser-microdissected and subjected to RT-PCR using an oligo-dT primer that amplifies messenger ribonucleic acid (mRNA) selectively, since it targets the poly-A tail.

Typically, cloning via PCR initially involves isolation of mRNA from a tissue of interest and construction of complementary DNA (cDNA) from this mRNA using a reverse transcriptase enzyme adapted from viruses. Figure 1 in a thermal cycling reaction, including a series of repeating denaturing steps, annealing steps, and elongation steps in sequence. An expression library can then be created by incorporating cleavage sequences at both ends of the cDNA via PCR. Screening of such expression libraries from isolated inner ear tissues has been a powerful tool to facilitate identification of genes that are important in those tissues. Genes can then be expressed in biologic systems, from bacteria to mammals, to determine their expression pattern, subcellular location, structure, and function (http://www.genexpression.info). Indeed, much of the developmental and functional information we have obtained thus far has been from animal studies. Herein, we will review the biology of middle ear and inner ear at the molecular level, as it pertains to human diseases and disorders. We will begin by reviewing what is known about middle ear pathology and otitis media, and a discussion of the knowledge of the inner ear molecular mechanisms subserving specific functions will follow.

MOLECULAR PATHOGENESIS OF OTITIS MEDIA

Otitis media (OM) is a common cause of hearing loss worldwide. OM with effusion causes conductive hearing loss and can contribute to delayed speech development in children. Chronic OM can lead to conductive hearing loss and even sensorineural hearing loss, particularly if cholesteatoma erodes the labyrinth. Advances in diagnosis, research, and potential treatments for middle ear (ME) disease involve molecular biology as well. OM susceptibility has been shown to be genetically mediated. The PCR has been instrumental in identifying microbes involved in OM, and quantitative PCR is utilized to measure middle ear responses to OM via cytokine production. Immunoregulation has also been investigated using in situ hybridization and implantation of genetically modified microbes.

Cloning bacterial genes has facilitated production of genetically engineered bacteria, including gene alterations or deletions, to investigate host interactions, virulence factors, and immunogenicity. These genetically altered bacteria can also be used to create vaccines. Host defense mechanisms are being studied via transgenic and knockout animal models.

Bacterial Adherence Factors in Otitis Media

The exact mechanisms by which bacteria attach to the mucosal surface of the ME are incompletely understood but likely involve receptor ligand-mediated interactions. The host receptor for Streptococcus pneumoniae is known to be Glc Nac1-3Gal, yet the receptor for nontypable Haemophilus influenzae (NTHi) is uncharacterized. While the receptor is yet to be identified, ligands include pilin (both 22 kD and 27.5 LKP1 kD, depending on serotype), a subunit of the surface appendage pilus that mediates hemagglutination, and fimbria (36.4 kD), a subunit of the surface appendage fimbria that is thinner than pilus and nonhemagglutinating. Expression of the gene that encodes 27.5 kD LKP1 pilin in Escherichia coli mediates bacterial binding to the buccal mucosal surface and hemagglutination. However, less than 5% of middle ear isolates expressed pil; therefore, their role in the pathogenesis of OM is unclear. Conversely, 100% of NTHi isolates from chronic ME effusion were fimbriated. Other potential ligands include high-molecular-weight outer membrane proteins (OMPs) (120 kD HMW-1 and HMW-2), which may facilitate binding of bacteria to the epithelial cell surface. OMPs show significant sequence homology with fimbria. Disruption of the fimbria gene resulted in decreased virulence and lack of adherence to the epithelial cell surface in vitro.
Virulence Factors in Otitis Media

Endotoxin is an important mediator in OM, and type b Haemophilus influenzae displays phase variation of the endotoxin lipo-oligosaccharide (LOS), which allows it to switch expression from one of the two stable genotypes. Phase variation of endotoxin expression is, in itself, a virulence factor and involves three genetic mechanisms: 

1. Insertional mutagenesis of the gene in S. pneumoniae resulted in decreased survival time intraperitoneally. 
2. A virally derived reverse transcriptase enzyme "copies" this mRNA molecule isolated from a tissue or cell type of interest represents the expression array of genes for the particular tissue or cell type. 
3. Messenger ribonucleic acid (mRNA) is a single-stranded RNA strand that is processed into mRNA via removal of intervening (intron) sequences and polyadenylation of the 3' end. This mRNA is then transported out of the nucleus into the endoplasmic reticulum, where ribosomes are abundant (not shown). 

Multiple ribosomes translate a single mRNA strand into multiple proteins. 

Several factors regulate the amount of gene expression in terms of mRNA transcript and protein produced, including DNA promoter sequences, enhancer and silencer elements, and the presence of transcription factors. 

MUC1, MUC2, MUC5AC, MUC5B, and MUC8 mucin genes.27–29 The proinflammatory cytokine, MUC7, and MUC8, are upregulated in rat ME mucosa following bacterial inoculation.19 Angiogenic growth factors and their receptors were also identified in cholesteatoma.20 Immunocytochemistry techniques have demonstrated expression of epidermal growth factor (EGF), fibroblast growth factor (FGF), platelet-derived growth factor, and keratinocyte growth factor.21,22 Downstream intracellular signaling molecules involved in the process appear to include ras, c-jun, and p53.23,24 Evidence for integrin signaling is suggested by the finding of increased tenascin in cholesteatoma keratinocytes, and this molecule is involved with growth factor receptor cross talk signaling as well. Known downstream signaling effectors, including mitogen-activated protein (MAP) kinases have been investigated with respect to OM. Mucin upregulation induced by H. influenzae inoculation involves activation of a Rac-dependent MEKK-SEK-p38 MAP kinase pathway.25 Additionally, radical oxygen species (ROS) may be involved in the inflammatory response via activation of p38 MAP kinase, leading to mucin transcription.26 Mucin is a high-molecular-weight glycoprotein that is the major component of mucus. Overproduction of mucus in OM with effusion contributes to defective mucociliary clearance and recurrent infection and causes conductive hearing loss. Human ME epithelial cells express mucin from the MUC1, MUC2, MUC5AC, MUC5B, MUC7, and MUC8 mucin genes.27–29 The proinflammatory cytokine, tumor necrosis factor-alpha (TNF-α), induces upregulation of mucin in rat ME mucosa.27
Proinflammatory transcriptional regulation is also evident in upregulation of cytokines via nuclear factor kappa B (NF-κB). Proinflammatory cytokines, such as interleukins, are upregulated in response to middle ear inoculation. Their expression is induced rapidly, peaking at 6 hours, and declines by 24 hours following inoculation. Interleukin-1 (IL-1) leads to downregulation of surfactant expression in the middle ear membrane, possibly contributing to contraction of the middle ear space with negative middle ear pressure, as observed in early acute and in chronic OM. Conversely, anti-inflammatory and immunoregulatory cytokines are induced over a longer time course, lasting up to weeks after inoculation. Nitric oxide (NO) synthesis is also increased, particularly in middle ear effusion.

**Host Defenses Against Otitis Media**

Innate immunity defends tissues of the aerodigestive tract against microbial invasion. Epithelial cells lining the middle ear, eustachian tube, and nasopharyngeal tract express antimicrobial peptides, including lytic enzymes, defensins, lysozyme, lactoferrin, and collectins. Defensins have broad-spectrum antimicrobial activity against bacteria, fungi, and even some enveloped viruses. Human β-defensins 1 and 2 (HBD-1, HBD-2) are expressed in the middle ear epithelium following contact with microorganisms or cytokine stimulation, and HBD-1 and 2 exhibit potent activity against gram-negative bacteria and candida but less activity against gram positives, such as Staphylococcus aureus.

Lysozyme is another important molecule involved in innate immunity. It is produced in secretory cells of the mucosal epithelium and is increased in middle ear effusions. Polymorphonuclear leukocytes and macrophages also express lysozyme as an antimicrobial enzyme, and lysozyme is a component of human breast milk that exhibits anti-NTHI activity.

Lactoferrin, an iron-binding glycoprotein detected in middle ear effusions, is also found in breast milk, secreted by exocrine glands, and released from neutrophilic granules during inflammation. Lactoferrin secretion has been localized to the serous cells of the eustachian tube glands, and in the cuboidal and transitional cells of the middle ear mucosal epithelium. Collectins are structurally and functionally related to complement protein C1q, the first component of the classic complement pathway. Collectins are thought to enable innate immunity via opsonization and complement activation. Surfactant proteins A and D, classified as collectins, are expressed in the middle ear and eustachian tube, where they are likely involved in protection against OM pathogens, particularly in the tubotympanum.

**Otitis Media Pathogens: Antibiotic Resistance**

Bacterial resistance is primarily enzymatic. The mechanism of ampicillin resistance is β-lactamase production, encoded within a large gene segment called transposon A, mediated by alterations in bacterial penicillin-binding proteins (PBPs). The basis for H. influenzae type b resistance to chloramphenicol is largely due to acetyltransferase expression from a gene that is also located within a transposon. Trimethoprim resistance results from overproduction of dihydrofolate reductase via chromosomal rearrangement.

**Vaccine Development in Otitis Media**

Knowledge of the factors that mediate virulence and adhesion has enabled scientists to develop vaccines against these bacteria. The nucleotide sequence information and expression of several OMPs have facilitated the identification of domains that are conserved across strains. Together with mapping of epitope molecules, this has provided structural and functional information, which is critical in selecting antigens for vaccine development. Monoclonal antibody production against the OMP P26 is an example of utilizing this information for vaccine development, since scientists were able to identify the sequence of the region of P26 that conferred bactericidal antibody production by inoculation in a polyclonal model. Pilin and fimbriae are also good candidates since antibodies directed at these proteins can prevent adhesion and reduce colonization and infection.

Viral upper respiratory infections often precede OM, and PCR data confirmed that a significant number of middle ear effusions contained upper respiratory viruses. In a chinchilla model, vaccination with attenuated influenza virus prevented pneumococcal OM after inoculation, indicating that the viral vaccine protected the animal from bacterial infection. Clinical trials to that effect in children have been performed in Finland with promising results. However, viral vaccines are prone to being ineffective since they utilize surface antigens and viruses’ surface proteins evolve rapidly and evade the host immune system. Use of interior viral proteins or viral DNA as vaccines may prove to be a more promising long-term solution.

**Future Directions: Middle Ear Mucosal Gene Transfer**

FGF-1 secreting middle ear mucosal cells have been successfully engineered via stable transfection and implanted into the subepithelial compartment. A adenoviral vector transduction is another method of inducing expression of a transgene that has been successful in the rat neonatal and guinea pig middle ear. The study of mouse genetics has been indispensable in terms of advancing knowledge about human development and disorders. Creating homologous mutations in experimental mouse models enables us to determine the function of genes mutated in human disorders. Techniques for developing animal models include creating transgenic animals, insertional mutagenesis, and site-directed mutagenesis.

**Transgenic Animals**

Insertion of a synthesized gene into the genome of a normal mouse embryo can result in the production of a transgenic mouse. The artificial gene is composed of a tissue-specific promoter sequence linked to the sequence coding for the protein of interest. This construct is then inserted into the fertilized mouse embryo through various means, including physical injection or retroviral transfection. If the transgene inserts into the genome DNA and if the embryo survives, the adult mouse will pass the gene on to future generations. In any transgenic animal, if there are cells that express a transcription factor that interacts with the promoter, the gene product will be expressed in these cells and may affect their function.

**Insertional Mutagenesis**

In a small percentage of the offspring of transgenic animals, the transgene will be randomly inserted into another gene in the genome, resulting in a mutation and a phenotype change in the animal. This process is termed as insertional mutagenesis. The position of the mutated gene is now marked by the transgene, which can facilitate its localization and identification.

**Site-Directed Mutagenesis**

Site-directed mutagenesis or gene targeting relies on the process of insertional mutagenesis. Basically, a mutant gene that confers antibiotic resistance and disrupts expression of a normal protein is flanked by sequences of a gene to be disrupted, and then it is inserted into an embryonic stem cell (Figure 3). The cultured cell then divides, and through homologous recombination,
targeted insertional mutagenesis occurs and simultaneously results in both gene deletion and antibiotic resistance in some of the progeny cells (Figure 3C). The progeny cells are then selected for antibiotic resistance and inserted into a blastocyst, which is then implanted into the uterus of a mouse (Figure 3D). The resulting offspring mice are chimeric, and subsequent breeding of the mice in which the germline is affected will eventually generate some homozygous mutants if the mutation is not lethal. This method was used by Mansour and colleagues to generate mice with a mutation in the int-2 gene, which encodes fibroblast growth factor 3 (FGF-3). Prior to production of this mutant mouse, Represa and colleagues had shown that disruption of int-2 expression in vitro prevented inner ear development. The mutant mice created by Mansour and colleagues, however, had normal induction of the inner ear despite having decreased FGF-3 production, suggesting the existence of a redundant pathway for induction. Interestingly, these mice did have hearing and vestibular defects that correlated with multiple inner ear abnormalities, indicating that such an alternative pathway is inadequate for compensation of the defect and still results in aberrant development.

An alternative method for studying gene expression and function is the analysis of mutant mice with hearing and balance defects. This has also facilitated our current understanding of inner ear development. The process of inner ear development is governed by complex gene interactions, which regulate a series of ontogenetic events. Generally, mutations in genes that play a role early in otocyst induction and patterning result in gross malformations, while mutations in genes expressed later tend to result in subtle inner ear structural abnormalities, often limited to discreet elements of the sensory neuroepithelium or dysregulation of inner ear homeostasis. Thus, phenotypic abnormalities can be used to predict the stage of development at which a particular gene is expressed. Some genes, however, display overlap in their developmental roles, such as those encoding Delta and Jagged—the Notch receptor ligands, as discussed below.

Additionally, subtractive hybridization technique, using chicken embryos, has led to the rapid identification of several inner ear genes that are expressed during development as unique inner ear proteins. Among them are otocardin, β-tectorin, calbindin, type II collagen, and connexins. Such genes are potential candidates for deafness genes based on their temporal expression, and several have subsequently been identified in humans in association with hereditary deafness.

### Microarray Technology

Thousands of genes and their protein products are essential to the finely coordinated process of mammalian inner ear development and function. The study of the genetics of mammalian development and disease has relied upon the single gene methodological approach. This is a low throughput analysis that provides a finite look at the complex cascade of genetic events. Scientists have thus far been limited in their ability to see the genetic "big picture." A new technology has emerged, DNA microarray, and it is providing scientists with a means to scan the entire genome, on a single chip. This is opening the door to the discovery of the combinatorial genetic interactions that lead to the generation of an organ as complex as the inner ear.

A microarray is an ordered arrangement of DNA samples that, based upon complementary base pairing, provides a platform for matching defined and, as yet, undefined DNA samples. Microarrays consist of thousands of sample spots (200 μm or less in diameter) linked to a particular medium (glass or nylon membranes). The use and analysis of microarrays requires highly specialized robotics and imaging systems. Each of these spots can be simultaneously probed by a known sequence, and through complementary base-pair interactions, these arrays provide an extremely high-throughput gene identification and or expression studies.

In general, microarrays can be found in two different varieties. In one, small fragments of cDNA are immobilized onto a solid surface (glass) and are exposed to a specific target allowing massive gene expression studies to occur in parallel. For example, variations in gene expression in a tissue of interest after delivery of a new drug can be studied using this technology. Similarly, the analysis of gene expression in a particular mutant mouse strain can be compared to the normal for a given tissue, giving insights into the developmental role played by the mutant gene in a particular process.

The other type of array involves the placement of oligonucleotide or peptide nucleic acid probes. These arrays are hybridized by a labeled DNA sample, and the abundance of complementary sequences is ascertained. This technology has become very useful for genetic testing. A "gene chip" can be created such that oligonucleotides associated with a particular mutation can be identified rapidly in at risk individuals. The state-of-the-art chips have opened a new era in human genetics. With the ability to scan the entire genome for single nucleotide polymorphisms (SNPs) across experimental and control cohorts, high-resolution genetic association studies are now possible (http://www.gene-chips.com/).

### RNA Interference

RNA interference (also called “RNA-mediated interference,” abbreviated RNAi) is a mechanism for RNA-guided regulation of gene expression in which double-stranded ribonucleic acid (dsRNA) inhibits the expression of genes with complementary nucleotide sequences. In most eukaryotic organisms, the RNAi pathway is thought to have developed as a form of innate immunity against viruses and also plays a major role in regulating development and genome maintenance.

The RNAi pathway is initiated by the enzyme dicer, which cleaves dsRNA to short double-stranded fragments of 20 to 25 base pairs. One of the two strands of each fragment, known as the guide strand, is then incorporated into the RNA-induced silencing complex (RISC) and base pairs with complementary sequences. The most well-studied outcome of this recognition event is a form of posttranscriptional gene silencing. This occurs when the guide strand base pairs with a mRNA molecule and induces degradation of the mRNA by argonaute, the catalytic component of the RISC complex. The short RNA fragments are known as small interfering RNA (siRNA) when they derive from exogenous...
The selective and robust effect of RNAi on gene expression makes it a valuable research tool, particularly well studied in certain model organisms such as the nematode worm Caenorhabditis elegans, the fruit fly Drosophila melanogaster, and the flowering plant Arabidopsis thaliana. The inner ear is a highly complex yet ordered structure in which induction and differentiation initiate the process of development, and maturation completes it. Studying gene expression during development in animal models has enabled identification of essential factors in each stage of inner ear development. Additionally, some of these observations have potential clinical implications.

**Transcription Factors**

The otic placode, which develops as an ectodermal thickening of either side of the neural plate in the hindbrain of mice at embryonic day 8.8 (E8.5), gives rise to all of the inner ear structures and cell types, except melanocytes and Schwann cells.\(^6\) Transcription factor gene expression is thought to specify the patterning of inner ear development at this crucial stage.\(^7\) Essential genes at this early stage that have been described include Pax2, Hmx3, Hoxa1, retinoic acid receptors (RAR), and NeuroD1. 

**Otx1 and Prx1/Prx2 Genes.** The horizontal semicircular canal is absent in Otx1 mutants and in double mutants of Prx1 and Prx2.\(^8\) Targeted deletion of Otx1 results in normal development of the cochlea and all other vestibular structures, while in double mutants of Prx1/2, the other semicircular canals are delayed in development.

**Pax Gene.** Disruption of the Pax gene in mice results in cochlear agenesis with absence of the spiral ganglion, while the vestibular apparatus is unaffected.\(^9\) Pax3, or paired box DNA-binding
protein 3, encodes a transcription factor essential for proper migration of melanocytes and organization of the stria vascularis, and, thus, appears to play an essential role in endolymph production. PAX3, the human homologue, is mutated in Waardenburg syndrome type I (WS-I).

**Hmx3 Gene.** Hmx3 is expressed in the inner ear as well as in the second branchial arch. Targeted deletion of Hmx3 results in vestibular dysgenesis.**78** Hmx3 appears to play a role in separation of the utricular and saccular maculae and development of the semicircular canals. The sensory organ within the horizontal semicircular canal is absent in Hmx3 mutants.

**RAR Genes.** Three genes encode RAR subtypes α, β, and γ that are expressed in the mouse embryonic inner ear and are important in otocyst development.**62,66** These RARs bind all trans retinoic acid, the major biologically active metabolite of vitamin A, as ligand and are activated to then bind retinoic acid response elements of target genes.

One such gene, which encodes bone morphogenetic protein 4 (BMP4), plays a role in patterning of the semicircular canals (SCC). BMP4 down-regulation by retinoic acid, mediated by RAR action at a promoter site of the second intron of the BMP4 gene, affects SCC formation.**64** Other genes involved in the retinoic acid signaling pathways are also essential, such as the mouse gene Hoxa1, a homeobox gene that is a putative downstream target of RAR.**65** Mutations in RAR-α and RAR-γ, together, result in severe vestibular and cochlear malformations which are similar to Hoxa1-deficient mice. Hoxa1 mutants display inner ear dysmorphogenesis with variable defects in the vestibular and cochlear components. Although RARs are widely expressed in the mouse inner ear, phenotypic defects are not displayed unless two or more receptors are absent, as in compound null mutants.**66** This fact underscores the redundancy of such receptor isoforms.

Furthermore, RNA encoding RAR-β has been found in the inner ear of embryonic mice.**51** In addition, when exposed to retinoic acid in vitro, embryonic supporting cells show premature differentiation into hair cells.**34** Retinoic acid or similar growth factors could thus eventually play a role in hair cell regeneration.

**BETA2/NeuroD1 Gene.** A basic helix-loop-helix transcription factor (BHLH TF) that is expressed in many cell types during development of the mammalian central nervous system is BETA2/NeuroD1. Its role in the inner ear is essential in that knockouts are deaf and have balance disorders, displayed by head tilting and circling.**58** Null mutations result in severely reduced numbers of cochlear and vestibular ganglion (C VG) cells in mice due to apoptosis after differentiation therefore, the role of BETA2/NeuroD1 appears to be in C VG cell survival. Additionally, mutants have defects in cochlear duct differentiation and patterning, sensory epithelium, and dorsal cochlear nucleus cells.

**Math1 Gene.** Determination of auditory and vestibular hair cell fate is an early event in embryogenesis and has not been completely elucidated. In mice, the BHLH TF Math1, is expressed early in hair cell (HC) differentiation and Math1 knockouts fail to develop HCs.**56** However, the fact that Math1 is expressed in several cell lineages suggests that its role is contributory and essential but that it does not act alone in determining HC fate. It is likely that combinatorial coding in TF regulation of gene expression occurs as a unique process in specifying cell type and initiating differentiation.**70**

**POU-Domain Genes.** At least two of the three members of the Brn-3 subfamily of POU-domain regulatory TF genes also play a key role in auditory and vestibular sensory neuron development. The Brn-3.0 (or Brn-3a) and Brn-3.2 (or Brn-3b) proteins are expressed in some spiral ganglion and Scarpa ganglion cells. The Brn-3.1 (or Brn-3c) protein is essential for auditory and vestibular HC development and appears to function downstream of Math1. Brn-3.1 knockout mice are deaf and have impaired balance function due to absence of sensory HCs.**71,72** Localization studies in mice embryos have shown that Brn-3.1 is expressed early in HC lineage after fate is determined but before HC morphology is distinguishable, and high-level expression continues throughout HC life. Brn-3.1 knockouts display normal migration of HC precursors, but HCs degenerate and undergo apoptosis by embryonic day 18 in mice.**73** The human homologues are Pou4f3 and Pou4f4, mutations of which lead to late-onset progressive nonsyndromic sensorineural hearing loss (SNHL). The Pou4f3 transcription factor may play a dual role. While the mouse homologue Pou4f3 determines late hair cell differentiation, and mutations lead to hair cell death prior to complete differentiation, the human Pou4f3 is a dominant deafness gene (DFNA15), inducing adult-onset hearing loss. Thus, Pou4f3 may play a role in long-term HC survival in the human, but its role is clearly distinct from that in mice.**74**

**SENSORY CELL DIFFERENTIATION AND DEVELOPMENT**

Differentiation and development of the organ of Corti in mice arises from the “zone of nonproliferating cells” (ZNPC), induced by asynchronous exit from the cell cycle promoted by the cyclin-dependent kinase inhibitor p27kip1.**75** Cell-cycle exit also seems to depend upon expression of Notch1 and its ligand, J agged1, which may define boundaries and patterning of sensory cell development in the cochlea, since J agged1 and Notch mutants display abnormal patterning of the cochlea.**76,77**

Sensory cell fate determination is orchestrated by Notch-Delta signaling via lateral inhibition, which results in precise patterning of sensory neuroepithelia of the cochlea and vestibular apparatus. The website, http://www.ihr.mrc.ac.uk, provides a table of genes expressed in mice and humans during inner ear development.

**Myosins in Inner Ear Development**

The mouse mutant Shaker-2 carries a M yosin XV mutation, for which the homologous human deafness gene is DFNB3, which results in shortened stereocilia.**71** M yosin XV a localizes to the tips of stereocilia of the cochlear and vestibular hair cells, overlaps with the barbed ends of actin filaments, and extends into the apical plasma membrane. M yosin XV a is essential for the graded elongation of stereocilia in formation of the characteristic staircase pattern of the hair bundle**78** (Figure 4).
A Myosin VI null mutation causes the mouse mutant Snell waltzer, which displays fusion of the stereocilia at birth and subsequent hair cell degeneration. These findings, combined with immunofluorescence and electron microscopy studies, revealed the function of myosin VI as an anchor between the cuticular plate of stereocilia and the apical membrane of hair cells. Both vestibular and cochlear HVs produce mRNA-encoding neurotrophic factors, especially BDNF and NT-3. Cochlear and vestibular neurons extend in vitro is inhibited with antisense oligonucleotides to BDNF and NT-3, but it is enhanced when NGF, BDNF, or NT-3 is added to the media. In addition, mice have been bred with gene knockouts of the BDNF gene, the NT-3 gene, and both genes. BDNF knockout mice lose most vestibular as well as type II cochlear ganglion cells and outer HC afferents. NT-3 knockouts lose type I cochlear ganglion cells in addition to inner HC afferent neurons. The mice without both genes lack vestibular and cochlear ganglion cells. The importance of these neurotrophic factors for the survival of inner ear neurons suggests that they have the potential to protect these cells from degenerating. Therefore, they might have a role in preserving spiral ganglion neurons for stimulation by the cochlear implant.

Other growth factors which have been identified as key players in inner ear development via animal models are discussed below.

**Jagged/Delta Gene.** Exit from the cell cycle is crucial for induction of differentiation and maturation. Cell-cycle exit in the cochlea seems to depend upon expression of Notch1 and its ligands, Jagged1/2 and Delta, which may define boundaries and patterning of sensory cell development. Mutants in Jagged1 and Notch display abnormal patterning of the cochlea. Notch-Delta signaling plays a crucial role in primary cell fate determination through lateral inhibition. Early in development of the organ of Corti in chicks, Delta and Jagged expression by developing inner hair cells appears to result in lateral inhibition of hair cell differentiation, committing adjacent progenitor cells to the fate of supporting cells and possibly induces outer HC development as well. Later in development, expression of Delta and Jagged appears to inhibit both inner and outer HC differentiation.

**Fgf3 Gene.** Although the fibroblast growth factor 3 (FGF3) is expressed widely in both brain and ear tissues, the role it appears to play in inner ear morphogenesis involves the endolymphatic duct (ELD) and sac. Fgf3 knockout mice display malformation of both the ELD and sac, among other abnormalities.

**Neurogenin1 Gene.** Auditory and vestibular ganglion neurons fail to develop in mice with targeted deletion of neurogenin1.

**Shh Gene.** Mesenchymal-epithelial interactions appear to play an essential role in inner ear development, based on observations in mice. The protein product of sonic hedgehog (Shh) is secreted by notochord in early development and is essential for ventral otic derivatives, such as the cochlear duct and cochleovestibular ganglion. Shh interacts with both Pax2 and BMPs during otocyst development, where it may induce mesenchymal condensation to form the bony otic capsule. Shh knockouts display a poorly mineralized otic capsule that occasionally lacks semicircular canals.

**INNER EAR HOMEOSTASIS**

Numerous studies have investigated genes involved in cochlear homeostasis and, in particular, the molecular basis of production and maintenance of ion gradients between cochlear fluids and cells. Such studies have particular relevance for disorders of fluid balance in the inner ear, including Meniere disease. Genes encoding isoforms of the ion channels, such as the sodium-potassium ATPase or the plasma membrane calcium ATPase (PMCA), are differentially expressed by cochlear cells within the spiral ligament and stria vascularis and the organ of Corti. This is likely related to the uniquely high electrochemical gradient against which the stria vascularis must transport ions to maintain the endocochlear potential. Furuta and colleagues found that, in particular, inner hair cells express high levels of PMCA1 mRNA, while outer hair cells express high levels of PMCA2, suggesting that the calcium regulation requirements of the two cell types are distinct, owing to their different functions and sensitivities.

Furthermore, the pendrin protein is involved in endolymph homeostasis through its role as an anion transporter in the inner ear. Targeted disruption of the Pds gene in mice leads to severe vestibular defects, endolymphatic hydrops with dilation of associated inner ear structures, reduced macular otocoria, and cochlear HC degeneration. The finding of excess endolymph in such mice has led to the assumption that pendrin plays an essential role in endolymph resorption.

In contrast, two other ion transporters of the inner ear have been identified in mice as having an essential role in endolymph production: the Na-K-Cl cotransporter encoded by Slc12a2, which is expressed at the basolateral membrane of stria vascularis in marginal cells, and the potassium ion channel KNCNE1 or Isk, which is expressed at the apical surface of strial marginal cells. In mice with targeted disruption of either gene, there is failure of endolymph production, resulting in endolymph compartment collapse, smaller than normal semicircular canals, and severe vestibular defects similar to those of Pds mutants. Characterization of human homologues will likely expand our knowledge of related human audiovestibular disorders.

**Figure 5** Schematic illustration of a cross-section through the cochlea displaying the endolymphatic compartment (scala media), perilymphatic compartments (scala vestibuli and scala tympani), and basilar membrane with the organ of Corti, containing the outer and inner hair cells and overlying tectorial membrane.
Connexins also play a crucial role in ion homeostasis in the inner ear via recycling of potassium ions to the endolymphatic compartment, as will be discussed in the nonsyndromic deafness section. For an overview of current connexin-related research, visit the URL: http://www genie.geneva.ch/deafness/.

Also of importance in inner ear homeostasis is the aquaporin (AQP) family of water channels. A QPs are transmembrane channel proteins that are expressed in many isoforms in the inner ear, including AQP2, AQP5, and AQP6. Their function in water transport and location in the inner ear suggest a role in maintaining endolymphatic fluid balance, and they may play a role in M eniere disease.96,97 A QP activity may be regulated by antidiuretic hormone (ADH) or vasoressin, which is elevated in some patients with M eniere disease.98

MECHANOELECTRIC TRANSDUCTION

The hearing and balance sensory systems require mechaanoelectrical transduction of sound and head movements. In the hearing process, a sound wave, a vibrational mechanical force, is transformed into an electrochemical signal that is transmitted as a nerve impulse to the brain. Investigation continues into the process of mechaanoelectrical transduction, which is thought to occur as follows. When an acoustic stimulus is received, the stereociliary bundle on the apical surface of hair cells is deflected. The stereocilia are connected by filamentous structures at their tips, called tip links. These are at least partially composed of Cadherin 23 (CDH23) and Myosin-1c (MYO1C), as well as a calcium channel.77,99–101 If the stereocilia are deflected toward the kinocilium, tension on these tip links activates a mechanically sensitive channel, and a transduction current is induced.102,103 If the deflection is away from the kinocilium, the channel will close, and no current is produced.104,105 Evidences place the transduction channel, which is responsible for inducing the transduction current, on the stereocilial close to the tip links103–105 (see Figure 4). If the stereocilia deflection is sustained, as frequently occurs in vestibular hair cells, then the cells appear to adapt actively, by readjusting the attachment site of the tip links.106 This adaptation maintains an appropriate level of tension at the tip links and enables the HC to maintain sensitivity over a wide range of stereociliary positions. The molecule that serves as a transduction channel has been identified as transient receptor potential no mechanoreceptor potential C (TRPN1) in zebra fish,107 but the human homologue has not yet been identified. Molecular studies have identified pres- tin108 as a candidate molecule for regulating the tensioning process, which appears to be controlled by 120 kD myosin motors that attach to the tip links and slide along the actin filaments that form the core of stereocilia.104,109–112

Neurotransmission

By understanding the patterns of neurotransmission within the inner ear, a pharmacologic approach to some forms of tinnitus might be developed. The afferent neurotransmitter from the hair cell to the spiral ganglion neurons has not yet been identified. However, spiral ganglion and vestibular ganglion neurons strongly express genes encoding glutamate receptors of the N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), and γ-aminobutyric acid (GABA) families,112–117 implicating a glutamate-like neurotransmitter. The olivocochlear efferent neurotransmitter that operates from the brainstem to the inner ear is primarily acetylecholine,118 acting at nicotinic acetylcholine receptors119 that are strongly expressed in hair cells.120 Other receptors found in the cochlea include muscarinic acetylcholine, γ-aminobutyric acid (GABA), and adenosine triphosphate (ATP) receptors,121–123 while olivocochlear efferent neurons express enkephalin mRNA.124

Fine-Tuning of the Auditory System: Outer Hair Cell Electromotility

The discovery of otoacoustic emissions has led to their use as a tool in infant hearing impairment screening, and audiologists use them widely as part of their battery of diagnostic testing.124 The basis for otoacoustic emissions is the electromotility of outer hair cells, first discovered in 1985, and thought to be responsible for both sharp tuning of the basilar membrane frequency response and for increased auditory sensitivity. Deflection of the hair cell stereocilia leads to a change in membrane voltage. For the outer hair cells, unlike inner hair cells, this voltage response induces changes in cell length that affect the motion of the basilar membrane. Several candidates for the outer hair cell motor are under investigation, including A P-Like protein125 and molecules containing a motif related to the S4 segment of voltage-gated ion channels,126 both of which change shape in response to changes in membrane voltage. A thorough discussion of these issues can be found in Chapter 7, “Cochlear Biophysics.”

HUMAN EVIDENCE OF A MOLECULAR BASIS FOR HEARING AND BALANCE DYSFUNCTION

Hearing loss is the most common sensory impairment. At least 1 out of every 750 babies born in the United States has sensorineural hearing loss (SNHL). Demographic studies estimate that approximately 50% of all congenital deafness can be traced to inheritable factors, most due to single gene mutations, and at least 90% are inherited as autosomal recessive (AR) traits. Of these, approximately 30% are syndromic and 70% are nonsyndromic. Considerable progress has been made in identifying and characterizing these deafness genes.

During the 1980s, advances in molecular genetic technology led to a rapidly progressive increase in the number of molecular markers that facilitate linkage analysis. These markers, or polymorphisms, define genetic locations and have enabled scientists to identify the approximate location of inherited mutations. Thus, gene mapping began to be applied to familial deafness in the late 1980s, resulting in the first definitive information regarding the physical site and nature of the mutations affecting the inner ear. The recent development of thousands of molecular tags for specific locations in the genome has dramatically enhanced the ability to link inherited disorders to their specific chromosomal location via recombination frequency analysis. When combined with information from prior localization studies of candidate genes or related animal mutations in the same chromosomal region, such linkage analysis has enabled the characterization of an increasing number of mutations that cause disorders of hearing. More than 100 deafness loci have been identified. Our knowledge of the identity and function of these genes has grown almost exponentially over the last decade. Today, more than 10 genetic mutations leading to congenital hearing loss can be identified with genetic testing (see http://www.genetests.com for testing laboratory information). This has improved our ability to provide genetic counseling and, in the future, may lead to gene therapy for aural diseases. Gene identification also allows determination of function through animal studies of homologous gene mutations which can be genetically engineered.

Syndromic Hearing Impairment

Genetic mutations causing hearing impairment in association with other morphological or clinical features are referred to as syndromic hearing impairment genes. Syndromic deafness accounts for 30% of inherited congenital hearing loss.127 Linkage analysis has been facilitated by the fact that affected individuals are more easily distinguishable from unaffected members within a given population or family with respect to a specific syndrome. The specific mutations causing Alport syndrome, Waardenburg syndrome, Usher syndrome, branchio-oto-renal (BOR) syndrome, Pendred syndrome, X-linked deafness with perilymph gusher, neurofibromatosis type 2 (NF2), and many other forms of syndromic deafness, as well as nonsyndromic deafness, have been determined, and many have been characterized, in terms of the molecular defect. The mitochondrial DNA mutation leading to inherited susceptibility to aminoglycoside-induced hearing loss has also been identified.128 Although the molecular genetics of inherited deafness is discussed in detail in Chapter 26, “Hereditary Hearing Impairment,” there are several disorders that merit further discussion in the context of molecular methodology.

Alport Syndrome. The first human mutation affecting the inner ear to be identified was that causing Alport syndrome, an X-linked disease associated with renal abnormalities and progressive hearing loss. The mutated gene was initially
linked to Xq22–26 and was subsequently identified as encoding the α5 chain of type IV collagen, which plays a critical role in the formation of basement membranes. Six subtypes of Aport syndrome have since been identified: types II, III, and IV are X-linked while types I, V, and VI are inherited in an autosomal dominant (AD) fashion.

**Waardenburg Syndrome.** WS can be inherited as an AD, AR, or sporadic mutation. WS-I is characterized by hearing loss and pigmented abnormalities such as white forelock and heterochromia irides. WS type II (WS-II) is distinguished from WS-I by the presence of dystopia canthorum, which presents as lateral displacement of the medial canthus. The autosomal dominant WS-I defect was initially localized to the long arm of chromosome 2 (2q35–37) because of de novo chromosomal malformation, and then further linked to a gene near 2q37. This locus is homologous to the Pax3 gene in Splotch mice, which had been proposed as a murine equivalent of WS-I. Mutations in the Pax3 gene of WS-I patients were subsequently shown to be responsible for WS-I and WS type III (WS-III). Pax3 encodes a transcription factor that regulates expression of other genes. The Pax3 protein product plays a regulatory role in melanocyte differentiation during embryogenesis when melanocytes migrate from the neural crest to various tissues, including the intermediate cells of the stria vascularis of the cochlea and the melanocytes apportioning the dark cells of the vestibular labyrinth, where they are necessary for production of endolymph and the endolympathic potential. In Vga-9 mice, harboring a transgenic mutation of Pax3 similar to that in Splotch mice (the murine equivalent of WS-I), the stria vascularis shows a lack of intermediate cells and disorganization of the basal layer. WS-II has not shown linkage to the region of chromosome 2 that includes Pax3, and WS-II appears to be caused by mutation of either the microphthalmia-associated transcription factor, MITF gene, which maps to 3p12.3–14.1, or SNA1, which is located at 8q11 and encodes the SLUG transcription factor. Type IV Waardenburg (WS-IV) maps to still other sites: (1) 20q13.2–3, where the EDN3 gene is located, encoding endothelin-3, (2) 13q22, where ENDRB encodes the endothelin receptor, type B; and (3) 22q13, encoding the transcription factor SOX10. Endothelin signaling is involved in neuronal survival, and patients with WS-IV develop Hirschsprung disease (lack of autonomic innervation to the distal large colon) in addition to signs and symptoms of WS-II.

**Usher Syndrome.** Usher syndrome (US) is inherited in an autosomal recessive fashion and is characterized by deafness and retinitis pigmentosa. Usher syndrome type I (US-I) is characterized by severe hearing loss and impaired vestibular function, while Usher syndrome type II (US-II) has less severe involvement of both. Additional subtypes based on severity and character of progression have been proposed: US-III and US-IV. Both US-I and US-II are genetically heterogeneous, with some US-I families linking to chromosome 14q32 and others linking to chromosome 11, and the Shaker-1 mouse mutation, which maps to a region homologous to human 14q32, was shown to involve a gene-encoding myosin VII. Based on this observation, myosin VIIA was subsequently identified as the gene responsible for US IB. Although incompletely understood, the role of myosin VIIA in the inner ear appears to involve inner hair cell integrity. Myosin VIIIA localizes to the cross-links between adjacent stereocilia and at the cuticular plate of inner hair cells (see Figure 4). It has been postulated to play a role in adaptation, which is the process of maintenance of lateral tip link tension and restoration of hair cell sensitivity after depolarization. Myosin VIIA can move upward on the actin core within stereocilia, and may connect with cadherin-catenin complexes via the primary decidual zone (PDZ) (uterine PDZ found in many cell junction-associated proteins) domain-containing protein, harmonin in an adaptation motor to maintain stereocilia tension as well as lateral link tension within hair cells (see Figure 4). Mutations in harmonin gene cause US IC. US-IIa links to chromosome 1q41, where the gene product, named usherin, is encoded. Usherin contains laminin-EGF and fibronectin domains and, thus, likely functions in extracellular matrix interactions. Overall, at least nine distinct chromosomal locations have been linked to the various forms of US.

**Pendred Syndrome.** An autosomal recessive disorder characterized by deafness and euthyroid goiter results from mutation of the PDS gene, also called solute carrier 26A gene family (SLC26A4), which encodes the pendrin protein. Pendrin appears to play a vital role in endolymphatic fluid homeostasis in the inner ear. Within the stria vascularis of the embryonic mouse, Pendrin is putative ion-transport molecule that appears to function as an iodide (in the thyroid), chloride, bicarbonate, formate, and nitrate transporter. Pendrin is discretely expressed in the endolympathic duct and sac and utricle and sacculus and on the apical surface of certain cells within the stria vascularis of the embryonic mouse. Pendrin appears to play a vital role in endolymphatic fluid homeostasis in the inner ear. The spectrum of inner ear abnormalities associated with PDS mutations ranges from isolated enlarged vestibular aqueduct syndrome to classic Mondini malformation, or incomplete partition type II with cystic apical and middle turns of the cochlea, lacking the intersemicircular septum, a mildly dilated vestibule, and EVA. Hearing is similarly variable, ranging from normal in early childhood to mild low frequency conductive loss to profound sensorineural hearing loss. Stepwise progression of hearing loss is the typical pattern, and there have been no reported cases with normal hearing beyond early childhood. In association with Pendred syndrome, euthyroid goiter, and a positive perchlorate discharge test are present.

**Neurofibromatosis Type 2.** Affecting 1 in 40,000 individuals, neurofibromatosis type 2 (NF2) is caused by a mutation at 22q12.1. Individuals affected with NF2 characteristically develop bilateral vestibular schwannomas, inevitably leading to hearing loss and balance dysfunction. The NF2 mutation is also associated with schwannomas of other cranial nerves, meningiomas, and spinal tumors. NF2 is inherited in an autosomal dominant fashion, but approximately 50% of cases are sporadic. Mosaicism of NF2 gene mutation also occurs in up to 25% of cases. The NF2 gene encodes merlin, or schwannomin, an intracellular tumor suppressor protein expressed in Schwann cells. Merlin shares extensive homology with the erbin/radixin/moesin family, is negatively regulated by phosphorylation, likely mediated by p21-activated kinase 1 (PAK1), and translocates to the cytoplasmic cell membrane in a paxillin-dependent manner, where it binds to ErbB2. ErbB2 is a growth factor receptor tyrosine kinase that couples with ErbB3 when stimulated by neu-reulin binding and activates intracellular signaling cascades, such as MAP kinase and pAkt/PI3-K, thus mediating Schwann cell proliferation and survival. Merlin also has been shown to translocate to the nucleus where it may affect gene expression in Schwann cells. However, the role of merlin as a tumor suppressor gene is still poorly understood.

**Other Deafness Syndromes.** A port syndrome is AD or, more commonly, sporadic and results from mutation of the fibroblast growth factor receptor 2 (FGFR2) gene at 10q26. Congenital stapedial footplate fixation results in conductive hearing loss, and craniofacial deformities, as well as developmental delay, are secondary to craniosynostosis in A port syndrome. Branchio-oto-renal syndrome is autosomal dominant in inheritance and is characterized by several branchial arch deformities, deafness, and renal anomalies. The mutation has been localized to a gene at 8q13.3, termed EYA1, for the "eyes absent" phenotype associated with the orthologous mutation in Drosophila. X-linked deafness with a perilymph gusher is an X-linked progressive mixed deafness associated with a perilymph gusher during stapes surgery, as the name implies. It was linked to Xq21.1 by examination of the cytogenetically visible deletion. The gene causing X-linked mixed deafness with stapes fixation has recently been identified to encode a transcription factor, Bm-4, which is a member of the POU-domain family and extensively expressed during cochlear development.

Other AD syndromic forms of hearing loss include Crouzon, DiGeorge, Goldenhar (oculoauricular vertebral dysplasia), osteogenesis imperfecta, Paget, Noonan, Pfeiffer, Sticker, Townes-Brocks, Treacher Collins, and velo-cardio-facial syndromes. Other AR syndromic hearing loss syndromes include Cockayne, Fanconi anemia A, Friedrich ataxia, Hurler, Jervell and Lange-Nielsen, osteopetrosis (Albers-Schonberg),

Non Syndromic Hearing Impairment

While 30% of prelingual hearing impairment is syndromic, 70% is non-syndromic hearing impairment (NHI).152 NHI is a diagnosis that applies to patients who suffer genetic HI without associated phenotypic abnormalities, and it results from mutations in an estimated 100 genes. Linkage analysis is difficult in this group of patients due to the genetic heterogeneity. However, using relatively isolated populations and large families, linkage analysis has facilitated the identification of over 70 loci and cloning of more than 21 genes responsible for NHI. Identification of genetic mutations associated with HI enables genetic testing, precise diagnosis, and genetic counseling. Human temporal bone studies have revealed morphologic defects resulting from such mutations, providing speculative information on gene function. A number of studies utilizing homologous-targeted mutations facilitate experimental studies of gene function and have been the major tool in expanding our knowledge of inner ear protein functions. Since the number of DNA polymorphic markers for genetic NHI is increasing exponentially, up-to-date information can be found on the Hereditary Hearing Loss Homepage (http://dnalab-www.uia.ac.be/dnalab/hhh).

Molecules Involved in Ion Homeostasis

Maintaining the endolymphatic potential within the cochlear duct is essential for normal Hearing function, and it is postulated that the potassium content in endolymph is highly regulated via a bimodal recycling pathway. A working hypothesis to explain the predominant theory, potassium is recycled both medially and laterally within the cochlea. The medial pathway involves the spir al limbus interdental cells medial to the organ of Corti, which recycle potassium ions (K+) back into the scala media after hair cell depolarization (see Figure 5; please refer to Chapter 1, “Anatomy of the Auditory and Vestibular Systems” for a description of cellular subtypes). The lateral pathway involves the supporting cells adjacent to hair cells within the organ of Corti, that recycle K+ through the spiral ligament and stria vascularis back into the scala media (see Figure 5). Potassium recycling requires a network of ion channels and transporters, including gap junctions assembled by connexins, the anion transporter pendrin, and potassium channels KCNQ and KCNE.152

Connexins. Currently, GJ B2, which encodes connexin 26, is recognized as the most frequent gene mutation associated with congenital HI. DFN A3, the dominantly inherited form, and DFNB1, the autosomal recessive mutation, account for up to 50% of cases of congenital HI. Although relatively small, with the entire coding sequence contained in one exon, over 50 mutations within the GJ B2 gene account for hearing loss. The most common is the 35delG mutation in European countries and the United States.153 In contrast, the 235delC mutation accounts for 73% of GJ B2 mutations in the Japanese population.154 The small coding region has facilitated targeted mutations facilitate experimental studies of gene function and have been the major tool in expanding our knowledge of inner ear protein functions. Since the number of DNA polymorphic markers for genetic NHI is increasing exponentially, up-to-date information can be found on the Hereditary Hearing Loss Homepage (http://dnalab-www.uia.ac.be/dnalab/hhh).

Other Ion Transport Molecules. A number of ion transport molecules important for fluid homeostasis in the inner ear are Claudin 14, a CL D N A14 gene product. Claudin 14 forms tight junctions within sensory epithelia of the cochlea and vestibular organs, and NHI results from mutation at the DFNB29 locus.155 The major pathway for K+ recycling appears to involve the stria vascularis (see Figure 5), and connexins have been implicated as part of the structure required for this process, via transcellular circulation of K+ through the spiral ligament and basal cells of the stria vascularis.156

Proteins with Unknown Function. A common form of AD low frequency nonsyndromic SNHI is caused by mutation of the WF 51 gene designated DFNA6/14. WF 51 encodes wolframin, a protein that localizes to the endoplasmic reticulum and is thought to play a role in protein sorting and trafficking, although the function is unknown.165

Cytoskeletal Proteins. Structural components of the cochlea and vestibular organs are highly organized, and their maintenance is essential for the function of hearing and balance, especially with respect to sensory hair cells. Mutation in many of the genes that encode cytoskeletal proteins within hair cells leads to NHI.
include (1) a conventional myosin, MYH9; (2) four unconventional myosins, MYO3A, MYO6, MYO7A, and MYO15; (3) stereocilin, a novel stereocilia-associated protein; (4) harmonin, a PDZ-domain protein; (5) a putative actin-polymerization protein, human homologue of the Drosophila diaphanosome gene (HDIA1); and (6) a cadherin, CDH23.122

Stereocilia are the main structures responsible for mechanosensory transduction in auditory and vestibular hair cells. Stereocilia are cellular organelles that are organized into rows of increasing height and create the characteristic staircase pattern seen by electron microscopy. Unlike vestibular hair cells, auditory hair cells do not contain a “kinocilium.” Stereocilia are exquisitely sensitive to mechanical vibration and can easily be damaged by overstimulation but undergo continuous renewal from tip to base to continue to function an entire lifetime. Each stereocilium is composed of a rigid central structure containing several hundred parallel, polarized, and cross-linked actin filaments. Different members of the myosin family are present with these actin filaments in specific locations within stereocilia: myosin XVa (MYO15A gene product) is located at the tips, while myosin VIIa (encoded by MYO7A) is located alongside actin at cross-links of adjacent stereocilia, and myosin VI (gene product of MYO6) is present at the cuticular plate (see Figure 4). Myosins bind actin, forming the molecular motor units that generate movement via ATP hydrolysis. The MYO7A gene, the causative gene mutation associated with US-IB, is associated with two forms of nonsyndromic deafness, DFNB2, an autosomal recessive disorder, and DFNA11, an autosomal dominant disorder.135,167

Harmonin, encoded by USH1C at 11p14-15.2, is associated with NHI via mutations linking to the DFNB18 locus. Harmonin contains a PDZ domain, which suggests that it may function as an assembling protein. PDZ domains organize protein complexes into their specific subcellular location, anchor transmembrane proteins, and recruit cytosolic signaling molecules, and may bind directly to the actin cytoskeleton.123

A putative actin-polymerizing protein is expressed as the gene product of HDIA1.168 HDIA1 is a formin gene family member, of which most are involved in cytokinesis and establishing cell polarity.

A novel cadherin-like protein is encoded by CDH23, which is also linked to Usher type 1D, and mutation at the DFNB12 locus results in NHI. Cadherins form adherens junctions which are critically important during embryogenesis and organogenesis. Stereocilia organization is disrupted early during hair cell differentiation in mouse mutants.169

**Synaptic Vesicle Trafficking.** OTOF mutation, associated with DFNB9, is reported to be a frequent cause of recessive prelingual NHI in Spanish patients, and accounts for 4.4% of recessive prelingual NHI not due to GJB2 (connexin 26) mutations.170 OTOF encodes otoferlin, which has been identified as a calcium-triggered synaptic vesicle trafficking protein that interacts with syntaxin1 and synapse-associated protein of 25 kD (SNAP25) of the synapse-associated receptor (SNARE) complex for Ca2+-dependent presynaptic vesicle exocytosis within inner hair cells. Otoferlin, therefore, appears to be important for afferent neural signaling, and mutations have also been found to be associated with auditory neuropathy.171

**Extracellular Matrix Components.** Overlying the auditory HCs within the organ of Corti is the tectoral membrane, which generates the hearing force that bends the stereocilia, opening transduction channels, and initiating depolarization. This comprises the mechanosensory transduction process that is necessary for hearing. Additionally, the tectorial membrane matrix acts as a second resonator and ensures that the outer hair cell bundles are displacement coupled to the sound stimulus. Thus, it facilitates optimal electromechanical feedback to the basilar membrane from outer hair cells. The tectorial membrane consists of collagen fibers and a noncollagenous matrix containing mostly α- and β-tectorin.123 Otoancorin mediates the attachment of the tectorial membrane to the apical surface of the hair cells (see Figure 4). TECTA encodes α-tectorin, OTOA encodes otoancorin, and COL11A2 encodes the type X1 collagen subunit 2. Mutations in any of these three genes result in SNHI, which can be dominant, recessive, NHI, or syndromic HI.152

**COCH** encodes cochlin, an extracellular matrix protein that is abundantly expressed throughout the inner ear, except in sensory hair cells.133 Mutations in COCH at the DFNA 9 locus lead to late-onset, progressive nonsyndromic HL (NHI), which is characterized by acidiphilic mucopolysaccharide deposits in the cochlea and vestibular organs,174 SNHI, and vestibular symptoms similar to Meniere disease. Interestingly, only missense mutations of the COCH gene have been identified in association with DFNA9 NHI.175

**Mitochondrial Deafness.** Mitochondrial mutations have recently been identified in association with some maternally inherited hearing losses. These can result from heteroplasmy or homoplasmic states with respect to the mitochondrial DNA pool. Heteroplasmy refers to a mixture (usually two, but “multiplasmy” has been reported) of mitochondrial genotypes, while homoplasmia refers to a single mitochondrial genotype present in all of the cells of the body.136 Mitochondrial mutations are associated with some forms of syndromic as well as NHI.137

Presbyacusis is thought to be inherited as a mitochondrial mutation, but the specific mutation(s) have yet to be identified. It is thought to involve at least one of the genes for the oxidative phosphorylation pathway, and the mitochondrial cytochrome oxidase II gene is a likely candidate.176,180

Besides the particular mutation in a single gene, other factors may modify the observed clinical phenotype. Such factors may include the genetic background, modifying genes, and environmental factors, such as noise exposure and ototoxicity. Modifying genes can influence the phenotype resulting from a given mutation at another locus. An extreme example is DFNM1, which acts as a dominant suppressor of DFNB2.181 Modifier genes may explain why the level of HI can range from mild to profound with identical NH mutations, as well as the phenotypic variance of identical syndromic and mitochondrial mutations.176

**Semicircular Canal Dysplasias.** Another class of disorders resulting in SNHI, conductive HL, or mixed HL is semicircular canal dysplasia.182 Although traditional hypotheses have held that semicircular canal dysplasias result from arrest in development during the sixth week of gestation, several cases of semicircular canal dysplasia or aplasia have been reported with normal cochlear development.183,184 The majority are nonsyndromic, although 12.5% were associated with known syndromes in a series of 16 cases.185 The genetic mutations leading to isolated semicircular canal abnormalities have yet to be identified. Additionally, there is a paucity of genetic disorders leading to isolated balance dysfunction, likely owing to compensation by the other sensory organs involved in the balance system: vision, proprioception, and central nervous system integration.
FUTURE CONSIDERATIONS

In the last decade, the dramatic increase in our knowledge of molecular biology of the inner ear has translated into a remarkable increase in diagnostic and treatment capabilities for inner ear disorders. One such possibility is the detection of gene mutations involved in hereditary deafness, and additional genes are being identified at an almost exponential pace. Of great interest is the potential for development of gene therapy and of the delivery systems that will enable clinicians to bypass the blood-perilymph barrier and directly administer various pharmacologic therapies to the inner ear. Gene therapy has been applied experimentally in the shiverer mouse, which shows deficits in the amplitude and latency of auditory evoked potential (AEP) responses secondary to a mutation in the myelin basic protein gene. Yoo and colleagues demonstrated improved AEP responses in a shiverer mouse in which a transgene coding for normal myelin basic protein was integrated into its genome. Gene therapy of this nature might one day be applied to humans with genetic hearing impairment, with the use of in vitro fertilization.

Research efforts at gene therapy are concentrating on the delivery of gene products or genes to the adult system. The development of such delivery systems for the inner ear is being approached in several ways, and this topic is discussed in greater detail in Chapter 5, “Inner Ear Drug Delivery and Gene Therapy.” The first approach is to infuse drugs directly into the inner ear with a microcatheter placed through the tympanic membrane, either against or through the round window membrane to gain entry into the scala tympani. This method has been used successfully in delivering neurotrophins to the scala tympani of guinea pigs to improve survival of neurons after ototoxicity-induced damage. An alternative approach is to embed the drug of choice into a polymer that, once placed in the inner ear, would protect the drug from degradation and help to sustain its release at a specific rate. This approach, however, requires a second operation to terminate the therapy. A third technique is to utilize carrier proteins that would link the drug of choice to endothelial cells lining the inner ear capillaries. These carrier proteins could facilitate the transportation of the drug across the endothelial cell barrier and release the drug into the endolymph or perilymph where the targeted cell population awaits. Early success with this technique has been achieved in brain when nerve growth factor was delivered across the blood-brain barrier utilizing an anti-transferrin antibody as the carrier protein.

Other approaches of gene therapy utilize the techniques of molecular biology (Figure 6). Viral vectors that carry and express genes that encode therapeutic proteins or factors can be used to infect cochlear cells. The advantage of this approach is that the delivery of the inactivated viral vector requires only one procedure, and once transfection has occurred within the target site, the therapeutic factor can be continually produced. These viruses can be driven by specifically designed promoters but do not retain the ability to replicate. The viruses being investigated for this purpose include retroviruses, herpes viruses, adenoviruses, and adeno-associated viruses with each virus having different cell type specificity. A in vivo report in 1992 documented that a herpes simplex viral vector, carrying a nerve growth factor gene, protected neurons of the dorsal root ganglion from the consequences of a traumatic injury. Several laboratories are using herpes viruses and adenoviruses to induce gene expression in inner ear cells.

A further approach is transplantation of cells that have been genetically modified to produce therapeutic factors. This method involves injecting genetically engineered cells into the inner ear where they can release the therapeutic factors in large quantities. These cells, however, must be incapable of reproducing, as uncontrolled proliferation and neoplastic processes might potentially be induced otherwise. Two studies have shown that genetically engineered fibroblasts could be used to deliver growth factors to the cochlear duct. The tools of molecular biology will enable us to develop these and other delivery systems further. Please visit http://www.nlm.nih.gov/medlineplus/genesandgenetherapy.html for an up-to-date overview of progress in this area.

In an emerging area is nanotechnology for drug delivery to the inner ear, among other tissues. Nanoparticles in the range of 1 to 100 nm in diameter can be coated with pharmacotherapeutics, in the form of DNA molecules, sRNAs, small molecules, or possibly even small peptides, for entry through the round window membrane into cells through the cell membrane or into tissues. The core may be composed of magnetic nanoparticles which are subject to manipulation when an external magnetic field is applied, for instance, to facilitate uptake.

Additionally, magnetic nanoparticles can be utilized to induce biomechanical force, as in the case of a middle ear implant that drives ossicular motion. This model simulates the completely implantable middle ear amplifiers but is potentially more durable owing to its smaller size as it would require less power to operate.

A further example of nanotechnology applications for the inner ear is the ongoing development of a vestibular implant. This resembles a gyroscope that senses angular motion, mimicking the semicircular canal sensation, and generates electrical pulses (mimicking those of the ipsilateral vestibular nerve activity during a similar angular motion) that stimulate the vestibular nerve.

An additional development is the micromechanical resonator array that is being designed as a completely implantable multiresonant transducer. It would ideally perform the function of a “bionic” cochlea.

With advancing technologies from the both diagnostic and therapeutic fronts, we are approaching an era in which we may have the capability to alter genetic disease, with respect to hearing and balance dysfunction.

AUDITORY SYSTEM

General Principles

Over the past three decades, major advances have occurred in our knowledge about how the ear achieves its high sensitivity, sharp frequency tuning, vast dynamic range, and precise temporal resolution. This accumulated wisdom has led to a new understanding about the unique functions of the inner hair cells (IHCs) and outer hair cells (OHCs) of the cochlea. Traditionally, the transfer of information about sounds from the environment to the higher centers of analysis in the central auditory nervous system was considered to be entirely a passive process. According to conventional thinking, the salient features of sound, including frequency, magnitude, and timing attributes, were principally encoded by peripheral processes and then simply passed relatively unaltered along the ascending system, from 1 structure to another, in a forward-moving manner. With the discoveries that the healthy ear can generate sounds in the form of otoacoustic emissions (OAEs) and that OHCs mechanically vibrate in response to depolarizing stimuli, the role of the cochlea in analyzing acoustic signals is now considered to represent an active process. Given the current view that the vibromechanical activity of the OHC along with certain aspects of its transduction properties underlies the generation of OAEs and the knowledge that a major portion of the cochlear efferent system innervates this particular class of hearing receptor, it is likely that central auditory centers also modify peripherally generated responses in an active manner. Thus, rather than conceptualizing the role of the auditory system as a passive analyzer of environmental sounds, the modern view is to consider it as an active participant in controlling acoustic information so that the most meaningful features are registered.

Auditory Apparatus

A traditional approach toward understanding the primary sensitivity, frequency tuning, and timing functions of the peripheral auditory system is to divide the periphery into 3 discrete parts. In this manner, the unique contributions that the external, middle, and inner ear, that is, cochlea, make to the overall analysis of sound can best be appreciated.

External Ear. The external ear or pinna of the mammal is regarded as a simple funnel that collects and crudely filters sound. Given the immobility of the human external ear, it is assumed that this frequency tuning function is performed passively. However, evidence from experimental studies suggests that the human pinna serves 2 functions: (1) it aids in sound localization, especially front-to-back and high-to-low distinctions, where interaural time differences provide no clues, and (2) along with the external ear canal, it increases acoustic pressure at the tympanic membrane in the 1.5 to 5 kHz range, which is the frequency range most important for speech perception. Evidence for the sound-localizing function of the human external ear includes the demonstration of accurate sound localization in patients with monaural hearing and the loss of this localization ability when the pinna of the hearing ear is strapped to the head. In addition, abnormally poor sound localization around an “imperfectly” remodeled pinna has been reported.1

In summarizing available data on the role that the external ear plays in boosting sound pressure at the tympanic membrane, Shaw described the contributions of the distinct parts of the head and neck and external ear by successively adding their different components in a model.2 According to this classic analysis, shown in Figure 1, most of the individual components of the external ear provide complementary gains, resulting in a significant increase in sound pressure from approximately 2 to 7 kHz. When the overall additive effect is appreciated (“T” in Figure 1), it can be seen that at certain frequencies this gain is substantial, resulting in sound pressure increases on the order of 20 dB.

Studies of models of the human external ear suggest that the pinna extracts information about sound location by altering the transmission properties of different frequencies according to the location of the sound source relative to the pinna. For example, when the sound source is behind the ear, interference of directly transmitted sound with sound waves scattered off the pinna flange or helix alters the response in the 3 to 6 kHz range. Thus, the external ear modifies the spectrum of the incoming sound, allowing an individual to make judgments about the location of unknown sound sources. This localization ability suggests that the central part of the auditory system can use very subtle spectral cues in the analysis of environmental sounds.3

Middle Ear. Figure 2 outlines the anatomy of the middle and inner ears. The middle ear ossicles form a transmission pathway that conducts sound energy from the tympanic membrane, at the interface of the external and middle ear, to the oval window of the cochlea. The discussion of middle ear function is separated into two categories: (1) “impedance matching” between the air of the external environment and the fluids (perilymph and endolymph) of the cochlea and (2) the acoustic reflex of the middle ear muscle system. A third set of functions is served by the eustachian tube (pharyngotympanic tube), a narrow,

Figure 1. Pressure gain contributed by the individual components of the outer ear in humans. The total (T) curve plots the overall gain based on the addition of the various components in the order listed with the sound source positioned 45° from straight ahead. (Reprinted with permission from reference 2.)
osseocartilaginous channel connecting the middle ear space with the nasopharynx. These include ventilating the middle ear; equilibrating the air pressure in the middle ear with that of atmospheric pressure, thus permitting the tympanic membrane to stay in its most efficient neutral position; draining mucous secretions from the middle ear; and protecting the middle ear from reflux of nasopharyngeal and laryngopharyngeal secretions and from the disturbing awareness of one’s own voice, breathing and other internal sounds (autophony). A discussion of eustachian tube anatomy, physiology, dysfunction, and treatment appears in Chapter 15, “Eustachian Tube Dysfunction.”

The widespread use of surgical modification of middle ear structures to improve hearing and the usefulness of immittance audiometry make the concept of acoustic impedance and its relationship to middle ear function important to the clinician. Accordingly, the discussion of the middle ear begins by reviewing some basic principles of acoustic impedance.

Transmission of Acoustic Energy through the Middle Ear. Figure 3A diagrams the route for the transmission of sound energy through the middle ear into the cochlear portion of the inner ear. The ossicular chain (see Figure 2), consisting of the malleus, incus, and stapes, can be thought of as a lever system. The tympanic membrane moves the manubrium or handle of the malleus. In turn, the long process of the incus and manubrium moves together because the malleoincudal joint is essentially fixed. In contrast, the joint between the incus and the stapes is flexible. Therefore, because the stapes is fixed at its posteroinferior border, movement of the tympanic membrane causes it to rock in and out of the oval window. The changes in acoustic pressure caused by the stapes moving in and out of the oval window are transmitted instantaneously by the perilymph through the cochlear partition and then to the round window. This pressure transmission through the cochlear partition causes it to move either upward or downward, depending on the direction of the pressure change. The pressure change initiates a mechanical traveling wave, shown in Figure 3B, that reaches a maximum at some point on the basilar membrane depending on the frequency of the stimulating sound. The mechanical traveling wave moves from the base to the apex of the cochlea largely owing to a reduced stiffness of the basilar membrane in the apical direction. As discussed below, this traveling wave disturbance causes the hair cells in the organ of Corti to stimulate the dendritic endings of the cochlear nerve, thus signaling to the central auditory system that a sound stimulus has occurred.

At high sound levels of approximately 100 to 110 dB SPL (sound pressure level), the mode of vibration of the ossicular chain changes. Thus, instead of rotating about its short axis, as shown in Figure 3A, the stapes footplate turns about its long axis. Because this change results in less efficient sound transmission through the middle ear, it likely serves a protective function. Interestingly, the change in vibration mode occurs at the threshold of feeling, thus suggesting that the somatic sensation caused by excessive sounds may result from the detection of the altered ossicular vibration by middle ear bone and tendon receptors.

Impedance Matching by the Middle Ear. Hearing by terrestrial animals requires transmission of sound from an air to a fluid environment. A useful way to appreciate the problem in conducting sound effectively between two distinct media is to recall how difficult it is to listen to sounds produced even a few inches above the surface while swimming underwater. Thus, direct transmission of sound across an air/water boundary is extremely inefficient because the specific acoustic impedances of air and water differ greatly. Moreover, whenever energy is transmitted between media with different specific impedances, much of the energy is reflected back from the boundary between the two media. To help solve this problem, the middle ear matches reasonably well the impedances of the air with those of the cochlea and thereby greatly increases the efficiency of

**Figure 2** Schematic drawing of the inner ear (labyrinth), which consists of a series of tunnels within the petrous portion of the temporal bone. The osseous labyrinth (outer tunnel) is clear, and the membranous labyrinth (inner tunnel) is stippled. SV = scala vestibuli; ST = scala tympani; SM = scala media; SG = spiral ganglion, containing the cell bodies of the auditory nerve; VG = vestibular ganglia, containing the cell bodies of the vestibular nerve; VIII (A) = auditory part of the eighth cranial nerve; VIII (V) = vestibular part of the eighth cranial nerve; VII = facial nerve; M = macula; CU = cupula; CR = crista; Sa = saccus; U = utricle. Semicircular canals are labeled AV (anterior vertical), PV (posterior vertical), and H (horizontal). EAM = external auditory meatus; RW = round window; M = malleus; I = incus; S = stapes; MA = mastoid air cells in temporal bone.

**Figure 3** (A) Transmission of tympanic membrane movement to the cochlea via the ossicles. The system at rest is unstippled. The stippled ossicles and dashed cochlear partition illustrate the system when the tympanic membrane is pushed inward by a sound wave. (B) Inward pressure (arrows) initiates a traveling wave that migrates toward the apex of the cochlea (toward the helicotrema). This propagation depends largely on fluid coupling and the fact that the basilar membrane changes in stiffness, with the traveling wave moving from a region of highest stiffness (base) to a point of lower stiffness (apex). (Reproduced with permission from reference 4.)
transmitting acoustic energy from the ambient environment into the cochlea.

The term impedance describes the opposition of a system to movement. Thus, the more force required to move a mechanical system at a given speed, the greater its impedance. Figure 4 illustrates the principles of mechanical impedance. The impedance of a mechanical system involves a complex relationship between the three physical parameters illustrated in Figure 4. Together, mass, stiffness, and resistance, that is, friction, determine the mechanical impedance of the middle ear system. Friction, the resistive component of impedance, consumes energy and is independent of the driving frequency. Stiffness and mass store energy; thus, they comprise the reactive component of impedance. For example, once the “fluid”-filled cylinder in Figure 4 is set in motion, it tends to continue because of inertia; and, if the spring representing stiffness is compressed, it tends to push backward.

A acoustic impedance represents a special type of mechanical impedance in which force is replaced by pressure, that is, force per unit area, and the system is driven by sound. Thus, Figure 4 could be converted into a diagram of an acoustic system by interposing a piston, or membrane, between the force and the mass.

When air conducts sound, the stiffness component of its acoustic impedance is determined by the elastic coupling between air molecules, the mass component is determined by the mass of the air molecules, and the frictional component is determined by frictional resistance between the molecules. Because water is much denser and less compressible than air, it might seem at first that mass and stiffness create the principal difference between the acoustic impedance of the cochlea and that of air. However, Figure 4 demonstrates that transmission of energy into the cochlea does not involve compression of the cochlear fluid itself. In addition, the elastic restorative forces of the cochlear partition and round window tend to cancel out the effect of the fluid’s mass. Thus, the effective acoustic impedance of the cochlea is primarily resistive.

As noted earlier, a primary function of the middle ear is to provide a means of “matching” the low impedance of air with the high cochlear impedance resulting from fluid flow and the compressibility of the cochlear membranes that separate the endolymph from the perilymph. Impedance matching by the middle ear is achieved by 3 factors: (1) the area of the tympanic membrane relative to the oval window, (2) the lever action of the middle ear ossicles, and (3) the shape of the tympanic membrane. The principles behind these factors are depicted in the 3 diagrams of Figure 5. By focusing the incident sound pressure from the large area of the tympanic membrane onto the small area of the oval window (Figure 5A), the effectiveness of energy transfer between the air of the external ear canal and the fluids of the cochlea is increased greatly. In the human, the area ratio of the tympanic membrane to the oval window is about 20 to 1. However, the tympanic membrane does not vibrate as a whole. Thus, the effective area ratio is only about 14 to 1. The ossicular chain also contributes to the transformer role of the middle ear by a levering action that increases the vibration amplitude (Figure 5B). The ossicular lever ratio is about 1.3 to 1. A final factor influencing the efficiency of energy transfer depends on the conical shape of the tympanic membrane that allows a buckling action to occur (Figure 5C). The buckling motion of the tympanic membrane results in an increased force and decreased velocity to produce approximately a fourfold increase in the effectiveness of energy transfer. Together, these actions of the middle ear system result in an estimated overall transformer ratio of 73 to 1.

Middle Ear Muscles. Mammals have 2 small skeletal muscles, the tensor tympani and the stapedius, which are attached to the ossicular chain. In primates, the stapedius muscle, which attaches to the stapes and is innervated by the stapedial branch of the facial nerve, contracts reflexively in response to intense sound stimuli. However, the tensor tympani muscle, which attaches to the malleus and is innervated by the trigeminal nerve, probably does not. In laboratory animals such as the cat, rabbit, and guinea pig, both muscles contract in response to loud sound. However, the threshold of the tensor tympani is often higher than that of the stapedius muscle. A four-neuron reflex arc consisting of the afferent fibers of the auditory nerve, neurons of the ventral cochlear nucleus, neurons of the medial superior olive, and facial motoneurons comprises the stapedius reflex pathway illustrated in Figure 6 for the rabbit. The reflex arc for the tensor tympani muscle is slightly different in that neurons of the ventral nucleus of the lateral lemniscus are also involved. From the neural pathway depicted in Figure 6, it is clear that clinical abnormalities of...
the acoustic reflex primarily implicates pathology at the level of the lower brainstem.

In Figure 7, the sensitivity of the stapedius reflex in humans is plotted as a function of sound frequency. The reflex threshold curve evoked by pure tones parallels the audibility threshold curve but is about 80 dB above it. Not surprisingly, because of greater overall energy levels, broadband stimuli, for example, white noise, elicit the reflex more effectively than do pure tones. Experimental evidence indicates that the stapedius reflex threshold decreases with increasing stimulus duration, with a time constant of about 200 ms. This value approximately the time constant of temporal summation for the percepts of loudness and sensitivity. These findings, along with the clinical observation that the stapedius reflex exhibits “recruitment” in patients with cochlear hearing loss, suggest that the acoustic reflex threshold correlates more with subjective loudness than with absolute stimulus intensity.

Contraction of the middle ear muscles can also be caused by nonauditory factors, including (1) spontaneous contractions, (2) body movements, (3) vocalizations in which contractions begin prior to vocalization, (4) movements of facial muscles involving only the tensor tympani, (5) stimulation of the external ear canal, and (6) voluntary contractions.

As diagrammed in Figure 8, the stapedius muscle moves the stapes footplate medially into the oval window, whereas the tensor tympani muscle pulls the manubrium inward. The effects of these contractions on the transmission of pure tones through the middle ear are illustrated in Figure 9. In summary, the transmission of low-frequency sounds is attenuated by contraction of either muscle, but the stapedius is probably a somewhat better attenuator than the tensor tympani.

The function of the human acoustic reflex has been studied by recording (1) gross muscle potentials via the electromyogram, (2) pressure changes in the external auditory canal, and (3) acoustic immittance changes. The clinical application of acoustic impedance measurements is known as immittance audiometry, with the terms “impedance” and “immittance” being interchangeable. In Figure 10, the time course is shown for the human stapedius reflex as recorded by the immittance change method. The latency or time to the first detectable change generally varies from 10 to 30 ms, whereas the reflex decays over about 500 ms after the onset of the stimulus. The initial reduction in impedance is frequency dependent.

To date, acoustics-based clinical evaluations of middle ear function using immittance audiometry are an important part of the audiologic diagnostic test battery. However, they are not specific enough to represent independent diagnostic tests. Middle ear function may also be functionally important. Observations that support a middle ear muscle role in vocalization and in speech discrimination are as follows: (1) patients with otosclerosis show significant deficits when administered the delayed feedback test for malingerer, (2) stutterers have a deficit in pre-vocalization middle ear muscle contraction, and (3) absence of the stapedius reflex results in decreased speech discrimination when the level of speech is raised above 90 dB SPL in patients with seventh and eighth nerve disorders and even in normal individuals.

Cochlea. The cochlea performs two basic functions as (1) a transducer that translates sound
energy into a form suitable for stimulating the dendritic endings of the auditory nerve and (2) an encoder that programs the features of an acoustic stimulus so that the brain can process the information contained in the stimulating sound. Each of these functions is considered below.

Transducer Function. Anatomy. As shown in Figure 11A, the cochlea is divided into three tubes or scalae. The middle tube or scala media is the cochlear extension of the membranous labyrinth and is filled with a potassium (K+) -rich, sodium (Na+) -poor electrolyte fluid called endolymph. The outer two tubes, the scala vestibuli and the scala tympani, fill the rest of the osseous labyrinth. They are separated by the scala media and filled with perilymph, a Na+ -rich, K+ -poor electrolyte fluid. When the cochlea is activated by sound, the scala media through the habenulae perforatae, where they lose their myelin sheaths. The reticular lamina and the tectorial membrane are two membranes in the organ of Corti that are particularly critical in stimulus transduction. The reticular lamina, supported by the rods of Corti, resembles a stiff net with its webbing enmeshing the apical surfaces of the hair cells. Together, the rods of Corti and the reticular lamina provide the skeletal support of the organ of Corti.

The boundary separating the high-K+ and high-Na+ electrolytes is formed by the reticular lamina. As diagrammed in Figure 12, tight junctions, which are generally thought to present a barrier against ionic diffusion, are observed by scanning electron microscopy (SEM) between all cells that face the endolymphatic space. Figure 12 also indicates that the junctions between nonsensory epithelium (eg, the cells of Hensen and Claudius, the cells lining the spaces of Nuel, and the cells of Reissner membrane) are not as “tight” (dotted line) as the junctions between the sensory cells and the basal cells (solid line) of the stria vascularis. The fluid within the organ of Corti (ie, between the basilar membrane and the reticular lamina) has been termed cortilymph. Thus, cortilymph is probably identical to perilymph with respect to its electrolyte content. The tectorial membrane resembles a rather stiff, oval, gelatinous tube. It is attached to the limbus by a flexible membranous band that allows it to move up and down like the cover of a book.

Mammals have 3 rows of OHCs. A fourth row of OHCs is seen in an occasional cross-section, especially in primates, but there is no well-defined fourth row. There is only 1 row of IHCs. The fine fingerlike projections present on the apical surface of the hair cells are called stereocilia. The detailed arrangements of the stereocilia on the hair cell apices are unique to each class of receptor and are illustrated in the SEM of Figure 13. The IHC stereocilia form a longitudinally oriented, relatively shallow curve, whereas the OHC cilia make a radially oriented curve.
Deiters cells; P = in a linear (or shallow “U”) pattern, whereas the 3 rows of
Figure 13 initially suggested that these proteins served a
nels participate in an amplifying process that
was that stereocilia and their associated ion chan-
nes from fusing together.40

cilium is covered with a charged cell coat mate-
from cochlear base to apex, and (3) each stereo-
30 to 150 stereocilia arranged in several rows of
described, including (1) each bundle consists of
reocilia bundles and individual cilia have been
detailed structure and arrangement of individual

“V,” with a notch at the apex marking the site of
the missing kinocilium that degenerates embry-
onically during development of cochlear hair
cells. The OHC stereocilia vary systematically in length in that they are longest at the apex of
the V and shorten progressively from the apex to
the distal limbs. Whereas the longest OHC ste-
reocilia attach to the undersurface of the tectorial membrane, it is probable that the shorter cilia do not.49 However, an interconnecting network
of fine fibrils links the entire bundle of stereocilia,
both laterally and from tip to tip, so that it moves as a unit.50

Unfit recently, little was known about stereo-
cilia bundles. However, their importance in the
transduction process has stimulated considerable
research directed toward understanding the morphologic and physiologic properties of hair
cell bundles and their separate stereocilia. The
detailed structure and arrangement of individual
hair cell bundles vary across species and even as
a function of position along the organ of Corti.
However, a number of general features of ste-
reocilia bundles and individual cilia have been
described, including (1) each bundle consists of
30 to 150 stereocilia arranged in several rows of
decreasing length, (2) individual cilia range from
0.8 to 0.2 µm in diameter and increase in length
in that they are longest at the apex of
Figure 14. Basilar membrane deformation
causes a shearing action between the reticular and
tectorial membranes. Because the long OHC
cilia are attached to both membranes, they are
bent (Figure 14B). In contrast, the IHC cilia, and
possibly also the shorter OHC cilia, which are
not attached to the tectorial membrane, bend in
response to some mechanism other than displace-
ment shear. One proposition is that this process
may involve fluid streaming between the sliding
parallel plates formed by the reticular and tectori-
armembranes.56 Fluid streaming would result
from differences in the relative velocities
of the two membranes rather than by their
relative displacements. Thus, the IHCs may
be velocity sensors and the OHCs displacement
sensors.51,52 However, other notions about the unique
functions of OHCs versus IHCs have also been
proposed.53 For example, von Békésy noted that
the shearing action between the 2 membranes
could reduce the displacement amplitude of the
stimulating energy while increasing its force.54
Thus, the shearing action serve to match

the impedances of fluid and solid transmission
media, just as the middle ear matches air and
fluid impedances.

Electrical Potentials of the Cochlea. Using gross
microelectrode methods, 3 cochlear bioelectric
events have been studied extensively: (1) the
decochlear potential (EP), (2) the cochlear
microphonic (CM), and (3) the summat ing
potential (SP). Whereas the EP is present at rest, the
CM and SP appear only when sound stimulates
the ear.

Endocochlear Potential. The EP is a constant
direct current (DC), +80 mV potential that
can be recorded with an electrode in the scala
media. The majority of evidence indicates that
the stria vascularis generates the EP.55 Because
it is extremely sensitive to anoxia and chemical
agents interfering with oxidative metabolism,56-58
its existence likely depends on the active meta-
bolic ion pumping processes of the stria vascularis.59 The anatomic distribution of the EP closely
approximates the limits of the endolymphatic
compartment formed by the tight junction bound-
aries shown in Figure 12. The augmentation of
the voltage drop across the apical ends of the hair
cells that the EP provides is thought to be criti-

cally important in cochlear transduction.60

Cochlear Microphonics and Summing
Potentials. When the appropriate stimulus is
applied, most sensory end-organs generate bio-
electric events called receptor potentials. These
potentials differ from action potentials in that
(1) they are graded rather than all or none, (2)
they have no latency, (3) they are not propagated,
and (4) they have no apparent postresponse refractoriness. The SP and CM form the recep-
tor potentials of the cochlea and can be recorded
indirectly from gross electrodes on the round
window or directly from the fluid spaces within
the organ of Corti.

The CM reproduces the alternating current
(AC) waveform of the stimulating sound (hence
the name “microphonic”[62]). The SP, illustrated
in the lowest inset at the top left of Figure 15,[63]
represents the DC shift that follows the “envelope”
of the stimulating sound. As depicted in Figure 15,
both the CM and SP are generated across the hair-
bearing end of the hair cells.[55,65] Based on experi-
mental findings, it is assumed that the generator
site for the receptor potentials is at the apical tips
of the stereocilia.[66]

The results of intracellular recordings from
IHCs and OHCs suggest that IHCs generate the
SP and the OHCs generate the CM. Generation
of the CM can be understood by examination of
the resistance battery model of Davis[69] depicted
in Figure 16. In this conceptualization, the EP
serves as the “battery” that provides the driving
force to move current through the high resistance
of the reticular lamina in which the apical ends
of the hair cells are embedded. The traveling wave
displaces the basilar membrane, resulting in the
deflection of the stereocilia and changes in hair cell
resistance. Thus, hair cells acting as variable
resistors modulate current flow across the reticular
lamina to produce a time-varying potential, the CM,
which follows the waveform of the input stimulus.[7]

Role of the Cochlear Potential in Stimulus
Transduction. Wever and Bray’s discovery of the
CM[70] led to the hypothesis that auditory nerve
fiber endings are stimulated electrically.[71] How-
ever, studies with the transmission electron
microscope (TEM) revealed that the morphology
of the interfaces between the afferent nerve end-
ings and the hair cell bases was unmistakably that
of a chemical synapse. The chemical synapse-like
structures found there include (1) a synaptic cleft,
that is, a uniform space between the hair cell and
nerve fiber membranes, (2) synaptic vesicles, and
(3) a synaptic bar in the form of an electron-dense
disk surrounded by vesicles that resembles the
synaptic ribbon of the retina.[72]

The presence of subcellular organelles consis-
tent with a chemical synapse at the hair cell/audi-
tory nerve junction supports the current view that
a chemical transmitter released by the hair cell
stimulates the auditory nerve endings.[73] Thus,
cochlear receptor potentials are probably either
directly involved in the cause-and-effect chain
leading to chemical stimulation of the auditory
nerve or are intimately related to a process that is
directly involved but does not stimulate the audi-
tory nerve fibers electrically.[59]

Current thinking about cochlear transduc-
tion, which originates primarily from the studies
of Hudspeth,[73] is illustrated in Figure 17. In this
formulation, displacement of the hair cell bundle
opens the transduction channels located at the tips
of the stereocilia to allow K+ to flow into the cell.
This influx of K+ depolarizes the cell, causing
calcium (Ca2+) channels at the base of the hair
cell to open, thus admitting Ca2+ into the cell.
The Ca2+ ions, in turn, stimulate the transmitter
vesicles to fuse with the hair cell membrane
and release transmitter into the synaptic cleft.
Transmitter substance then diffuses across the
synaptic space to initiate action potentials in the
adjacent auditory nerve fibers.

Cochlear Transmitters. One area of intense
research interest in the study of cochlear trans-
duction leading to intercellular communication
has been the identification of the afferent trans-
mitter substance that is released onto the primary
afferent neurons at the bases of the IHCs and
OHCs. In combination with these studies, other
efforts have attempted to characterize the efferent
neurotransmitter released on the hair cells and on
afferent endings terminating on hair cells by effer-
ent neurons originating in the brainstem. Recent
evidence indicates that the efferent neurotrans-
mitt is probably a single excitatory amino acid,
or a structurally related compound, which is
responsible for initiating auditory nerve action
potentials. Besides this chemical transmitter
substance, other chemicals, called neuromodula-
tors,[74] that influence the action of the transmitter
are also believed to be released into the synaptic
cleft.[75]

In the search for neurotransmitters, several
criteria have been established that are requisite
for the identification of transmitter substances.[76]
These criteria require that (1) the transmitter must
produce the same response when applied to the
synapse as the natural stimulation of presynaptic
elements, (2) extraneous substances that alter nat-
ural synaptic transmission such as blocking agents
should produce the same effect on the transmitter
candidate, (3) stimulation of presynaptic elements
should release the transmitter substance, (4) the
transmitter substance must be shown to exist
presynaptically, (5) enzymes responsible for the
synthesis of the transmitter candidate must be present, and (6) a mechanism must be demonstrated that can deactivate the transmitter once it has been released into the synaptic cleft. To date, concrete evidence for the auditory transmitter in the mammalian cochlea is scanty when compared with the findings of other studies of the central nervous system. That is to say, all of the criteria have yet to be met for any candidate afferent transmitter substance. However, based on our present ability to satisfy the above criteria, one of the most likely afferent transmitter substances is believed to be the excitatory amino acid glutamate,77 and aspartate, too, represents a more recently documented potential candidate.78

Documentation regarding the efferent transmitter in the mammalian cochlea is considerably stronger with the most persuasive evidence favoring acetylcholine (ACh). The strongest support for ACh comes from a set of experiments demonstrating that anticholinergic compounds block the effects of efferent stimulation but do not influence afferent cochlear activity.79 From other histochemical and immunostaining studies of the mammalian cochlea, there is considerable evidence for a GABAergic, that is, γ-aminobutyric acid, efferent innervation of the OHCs, as well as the IHC afferents, including (1) measurements of the uptake of tritiated GABA,80 (2) immunostaining for glutamic acid decarboxylase,81 and (3) immunostaining for GABA.81 Interestingly, evidence that isolated OHCs stain for GABA82 and that GABA application to isolated OHCs induces membrane hyperpolarization and membrane elongation83 infers that the functional consequences of this candidate transmitter substance is inhibition of the electromechanical transduction process. For a more in-depth treatment of studies of cochlear transmitters, readers are encouraged to consult an excellent review.84

Coding in the Cochlea. The cochlea must encode acoustic features into properties of neural activity. The principal acoustic parameters to be encoded are frequency, intensity, and temporal pattern, whereas the basic biologic variables available for neural encoding are place, that is, the location of the activated cell, amount of neural firing, and temporal pattern of firing. Because they are the percepts most studied, the cochlear encoding of frequency and intensity is addressed below. For excellent discussions of temporal processing, see Frisina85 or Eggermont.86

Frequency Coding. In the late nineteenth century, 2 opposing theories of frequency coding in the auditory periphery were proposed. These classic “place” and “frequency” theories have influenced subsequent thinking about cochlear frequency coding.3 The place theory of Helmholtz held that the basilar membrane acts as if it were a set of tuned resonators, analogous to a set of piano strings. Each tuned resonator vibrates sympathetically to a different frequency and thus selectively stimulates a particular nerve fiber. Rutherford’s frequency theory, later termed “telephone” theory, proposed that all frequencies activate the entire length of the basilar membrane, which transmits, essentially unchanged, the temporal pattern of the auditory stimulus. According to the telephone theory, it remains for more central neural structures to “decode” these temporal patterns to deduce the features of the acoustic stimulus.

Evidence for Place Coding: Mechanical and Neural Tuning Curves. Von Békésy used optical methods to make the first direct observations of the mechanical place analysis of
stimulus frequency in the cochlea. Subsequent observations using more sensitive techniques (eg, Mössbauer radioactive source, capacitive probe, laser interferometry) confirmed the general nature of von Békésy’s results but, as discussed below, modified his conclusions with respect to several important details.

The principal features of the mechanical responses that von Békésy observed are illustrated in Figure 18A. Each pure-tone cycle elicits a traveling wave that moves along the cochlear partition from base to apex. As it travels, the wave’s amplitude increases slowly, passes through a maximum, and then declines rapidly (Figure 18A). As the frequency of the stimulating tone is increased, the maximum of the traveling wave moves basally toward the oval window.

The inset at the bottom of Figure 18B illustrates the tuned behavior of the vibration of a specific locus on the cochlear partition that results from the traveling wave patterns generated by stimuli of different frequencies (4 plots above). The bottom plot of Figure 18B, called a cochlear mechanical tuning curve, was obtained by plotting the vibration amplitude of a single cochlear partition point against the exciting frequency. The frequency that generates the maximum vibration of a specific place on the cochlear partition at a point’s characteristic frequency (CF). Thus, the plot at the bottom of Figure 18B illustrates the mechanical tuning curve for a place on the cochlear partition with a CF of 150 Hz. Mechanical tuning curves at all cochlear partition locations have the same general shape, that is, a rapid falloff for frequencies above the CF (>150 Hz) and a gradual drop-off for frequencies below the CF (<150 Hz).

Microelectrode recordings from single hair cells and auditory nerve fibers yield an analog of the cochlear mechanical tuning curve. Figures 19 and 20, respectively, show examples of neural tuning curves obtained from primary auditory nerve fibers with traditional glass micropipets and mechanical tuning curves for the 9 kHz point on the basilar membrane made by a laser-Doppler vibrometer for a number of vibration criteria. Essentially, neural tuning curves are plots of response threshold against frequency (see Figure 19), and similar tuning curves can be recorded from single neurons throughout the auditory neural pathway. Note the relatively similar tuning capabilities of the nerve fiber with the 9 kHz CF (middle panel at the right of Figure 19), the most sensitive membrane velocity response (thick solid line of Figure 20) with respect to frequency selectivity (ie, the Q10dB “tuning,” at 10 dB above threshold, of ~2), and the tip-to-tail distance of about 80 dB.

The tuning curves of primary auditory nerve fibers have the same basic shape (ie, steep high-frequency slope, shallow low-frequency slope) as the mechanical tuning curves. Thus, the mechanical place code of the cochlea is clearly imprinted on the auditory nerve’s neural response pattern.

**Cochlear Tuning.** Two characteristics of cochlear tuning are critical to the determination of its location and mechanism. First, the process by which filtering takes place is too rapid to permit a neural delay; thus, there is no possibility that tuning is sharpened by some sort of neural “lateral inhibition” analogous to that occurring at higher levels in the auditory pathway (see below). The second important characteristic of cochlear filtering is that it is physiologically vulnerable. Almost all damaging agents, including hypoxia, ototoxic drugs, local mechanical damage, and acoustic trauma, detune the neural tuning curves so that they closely approximate the broader mechanical tuning curves. As Figure 21 shows, the detuning by damaging agents occurs not only for neural tuning curves but also for mechanical tuning curves, SP tuning curves measured with electrodes placed intracellularly in IHCs, and psychophysical tuning curves from humans with cochlear deficits. Until recently, the vulnerability of mechanical tuning curves was a controversial point. The first published “modern” mechanical tuning curves measured using Mössbauer and capacitive probe techniques were tuned about as poorly as von Bekesy’s. However, even at this early stage, the sharpness obtained by different laboratories differed. It has now become clear that the sharpness of cochlear mechanical tuning is extremely vulnerable and that, even when great care is taken, the surgical and other manipulations necessary to obtain mechanical tuning curves in experimental preparations unavoidably cause broadening of the mechanical frequency response. Cochlear mechanical tuning curves obtained under conditions in which extreme precautions were taken to minimize cochlear damage have demonstrated tuning that is as sharp as that of neural tuning curves. In addition, the existence of nonlinear behavior in the normal cochlear mechanical response has been confirmed. Thus, the sharpness of tuning observed at the primary neuron level is already accomplished at the level of the mechanical traveling wave.

The question remains, however, of how the physiologic vulnerable sharpening of mechanical tuning is accomplished. One critical consideration in answering this question is the calculation by Kim and coworkers that mechanically tuning a location on the basilar membrane requires the local addition of mechanical energy.
healthy cochlea\textsuperscript{[1]} and can be recorded simply from human and animal ear canals provided indirect evidence for the presence of such a mechanical energy generator within the cochlea. The results of further studies on OAEs in vertebrates and more recent investigations of the biophysical properties of isolated OHCs have implicated micromechanical processes at the level of the OHCs as being responsible for the normal frequency selectivity of the cochlea.

The OAEs are traditionally classified into 2 general categories: those that are elicited with deliberate acoustic stimuli (evoked OAEs) and those that occur in the absence of stimulation (spontaneous OAEs). All OAEs can be simply recorded using conventional averaging techniques by a sensitive subminiature microphone assembly inserted snugly into the external auditory canal. Over the past several decades, 4 types of emissions, illustrated in Figures 22 and 23, have been studied extensively. These include the spontaneous OAE (SOAE), which is measured in the absence of acoustic stimulation (see Figure 22A); the stimulus frequency OAE (SFOAE), which is...
evoked by a low-level, continuous pure tone (see Figure 22B); the transient evoked OAE (TEOAE), which is elicited by clicks or tone pips (see Figure 22C) and distortion-product OAE (DPOAE), which is elicited by 2 simultaneously applied pure tones (see Figure 23) known as the lower- \( f_1 \) and higher-frequency \( f_2 \) primary tones.

The following facts support the notion that OAEs come from the cochlea and are related to the active frequency filtering process: (1) The frequency of the TEOAE varies considerably from subject to subject, and across subjects there is a systematic relationship between the emission’s delay (ie, latency) and its frequency. This suggests that the origin of OAEs is the cochlear bandpass filtering mechanism. (2) Stimulation of the crossed olivocochlear bundle (OCB), which preferentially provides efferent innervation to the OHCs, modulates the magnitude of OAEs.

(3) The emission is extremely sensitive to the determinantal effects of cochlear pathology, acoustic trauma, and ototoxic drugs. The most parsimonious interpretation of the existence of the various OAE types, their duration, bandwidth, and delayed-onset characteristics and their relationship to the activity of the cochlear efferent system is that they originate in the OHCs, which possess a mechanical energy that generates the frequency-selective output of the cochlea.

Brownell and Zenner and their colleagues were the first to show that in in vitro preparations of mammalian hair cells OHCs display electromotility. Using mechanical trituration to dissociate single OHCs from other organ of Corti tissues and video-enhanced imaging to visualize the isolated OHC directly, these investigators developed the hypothesis that the OHCs comprise a sensitive low-level detector system that has poor place-coding ability, has been abandoned in favor of more recent notions based on the active biomechanical functioning of the organ of Corti. That the OHCs possess effector abilities supports the proposal of Kim that these receptors are bidirectional transducers capable of converting acoustic energy into neural energy, that is, mechanoelectrical transduction, and electrical into mechanical energy, that is, electromechanical transduction.

It seems clear that the OHCs and IHCs are functionally different, but our concept of the nature of this difference is changing. The classic view that the relatively insensitive IHC system carries the frequency place code, whereas the OHCs comprise a sensitive low-level detector system that has poor place-coding ability, has been abandoned in favor of more recent notions based on the active biomechanical functioning of the organ of Corti. That the OHCs possess effector abilities supports the proposal of Kim that these receptors are bidirectional transducers capable of converting acoustic energy into neural energy, that is, mechanoelectrical transduction, and electrical into mechanical energy, that is, electromechanical transduction. Kim elaborated on this notion by postulating the existence of 2 distinct but parallel cochlear subsystems that use OHCs as the modulators and IHCs as the carriers of auditory information. Table 1 presents a summary of a comparison of the 2 subsystems.

There is good evidence that the vulnerable filter sharpening described previously involves some kind of interaction between the IHCs and...
OHCs including the following: (1) selective damage to OHCs causes detuning of neural tuning curves (Figure 27), which presumably are from IHC fibers; (2) crossed OCB stimulation, which presumably affects only OHCs (see below), strongly depresses the auditory nerve's click-evoked, whole-nerve, or compound action potential (CAP), which apparently originates entirely from IHC fibers; (3) crossed OCB stimulation also reduces the amplitude of the receptor potential recorded intracellularly from IHCs; (4) crossed OCB stimulation as well reduces the firing rate and synchronization index and shifts the dynamic range of auditory nerve fibers; and (5) a trapezoid acoustic stimulus elicits from an auditory nerve fiber a spike train with a complex time course, suggesting combined IHC and OHC influences, whereas selective damage to OHCs by kanamycin treatment simplifies the trapezoidal response pattern in a way compatible with isolated IHC influence.51

The precise mechanism by which OHCs influence the response of IHCs is unknown at this time. However, because the physiologically vulnerable cochlear filter-sharpening process appears to involve basilar membrane vibrations, the mechanism requires that the OHCs directly influence the mechanical vibration of the basilar membrane. A corollary to this conclusion is that the OAs recorded from the human ear canal reflect OHC function. Indeed, 1 intensely studied subfield of OAE research is focused on using emitted responses to evaluate the normality of central auditory processing based on the influence of the descending efferent system on OHC-generated activity.120,121

Clinical Consequences. The existence of a vulnerable cochlear filtering process and a related cochlear emission that can be recorded noninvasively have some important implications for our understanding of pathophysiologic processes in the cochlea. First, although it is unlikely that the majority of cases exhibiting severe tinnitus are related to spontaneous OAEs, emissions may elucidate the mechanism of at least some kinds of tinnitus.122 Moreover, by separating the sensory from the neural aspects of ear dysfunction,
OAEs may reveal the critical underlying causes of some common but puzzling otologic diseases such as Meniere disease\textsuperscript{123} and sudden idiopathic sensorineural hearing loss.\textsuperscript{124} Second, as shown in Figure 28, detuning of the neural response in cochlear pathologic conditions may also explain recruitment.\textsuperscript{125} As previously described, detuning caused by cochlear pathology eliminates the low-threshold, sharply tuned tip region of the tuning curve but preserves the high-threshold tail region. Elimination of the tip region raises threshold, but preservation of the tail region preserves neural responsiveness at high intensities. Thus, the loudness function (bottom right plot) is made abnormally steep because threshold is elevated. However, at high intensities, loudness is normal because a normal number of neurons are responding.

Evidence for Telephone Coding. The aforementioned evidence for place coding has not invalidated Rutherford’s telephone theory because there is also considerable evidence for a telephone code at low frequencies. For example, cochlear tuning becomes progressively poorer as frequency is lowered, and below about 100 Hz, there are no cochlear partition amplitude maxima and no tuned auditory units.\textsuperscript{126} Thus, the physiologically observed frequency place code becomes progressively worse as frequency is lowered.

A neural telephone code has been demonstrated that, in contrast to the place code, becomes progressively better as frequency is lowered. A nalyzing the spike discharges of single auditory nerve fibers to low-frequency stimulation demonstrated “phase-locking” to the individual cycles of the eliciting tone that preserves the temporal firing pattern.\textsuperscript{127} Compiling large

**Figure 25** Diagram of the cochlea’s afferent innervation pattern. The view is through the Reissner membrane, looking down on the organ of Corti. Principal fiber bundles are 1 and 2, intraganglionic spiral bundles (fibers labeled “1” are efferent olivocochlear fibers); 2a and 3a = internal spiral fibers; 4 = external spiral fibers, traveling in radial bundle to innervate outer hair cells (OHCs); 5 and 6 = radial fibers, innervating inner hair cells (IHCs). The “V” shape of the cilia pattern on the OHCs and the shallower “U” pattern on the IHCs are shown in the upper corners of the diagram. (Reproduced with permission from reference 131.)

**Figure 26** The descending auditory system. (A) Origination in the brainstem, distribution, and termination within the cochlea of the olivocochlear bundle efferent fibers of the cat. (B) Organization of the lateral and medial olivocochlear (OC) systems. Lateral OC neurons project to the region beneath the inner hair cells, where they form axodendritic contacts on the dendrites of type I spiral ganglion cells. Medial OC neurons project to the region beneath the outer hair cells and synapse directly with them. (A reproduced with permission from reference 143; B reproduced with permission from reference 167.)
The limitations of fiber discharge rate place encoding in neurally representing the frequency components in speech sounds, especially those of moderate to high intensities. More recently, the single-unit population studies of Sachs and Young on the representation of speech sounds in hundreds of auditory nerve fibers have demonstrated that the temporal pattern of fiber discharges in the form of phase locking provides considerable information about the frequency content of the stimulus at all levels of stimulation. These population measures of temporal synchrony were based on Fourier transforms of period histograms from fibers with CFs near each frequency component of the sound. Such measures were combined to provide discharge rate profiles for groups of active nerve fibers. Because information concerning rate, timing, and place is represented in these measures, these spectra provide details concerning temporal fine structure from a localized cochlear region and thus represent a type of temporal place code.

Our use of sounds in communication is greatly aided by our keen sensitivity to the frequency region between 1 to 4 kHz, and although our sensitivity falls off beyond 4 kHz, we still depend on the higher frequencies for many of our discriminations of consonants and sharp transients. The appearance and elaboration of the place principle for frequency representation, therefore, was a major event in the evolution of the ear.
Intensity Coding. Loudness is the approximate subjective correlate of the physical dimension of sound intensity. It is generally assumed that the neural correlate of loudness is the amount of nervous activity, with the amount factor meaning the total number of action potentials delivered by a population of nerve fibers over a given time period. Thus, loudness is encoded as a combination of the number of fibers firing and the rate at which they are firing.

Figure 29 compares plots of stimulus level versus single auditory nerve fiber firing rates (left) and stimulus level versus subjective loudness (right). The agreement in the general shapes of the curves supports the view that the amount of auditory nerve firing encodes loudness. On closer scrutiny, however, it is apparent that firing rate changes only over a 20 dB sound intensity range, whereas loudness varies over a 100 dB range. This limited dynamic range is a general property of all primary auditory neurons.133

The obvious way to solve this loudness-encoding problem is to assume that additional nerve fibers are “recruited” as stimulus level is increased. This process would increase the total number of discharges per unit time by increasing the number of fibers firing rather than the firing rate for an individual fiber. However, most studies of auditory nerve single units agree that the thresholds of the nerve fiber population fall within a relatively restricted stimulus range, that is, within 20 to 30 dB of behavioral threshold.134 Thus, there is no possibility of recruiting additional fibers as sound level is increased more than 60 dB above threshold. The fiber recruitment hypothesis also creates problems for frequency place coding because adding new responding fibers as stimulus level is increased would quickly require the spread of activity to fibers of adjacent CFs. This tradeoff between the ability to recruit new fibers and the ability to place code is especially bothersome for explaining the perception of complex sounds for which multiple frequencies must be distinguished simultaneously. Thus, the dynamic range problem becomes apparent.135 The dynamic range of auditory nerve fibers, that is, the range over which the spike rate changes as stimulus level is altered, is too narrow to account for (at least in simple terms) the extent over which the human ear discriminates sound levels.

Several subsequent observations shed light on the dynamic range problem. Evans and Palmer discovered that approximately two-thirds of the cells in the dorsal cochlear nucleus (DCN) had dynamic ranges that extend to well over 100 dB and thus could easily “code” loudness over the necessary sound intensity range.136 However, the problem of the input pathway to these DCN cells remains to be resolved. In addition, some auditory nerve units have been found that do, after all, have wide dynamic ranges, but these are only a minority of the total auditory nerve fiber population.137 Other studies have also demonstrated that relative degrees of phase locking138 of different frequency components in complex sounds could code the relative intensity levels of the frequency components. However, because phase locking does not occur above 3 to 4 kHz, this mechanism could not account for the loudness coding of high frequencies.

A nother approach to the dynamic range problem is the concept of an automatic gain control operating at the input of the auditory system.135 Such a control mechanism would feed back a decreased gain command signal to the input to maintain the cochlear output within an acceptable operating range. Possibilities for such a control

---

**Figure 28** Possible explanation of recruitment (elevated threshold and abnormal growth of loudness) based on detuning with pathology. Solid diagrams at bottom depict increase in number of active auditory nerve fibers as tone level is increased in normal (left) and abnormal (right) ears. The tone’s frequency (T) is indicated by the dashed line in the upper diagram. Because the effect of disease is to remove the sharply tuned “tips” but leave the broadly tuned “tails” relatively unaffected, the threshold of the pathologic cochlea is increased. However, as tone level is increased into the normal tail regions, the number of active fibers responding becomes normal; hence, loudness grows abnormally rapidly from the elevated threshold. (Reproduced with permission from reference 126.)

**Figure 29** Effects of sound intensity on subjective loudness (right) and auditory nerve fiber firing rate (left). The shapes of the curves are similar, but the dynamic range of the single auditory nerve fiber is much narrower than that of the auditory system as a whole. Above the auditory nerve firing rate curve (B) are single-fiber responses to sounds of progressively increasing levels (A). Subjective loudness curve from Gulick (1971) noted in the legend for Figure 21. (Auditory nerve curve reprinted with permission from reference 132.)
system include the middle ear reflex and the olivocochlear efferent system.

Finally, Liberman classified auditory nerve fibers into 3 functional subclasses according to spontaneous discharge rate as low-, medium-, and high-firing units.118 Whereas high spontaneous rate (SR) fibers exhibited low thresholds and restricted dynamic ranges of about 20 dB, the medium and low SR units displayed higher thresholds and dynamic ranges as great as 60 dB. Thus, it is possible that although fewer in number than the high SR fibers, the low and medium SR fibers are available to encode the higher intensity sounds.140

Viereck concluded from his review of the psychophysical and physiologic literature relevant to intensity encoding in auditory nerve fibers that a localized rate code “seems theoretically possible and, at present, appears to be the best candidate for a general intensity code.”141 The conclusion that rate information from a frequency-specific population of active nerve fibers provides the neural basis for a code of stimulus intensity is consistent with the findings discussed above concerning the encoding of high-level speech sounds by a population of auditory nerve fibers that possibly exhibit low to intermediate spontaneous firing rates.

Efferent Auditory System. Anatomy. Ras- umussen established the existence of a chain of descending auditory neurons that links auditory cortex to hair cells and that parallel the classic afferent projection pathway (discussed below).142 The OCB, the final link in the descending chain, originates in the superior olivary complex (SOC).

Figure 26A summarizes schematically the origins, course, and distribution of the OCB to 1 cochlea, whereas Figure 26B analyzes the principal relationships between the 2 afferent and the 2 efferent innervations of the organ of Corti.143 The OCB is divided into crossed and uncrossed components. The crossed component is composed primarily of relatively large myelinated fibers that originate in large globular neurons surrounding the medial region of the SOC.144 Most of the uncrossed component is composed of small fibers,145 a large percentage of which may be unmyelinated and which originate in the small fusiform neurons in the lateral region of the SOC.144 The majority of the large crossed fibers innervate OHCs, whereas most of the small uncrossed fibers innervate IHCs.144

The crossed olivocochlear fibers decussate just beneath the floor of the fourth ventricle and then enter the vestibular nerve. At this point, they are joined by the uncrossed fibers. The combined crossed and uncrossed fibers travel in the vestibular nerve and cross into the cochlear nerve via the vestibulocochlear anastomosis. Within the cochlea, efferent fibers have been identified among the external spiral fibers (3b in Figure 25), the tunnel spiral fibers, and the internal spiral fibers.146

Physiology. In cases in which olivocochlear axons have been labeled histochemically and traced following single fiber fiber recordings, the labeled fibers terminate beneath OHCs in cochlear regions with best frequencies corresponding to the CFs of the fiber.147 Such direct recordings from efferent axons within the periphery have demonstrated that these units possess thresholds and tuning curve properties that are essentially identical to those of primary afferents with similar CFs.148 Although the proportion of olivocochlear neurons that can be excited by ipsilaterally and contralaterally stimuli is consistent with the predominant efferent innervation to a given cochlea, many units are binaurally responsive.149

The effects of stimulating the crossed OCB are almost certainly mediated by the release of A Ch as the major neurotransmitter at the OHCs,149 as noted above. In turn, A Ch acts on A Ch receptors (A ChRs) located on the OHC postsynaptic membrane to modulate the electrical properties of the OHCs. Elgoyhen and associates established that A Ch acts on nicotinic A ChRs (nAChRs) containing the alpha9 (α9) subunit, which mediates synaptic transmission between the cholinergic olivocochlear fibers and the OHCs.150 It has long been known that stimulating the crossed OCB in the floor of the fourth ventricle causes depression of the auditory nerve’s response to sound stimulation, that is, the CAP, and a simultaneous increase in the amplitude of the CM.151 It is likely that the α9 nAChR subunit mediates such efferent inhibition because an α9 knockout mouse model showed no suppression of either CAPs or DPOAEs by electrically stimulating the OCB at the floor of the fourth ventricle.152 It was further shown that the α9 nAChR protein opens its ion channel via associated Ca2+-activated K+ channels.153

Much less is known about the uncrossed OCB. Stimulation of the uncrossed bundle decreases the click-evoked CAP amplitude, but the effect is much less than for the crossed bundle.153 In addition, unlike the crossed bundle, the terminations of the uncrossed bundle do not show high concentrations of acetylcholinesterase.154 and curare does not block the effect of stimulating the uncrossed bundle (although strychnine does).149

Thus, the uncrossed system may not be cholinergic.

Functional Significance. The function of the olivocochlear efferent system is, at present, largely unknown. Several attempts to demonstrate functional deficits after sectioning the crossed OCB have failed.155 A series of more recent studies has systematically examined the effects of electrically stimulating the crossed OCB on auditory nerve fiber dynamic ranges that have been compressed by broadband noise stimulation.156 The restoration of dynamic range in the presence of background noise supports the notion that the cochlear efferent system may function to improve the ability to discriminate complex signals, that is, the signal-to-noise ratio. However, the hypothesis that the olivocochlear system primarily provides some sort of input gating mechanism may not be completely correct.

The most recent and unexpected effect of stimulating the crossed OCB is a decrease in the levels of OAEs that are generated mechanically by the cochlea and recorded in the ear canal. Mountain was first to report that electrical stimulation of the olivocochlear efferent system directly affected the active nonlinearity of OAE mechanisms inferred from decreases in DPOAEs.157 A number of other studies evaluating the influence of contralateral acoustic stimulation with wideband noise on OAEs recorded ipsilaterally reported small reductions in DPOAEs158 and in 2f1-f2, DPOAEs. The influence of contralateral stimulation on OAEs also supports the notion that the cochlear efferent system is involved in the modulation of OHC micromechanics. These effects, along with the reductions in neural discharge rate and tuning, suggest that the function of the crossed OCB is to allow the central auditory system to govern the mechanical properties of the basilar membrane by controlling the vulnerable cochlear tuning mechanism previously discussed. Because detuning a frequency bandpass system increases damping, the detuning effect of the crossed OCB could be useful as a method of improving auditory temporal resolution, for example, to improve speech perception. The consensus view at present is that the active transduction process159 is regulated in some way through efferent innervation of the OHCs.111 Also, as noted above, the olivocochlear efferent system may also contribute toward extending the dynamic range of the auditory system.158

In addition, other experimental results suggest that the olivocochlear system may help protect against acoustic trauma.158 In this work, it was discovered that the amount of threshold shift induced by overstimulation of 1 ear could be reduced by the presentation of a simultaneous tone to the contralateral ear, thus inferring that activating the efferent system reduced the effects of overexposure.160 One intriguing line of current research on the traumatic effects of noise exposure is the notion of “training” the cochlea to become less susceptible to damaging sounds.159-161 One common protocol to induce the training (or conditioning or toughening) effect is to apply daily, moderate-level sound exposures to reduce injury from a subsequent high-level noise exposure.162 Although the underlying mechanism(s) responsible for the trained protective effect is, at present, unknown, the most likely site is the crossed cochlear efferent system.163 Indeed, LePage demonstrated that loud sound induces a mechanical baseline shift in the position of the cochlear partition.165 It is highly probable that such a gain control system is effected by cochlear efferents.

Central Auditory Pathway

Each of the 5 primary senses sends information into the brain via 2 separate pathways: a direct or specific pathway and a nonspecific pathway. The nonspecific pathway involves structures in the core of the neuraxis, collectively known as
the reticular system. In the reticular system, all sensory modalities share the same gross neural structures (hence the name nonspecific). A scent via the nonspecific structures is multisynaptic and hence is characterized by long delay times. The direct pathways for each sensory modality are separate and involve all axonal processes, with a minimal number of synapses; consequently, compared with the indirect pathway, transmission along the direct pathways involves minimal delay times. The synapses of the direct pathways tend to congregate in well-defined neural structures called nuclei. Clinically, lesions of the central auditory system are localized according to their level in the direct projection pathway. Therefore, the following discussion emphasizes this pathway.

**Anatomy.** Figure 30 diagrams the direct auditory projection pathway. The numbers in each nucleus indicate neuronal order (determined by the number of synapses). The auditory projection pathway is more complex than the pathways of other sensory systems, possibly because it developed relatively late on the phylogenetic scale and had to incorporate pieces of other already developed neuronal systems. Although the basic wiring diagram depicted in Figure 30 has remained relatively unchanged for many years, it should be emphasized that within the last half century, a number of advances have been made in the development of methods for describing neuronal connectivity. These breakthroughs have relied on the discovery that, when certain amino acids, conjugated enzymes (eg, horseradish peroxidase-conjugated lectin from soy bean), sugars, or immunocytochemicals (eg, polyclonal or monoclonal antibodies) are injected into a neuronal or fluid (eg, cochlear duct) region of interest, they will be taken up by the cells or fiber endings in this region and transported by the normal cellular process of axonal transport in both retrograde and anterograde directions. Other techniques make use of such labels as lipophilic dyes (eg, dilinoleyl-tetramethylindocarbocyanine or Dil), which can be retrogradely transported in fixed tissue by diffusion.

Visualization of the location of cellular projections or the cellular/subcellular location of labeled substances at the light and electron microscope levels is achieved either by autoradiography, in the case of radioactive compounds, or by catalyzation of histochemical reactions, which are typically viewed under epifluorescence or dark-field optics. With recent refinement of these tract tracing and cell component-labeling techniques using immunohistochemical markers, virtually all projection pathways and cell types of the auditory system have been described. Lagging far behind our description of the connections of the neural pathway for hearing is our understanding of how this network of interconnections interacts to produce our complex auditory sensations. Presented below is a brief description of the major projections of the auditory pathway sufficient for the clinician to understand the transfer of information within the auditory system, without consideration of the many lesser connections revealed by modern immunocytochemical staining techniques. The reader is referred to several comprehensive reviews that provide more details of the intricate interconnections of the central auditory system.

Cochlear Nucleus. Central processing of the information carried in the auditory nerve begins in the cochlear nucleus (CN), the first obligatory synapse for all nerve fibers. On entering the CN, the auditory portion of the eighth nerve bifurcates into two branches, one that sends fibers to synapse in the anteroventral cochlear nucleus (AVCN) and one that synapses in the posteroventral cochlear nucleus (PVCN) and dorsal cochlear nucleus (DCN). The distribution of fibers within the CN is not random but follows an orderly pattern of tonotopic projection throughout the nucleus, with low-frequency fibers projecting ventrally and high-frequency fibers distributed dorsally. Thus, both neurophysiologic and anatomic observations show that cochlear place is represented in an orderly manner throughout the projection pathways of the central auditory system. The security of tonotopic organization is also apparent in the multiple representation of the stimulus frequency domain. For example, typically, along any 1 penetration of a microelectrode trajectory within a principal nucleus, there are 2 or more breaks in the orderly progression of best frequencies. Thus, as in the direct projection pathways of all sensory systems, multiple representation of the receptor surface occurs. It is likely that nerve fiber branching in the various nuclei, as described for the CN, is the anatomic basis of this multiple frequency representation.

All auditory nerve fibers display relatively uniform response characteristics to pure-tone stimuli compared to the activity of CN cells when categorized by the use of a poststimulus time histogram (PSTH). The PSTH plots the number of nerve discharges that occur in small time bins within the period that begins slightly before and extends throughout the duration of the stimulus. PSTHs are shown for an auditory nerve fiber and various CN cells in Figure 31. The CN consists of at least 9 different cell types described for their anatomic characteristics revealed by various staining techniques. It can be seen from the unit activity patterns of Figure 31 that the uniform response characteristics of auditory nerve fibers are soon elaborated by the various cells of the CN to produce a variety of response types named after the patterns seen in the PSTH. When examined in the frequency intensity domain, some CN cells exhibit complex response patterns that describe regions of excitation and inhibition produced by a pure-tone stimulus. An example of such complex response patterns by cells in the CN is shown in Figure 32.

Three fiber pathways project information from the CN to higher brainstem centers. These fiber tracts include the ventral (trapezoid body), intermediate, and dorsal acoustic striae. The ventral acoustic stria, originating from AV CN and PVCN regions, projects ventrally and medially to send fibers ipsilaterally to the lateral superior olive (LSO) and the medial superior olive (MSO) and then to the medial nucleus of the trapezoid body (MTB). The fibers then cross the

---

**Figure 30** Diagram showing the diverse single-unit response types obtained from cells in the cochlear nucleus compared to the uniform response pattern found for fibers of the auditory nerve. The poststimulus time histograms were obtained by presenting short 25 to 50 ms tone bursts at the unit’s characteristic frequency. Response types from top to bottom are pauser, on, primary like with notch, chopper, and primary like. Cell types presumably associated with these response patterns from top to bottom are pyramid, octopus, globular, multipolar, and spherical. (Reproduced with permission from reference 171.)
midline to terminate on the contralateral M SO and M TB but do not innervate the LSO on the opposite side. Thus, for any 1 ear, connections are bilateral only to the M SO and M TB. The intermediate acoustic stria, the primary output of the PVCN, sends some fibers ipsilaterally to a group of cells around the superior olivary complex (SOC) called the periolivary nucleus (PON), whereas other fibers ascend in the lateral lemniscus (LL). This pathway also crosses the midline to innervate the same structures on the contralateral side. Fibers of the intermediate acoustic stria, which enter the LL, synapse within the nuclei.

The dorsal acoustic stria, the principal output of the DCN, bypasses the SOC to synapse in the contralateral dorsal nucleus of the LL and the inferior colliculus (IC). Superior Olivary Complex. The SOC is composed of the LSO, M SO, M TB, and PON. The SOC receives fibers from both CNs and consequently receives information from both ears. This feature allows this group of nuclei to monitor the arrival time and level of sounds to both ears and provides the cues for the localization of sound in space based on the stimulus arrival time and intensity to both ears. In fact, localization of sound in the horizontal plane provides the most straightforward relationships that have been observed between central auditory single-unit behavior and psychophysical function. As a sound to 1 ear is made progressively louder or earlier than sound to the opposite ear, some SOC units change abruptly from inhibitory to facilitatory response patterns. By assuming a facilitatory contralateral input and an inhibitory ipsilateral input (or vice versa), the neurophysiologic behavior of these units can be explained. Thus, slight binaural differences in level and/or arrival time provide the auditory cues for localization of sound in the horizontal plane (sound lateralization). The acoustic image is located on the side of the louder or earlier sound. As a whole, the SOC represents the lowest level in the auditory system at which binaural processing takes place. However, at all levels in the auditory projection pathway above the trapezoid body, there are units that are sensitive to binaural time and level differences.

Lateral Lemniscus. The LL is the major ascending projection from the CN and SOC to the IC and contains both contralateral and ipsilateral fibers from lower auditory brainstem structures. Although there are 3 distinct nuclei within the LL, historical emphasis has been simply on its function as a connection between the SOC and IC. Recently, these nuclei have received more attention in efforts to define their role in auditory processing.

Inferior Colliculus. The IC receives synapses from the majority, if not all, of the fibers projecting from the lower auditory nuclei. The 3 neuronal areas that make up the IC are the central, external, and pericentral areas. The predominant termination zone for the ascending auditory projections is in the ventrolateral region of the central nucleus. This region receives inputs from the SOC and is heavy contralateral input from the DCN. Other major projections come ipsilaterally from the M SO and bilaterally from the LSO. The function of the IC is far from completely understood, with many neurons exhibiting complex excitatory-inhibitory interactions. A simple view is that the IC integrates the frequency analysis features of the DCN with the localization abilities of the SOC.

Medial Geniculate. The medial geniculate (MG) is the thalamic relay nucleus for auditory information. All auditory projections from the IC to the auditory cortex pass through the MG. This nucleus is also composed of 3 divisions, the ventral, dorsal, and medial nuclei. The ventral nucleus receives heavy ipsilateral projections from the ventrolateral portion of the central nucleus of the IC. This portion of the MG projects to the A I, A II, and EP regions of the auditory cortex (see below). A gain, a wide variety of single-unit response types have been recorded in the MG. In attempting to understand the MG’s role in auditory processing, special efforts have been made to examine MG single-unit responses to complex sounds. Thus, David and associates and Kiehl demonstrated that MG neurons in the unanesthetized cat were responsive only to specific parameters of complex speech sounds. In general, it has been extremely difficult to attribute specific feature extraction capabilities to neurons in the higher auditory nuclei that cannot be explained by complex responses already present at the level of the CN.

Auditory Cortex. The auditory cortex has been most extensively studied in the cat and can be divided into 3 areas based on similarity of Nissl stained cytoarchitectural details. These include a primary area A I, a secondary area A II, and a remote projection region EP. In human and nonhuman primates, the primary auditory projection area is located in the temporal lobe but hidden by the sylvian fissure. The ventral division of the MG projects almost entirely to A I, which can be considered the primary auditory cortex. Surrounding auditory areas receive projections from all divisions of the MG. Like the auditory relay nuclei, the auditory cortex is also tonotopically organized. As might be expected by the many intricate interconnections of the auditory system prior to input arriving at the cortex, the understanding of cortical processing has been a complex and difficult task. One approach to solving the problem of cortical function has been the use of ablation studies in which the auditory cortex is removed after training an animal to perform a specific auditory task. These studies have demonstrated that cortical ablation does not result in a complete loss of function as do similar lesions in the visual system. In fact, for many simple tasks, no long-term deficits can be detected. Based on these results, it is reasonable to assume that the auditory cortex is involved in numerous details of more complex auditory processing. Consequently, it is unlikely that a simple unifying concept will be uncovered that describes the functional role of the auditory cortex.

Summary. Although there have been many studies of single-unit activity in the auditory nuclei over the past half century, they have thus far yielded few unifying principles about the data-processing mechanisms of the auditory nervous system. However, a number of recent studies suggest that, in many instances, the brain makes use of patterns of activity distributed over many cells to extract relevant information. Consequently, if future studies focus on describing the responses of individual cells without viewing their participa- tion, as a whole, in some functional unit, they may be doomed to result in failure as a means of understanding central auditory processing.

**Auditory-Evoked Electrophysiologic Responses**

Modern averaging techniques have made it possible to record from humans, with surface electrodes, electrical responses reflecting the entire auditory pathway, from cochlea to cortex. Clinical applications of this technique have
Evoked responses to clicks of opposite polarity are shown in Figure 33A. The whole-nerve CAP has 2 or more ear canal negative peaks designated N1, N2, N3 (N2 and N3 not labeled here), and so forth. Each peak lasts about 1 ms and, in normal ears, N1 is always the larger peak. In Figure 33B, the CM appears as a series of sinusoidal oscillations, typically about 3 kHz, on the leading edge of the N1 peak. The SP in Figure 33C appears as an ear canal negative hump on the leading edge of the N1 peak, with the CM oscillations superimposed.

The auditory nerve CAP (see Figure 33A) is the sum of the synchronous firing of single-fiber auditory nerve fibers as seen by the distant recording electrode as illustrated in Figure 34. The single-unit spikes are triggered by the passage of the cochlear traveling wave. Thus, spikes from basal (high-frequency) fibers appear at the recording electrode earlier than spikes from apical (low-frequency) fibers. Because the degree to which single neural unit responses contribute to the evoked potential is determined largely by their synchrony, high-frequency (basal) fibers contribute more effectively to the whole-nerve CAP and also to the evoked auditory brainstem response (ABR) than do low-frequency fibers.

This principle leads to several important conclusions for clinical applications: (1) Broadband-click-evoked CAPs preferentially reflect high-frequency fiber activity, and, as a corollary, high-frequency clicks are more effective generators of auditory-evoked potentials than low-frequency clicks. (2) High-frequency hearing loss caused by selective removal of basal units tends to bias the broadband-click-evoked CAP and ABR toward more apical units. Therefore, high-frequency cochlear deficits prolong N1 peak latencies. (3) A low-frequency deficit does not cause a corresponding basalward shift because of the already existing heavy bias toward basal units in the normal response. Therefore, low-frequency cochlear deficits have no apparent effect on CAP and ABR latencies. Because the CM response follows the waveform of basilar membrane vibration, it reverses polarity when click polarity is reversed, whereas the envelope-following SP does not. The neural response also maintains the same polarity. Thus, adding together responses to opposite polarity clicks cancels out the polarity-reversing CM and allows a better view of the SP (see Figure 33C). In contrast, subtracting the condensation and rarefaction responses preserves the CM, while canceling the SP and most of the CAP (see Figure 33B).

The cochlear receptor potentials (CM, SP) can also be separated from the CAP because receptor potentials are nonrefractory and do not adapt, whereas neural responses do. Thus, masking and increasing click rate are often used in clinical testing to depress selectively the neural response while preserving the CM and SP.

Reliable methods for separation of the SP from the other cochlear potentials have made this response useful in the diagnosis of M eniere disease. A number of studies have demonstrated that the SP is enlarged in a certain percentage of patients with M eniere disease. Evidence supporting the notion that SP enlargement is specifically related to endolymphatic hydrops is provided by observations that manipulations expected to reduce fluid accumulation within the endolymphatic space, for example, administration of hyperosmotic agents such as glycerol, often shrink abnormally enlarged SPs.

### Figure 33
Examples of cochlear and auditory nerve electrical responses to clicks recorded from the human outer ear canal. The cochlear potentials are the cochlear microphonic (CM) and summating potential (SP). (A) The whole-nerve compound action potential typically has a large negative peak (N1). R and C are shown as separate condensation (dashed line) and rarefaction (solid line) rectangular-pulse click responses recorded from the outer ear canal with a nasion “reference” electrode. (B) R − C is the waveform produced by subtracting C from R responses. (C) R + C is the waveform produced by adding C and R responses. Upward deflections represent negativity at the ear canal, and time scale zeroes are set at the leading edge of the rectangular pulse driving the ear speaker. Click rate was 8/s; click level was 115 dB peak equivalent SPL. Each C and R response was the average of 1,000 single sweeps.

### Figure 34
Summation of the single-unit spikes (amplitude exaggerated) picked up by a distant electrocochleographic (ECochG) electrode to form the whole-nerve compound action potential (CAP). Note that the highly synchronized spikes from the basal end of the cochlea sum more effectively than the poorly synchronized spikes from the apical end of the cochlea. The records of unit action potentials (APs) and the whole-nerve CAP at the bottom are from a simplified computer experiment. (Reproduced with permission from reference 187.)
**Middle Latency Response.** The middle latency response (MLR), labeled N₀, P₀, N₁, P₁, and so forth (Figure 35B), occurs between 8 and 40 ms after the auditory stimulus. In animals, wave P₀ appears to be generated in the primary auditory cortex by cortical elements on the side contralateral to stimulation. However, in humans, P₀ seems to be generated in both hemispheres, even with monaural stimulation. Human cortical mapping localizes this potential to the region of the sylvian fissure, whereas studies based on clinical correlations indicate involvement of thalamocortical projections to the primary auditory area located along Heschl gyrus in the genesis of this response. Site-of-lesion studies suggest that wave N₁ originates in the midbrain, including such structures as the MG and thalamocortical projections.

Although the MLR is not used nearly as frequently as ABR, useful clinical information can be obtained from this response, particularly in conjunction with ABR testing. The MLR is robust at all frequencies including low frequencies below 1,000 Hz and, consequently, offers a complementary index of high- and low-frequency hearing. The MLR can also be useful in assessment of central auditory system disorders, neurologic evaluation, and, most recently, as a tool for cochlear implant assessment. The most significant disadvantage of MLR is that subject variables such as sleep state or sedation can severely reduce the amplitude of this potential. Thus, behavioral state must be controlled to obtain meaningful results.

**Late Auditory Evoked Response.** The relatively high-amplitude late auditory-evoked response (LAER), labeled P₁, N₁, and so forth (also called the vertex potential), occurs between 50 and 250 ms after the stimulus (Figure 35C). It is a cortical response, but its long latency suggests that the LAER is not generated within the primary auditory cortex but rather that it originates in the associative cortex. These potentials are often dependent on the subject’s state of alertness and consequently have received little use in clinical situations.

**Auditory Brain Mapping.** One technique that is receiving considerable attention as a new and potentially powerful diagnostic tool is the use of auditory brain mapping. Methods for this procedure are highly similar to those used to obtain the traditional evoked responses already described. The primary difference is that brain mapping simultaneously records the electrical activity from an array of scalp electrodes. Although this mass of data could be viewed as many evoked potentials, the human observer cannot readily interpret such a massive amount of data. Therefore, brain mapping was developed using computer-processing techniques to provide a visual display of the potential fields among all of the electrodes simultaneously. This method reduces the data into a multicolored or shaded plot in which intense activity is usually given the most brilliant color or the darkest shading. An example of the typical electrode placements and the derivation of a simple brain map are shown in Figure 36.

**Magnetoencephalography.** Magnetoencephalography (MEG) involves the completely noninvasive recording of weak cerebral magnetic fields, which represent about 1 part in 10⁹ of the earth’s geomagnetic field, outside the head. The neuromagnetic technique was made possible by the invention of superconducting quantum interference device (SQUID) magnetometers. Using a whole-head neuromagnetometer, magnetic brain signals are averaged by time locking them to the onset of acoustic stimulation. It is assumed that the probable sources of cerebral magnetic fields are the electric currents in the synapses of synchronously activated cortical pyramidal neurons, and the sinks or volume currents, to complete the electrical circuit, are generated in the surrounding tissue. The development of multichannel systems increased the speed and convenience of neuromagnetic recording and made it feasible to apply MEG for clinical purposes.

Based on the accurate spatiotemporal resolution of whole-head MEG, Hari and Maula have been instrumental in applying MEG to investigate the activity of the auditory projection areas, particularly with respect to language-related sites. A schematic illustration of a typical experimental setup for auditory measurements is illustrated in Figure 37 and shows the relationship of the SQUID to the patient’s head. The inset above indicates the isocontours across the scalp for the
component of the magnetic field, which is generated by the active region of the auditory cortex. An example of the averaged magnetic responses from measurement sites anterior (above) and posterior (below) to the sylvian fissure of the right hemisphere, that is, along the superior surface of the temporal lobe, is shown for 1 subject for a spoken word (solid line) and noise bursts (dashed lines) on the left side of Figure 38. The right side of Figure 38 illustrates the effects of increasing the duration of the onset of the word in another subject. It is clear that sound evokes a complex magnetic waveform, which lasts several hundred milliseconds after stimulus onset. Interesting and clinically useful data have been obtained about the perception of speech of deaf patients with cochlear prostheses by examining the activity of their auditory cortices with MEG. Information of this real-time sort implies that neuromagnetic recording may be used to assess functional disorders in more detail than what is possible by other clinical evidence; thus, it is likely to become an important diagnostic tool of the future.

Neuroimaging. The beginning of in vivo imaging in awake and behaving subjects has revolutionized the ability to relate structure to function, particularly in the human brain. For example, 3-dimensional magnetic resonance imaging (MRI) provides detailed static images of the in vivo brain, with spatial resolution on the order of cubic millimeters. Other functionally related techniques in neuroimaging such as positron emission tomography and functional MRI provide excellent spatial and temporal resolutions for recording changes in regional blood flow and cellular metabolism during auditory stimulation. These techniques have been used to study a number of central auditory processes, including speech perception, revealing tinnitus-related abnormalities in brain function. Although these individual functional imaging approaches still have some limitations, the results are converging to improve our understanding of the neural processes underlying both normal and pathologic auditory function. Central auditory processing and functional neuroimaging are discussed in Chapter 8, “Central Auditory Processing and Functional Neuroimaging.”

Evoked Otoacoustic Emissions. One of the principal benefits of OAEs with respect to clinical testing is that they provide an objective and noninvasive measure of cochlear activity, which is completely independent of retrocochlear activity. In particular, OAEs measure the functional responses of OHCs that are uniquely sensitive to agents that damage hearing. Kemp, the pioneer investigator into the basic features of OAEs, has also been instrumental in establishing 1 class of evoked emissions, the click-based TEOAE (see Figure 22C), as a potentially useful diagnostic indicator of various ear diseases including Meniere disease and acoustic neurinoma. In addition, Kemp and Ryan have also established the use of the click-evoked OAE as a method of screening for hearing dysfunction in newborns.

Because of the frequency specificity of the eliciting pure tones, DPOAEs (see Figure 23)
also have a beneficial clinical applicability. This stimulus-related frequency specificity permits DPOAEs to be measured after averaging the responses to only a few stimuli. Thus, under computer control, the fine resolution of DPOAEs in both the stimulus frequency and level domains permits the precise determination of the boundary between normal and abnormal OHC function. Data from our laboratory illustrate this feature of DPOAEs in the plots of Figure 39A, which show the development of ototoxicity during a course of antineoplasm therapy with cisplatin. Comparing the OAE findings with behavioral hearing (top), note the abrupt change in hearing and emission activity between 2 and 3 kHz (open circles), which accurately followed the 40 dB loss in hearing sensitivity produced by the ototoxic agent.

For example, the records shown in Figure 39B represent a typical pattern of audiometric loss in early Meniere disease, which is accompanied by thresholds that are >40 dB HL and, not unexpectedly, no TEOAEs (bottom left) and abnormally low-level DPOAEs (solid circles). Together, these results imply that the OHC system is involved in this patient’s disease. However, other patients with Meniere disease, who show a similar hearing loss, can demonstrate rather robust DPOAEs, even for test frequencies for which behavioral thresholds are >50 dB HL. Such differential findings for patients with Meniere disease suggest that OAEs can distinguish between disease states that involve either OHCs (see Figure 39B) or other cochlear processes that are probably neural in origin, for example, degeneration of the unmyelinated dendritic endings of the cochlear nerve. A comparable example of this feature of OAE testing to contribute toward differentiating between cochlear versus noncochlear involvement in hearing disease is illustrated in Figure 40 for 2 patients diagnosed with vestibular schwannomas. The patient in Figure 40A displays the expected outcome for OAE testing in the presence of a retrocochlear disease. That is, in the presence of a moderate hearing loss on the tumor side (solid circles), both TEOAEs and DPOAEs are measurable. However, it is clear for the patient in Figure 40B, diagnosed with a right-sided (open circles) vestibular schwannoma, that the tumor has modified cochlear function in a manner that mimics the frequency configuration of the hearing loss. Thus, in certain retrocochlear disorders such as tumors of the cerebellopontine angle, cochlear function can be adversely affected, probably owing to compromise of the vascular supply to the inner ear. One benefit of OAE testing illustrated in Figure 39B is its sensitivity to changes in hearing status, which are mediated by the OHC system. In this instance, at the time the patient returned for follow-up testing (open circles), her hearing had improved, particularly over the low-frequency test range. The 20 to 30 dB improvement in low-frequency hearing was

Figure 39 Conventional audiograms (top), distortion-product otoacoustic emission (DPOAE) frequency/level or DP-gram functions (middle) relating emission magnitude to stimulus frequency, in 0.1 octave steps from 0.8 to 8 kHz, for primary tone levels of 75 dB SPL, and click-evoked transient evoked otoacoustic emissions (OAEs) (bottom) elicited by the “default” mode of the ILO88 Otodynamic Analyser. (A) Behavioral hearing and evoked OAE findings for the right ear of an 8-year-old girl comparing pre- (solid circles) versus posttreatment (open circles) responses following a course of antineoplasm therapy with cisplatin. Immittance and speech testing results were normal for the baseline session and were not tested during the posttreatment examination. (B) Audiometric and OAE results for the left ear of a 49-year-old woman for 2 test sessions separated by about 2 weeks. The patient complained of a fluctuating hearing loss, tinnitus, aural fullness, and episodic dizziness of several months duration. Immittance findings were normal, whereas the speech discrimination score and speech reception threshold improved from 72 to 96% and 55 to 25 dB HL, respectively, at the last evaluation period (open circles). (Reproduced with permission from reference 211.)
mirrored by a similar increase in DPOAEs and by the ability to now measure TEOAEs.

In addition to the clinical applications noted above for OAEs, a number of studies have also demonstrated the utility of using emitted responses to understand the fundamental basis of common cochlear lesions, including the effects of noise-induced hearing loss,213 hereditary hearing impairment,214 congenital hearing disorders,212 ototoxicity,215 bacterial meningitis,216 and presbyacusis217 on both TEOAEs and DPOAEs. The interested reader is encouraged to refer to these comprehensive reviews concerning the strengths and limitations of the clinical application of OAEs.218,219

Exactly how OAEs in general arise and how they are propagated in the cochlea is still a matter of debate. Recent experimental and theoretical findings suggest that there may be 2 mechanisms of OAE generation.220–223 SOAEs, TEOAEs, and SFOAEs probably arise predominantly as reflection OAEs via coherent linear reflection from impedance discontinuities (ie, out of place OHCs, disarranged stereocilia) distributed along the cochlear partition. DPOAEs likely result mainly from distortion processes due to the nonlinear interaction between the \( f_1 \) and \( f_2 \) primary tones at their "overlap" region on the basilar membrane. Knight and Kemp221,222 established the terms "wave-fixed" and "placed-fixed" OAEs to describe the corresponding emission sources that are physically associated with either fixed structures (ie, reflection emissions) or the traveling-wave peak (ie, distortion emissions) within the cochlea, respectively. Moreover, it is probable that the electromotility of the OHCs has a closer association with the generation of SOAEs, TEOAEs, and SFOAEs than DPOAEs. Rather, DPOAEs appear to be generated principally in the nonlinear aspects of the OHC transduction process, probably involving the opening and closing of transduction channels at the tips of the OHC stereocilia. This analysis may explain why following the administration of furosemide in experimental preparations, DPOAEs evoked by high-level primaries typically persist.224 Thus, with ototoxicity, the fundamental processes underlying OHC nonlinearity in the form of somatic electromotility are probably only minimally damaged. However, the "cochlear amplifier" gain71 associated with basilar membrane vibration is severely reduced or absent due to a decrease in the driving voltage across the cell membrane, which was prevented from developing normally by insufficient stimulation of the nonlinearity located in the OHC stereocilia. For high-level primary tones, then, the low or absent gain is overcome and DPOAEs can again be observed. Such an explanation is supported by the findings of Liberman and colleagues,48 using mutant mice lacking the molecular motility motor protein, prestin. Specifically, with prestin deletion, OHC microvibrations were not necessary for the production of high-level DPOAEs.

However, although there is general agreement with respect to the existence of two OAE generators, a growing debate concerns the role of reverse propagation of OAEs within the cochlea. That is, it is commonly believed that the cochlea emits sounds through backward traveling waves. However, based mainly on the relationship between OAE latencies and the specificity of origin location,225–227 the possibility of compressive waves propagating through

Figure 40 Audiometric and otoacoustic emission findings for 2 patients with vestibular schwannomas confirmed by magnetic resonance imaging. (A) A 39-year-old man with a vestibular schwannoma on the left side who had normal tympanograms but absent reflexes bilaterally. Although speech testing was normal for the right ear (open circles), the speech discrimination score and speech reception threshold were 0% and 70 dB HL, respectively, for the involved left ear (solid circles). (B) A 47-year-old woman with a right-sided vestibular schwannoma. Whereas her tympanograms were normal, the only measurable acoustic reflex threshold was for ipsilateral stimuli at 1 kHz. Speech testing was normal for the left ear, whereas the right ear was associated with a speech discrimination score of 60% and a speech reception threshold of 35 dB HL. (Reproduced with permission from reference 211.)
cochlear fluids is being actively investigated. In any case, the lively discussions noted above are leading to focused experiments on these issues. Most certainly, by developing a more complete understanding of OAE generation and propagation processes, the resulting more exact interpretation of emissions will vastly improve the clinical utility of this intriguing measure of cochlear function.

VESTIBULAR SYSTEM

General Principles
The nonsensory part of the inner ear (termed the vestibular apparatus) consists of 2 functional subdivisions: (1) the semicircular ducts consisting of 2 vertical and 1 horizontal and (2) the otolithic organs consisting of the saccule and the utricle. The semicircular ducts respond to head rotation, that is, angular acceleration, whereas the otolithic organs are stimulated by the effects of gravity and linear acceleration of the head. The primary function of the utricle is to signal head position relative to gravity. Ablation of the saccule produces a less significant deficit than ablation of the utricle; hence, the function of the saccule is less well defined than that of the utricle. In fact, it has been proposed that the saccule is a low-frequency auditory receptor. However, a series of systematic studies using single-unit recordings have revealed that saccular nerve fibers respond only to linear acceleration. These findings suggest that the saccular system provides the high-level vertical acceleration signals required to elicit the motor response necessary to land optimally from a fall.

Conventionally, the vestibular system is regarded as one of 3 sensory systems that function to maintain body balance and equilibrium. The other 2 are the somatosensory (chiefly proprioceptive) and visual systems. Loss of proprioception, for example, as in tabes dorsalis, or vision causes more significant balance and equilibrium difficulty than does loss of vestibular function. With bilateral vestibular function loss, difficulties occur only when 1 of the other systems is disrupted, for example, when walking in the dark or on a soft surface, or when balance must be maintained under particularly difficult conditions, for example, walking on a narrow beam. Thus, in humans, under physiologic conditions, the vestibular system is probably the least important of the 3 balance and equilibrium sensory systems. The most significant functional deficits occur when the vestibular system suffers acute, asymmetric damage and generates “false” head position or head rotation signals.

Vestibular Apparatus
The top portion of Figure 2 illustrates the general anatomic plan of the vestibular apparatus. There are many similarities with cochlear anatomy. For example, both end-organs are located in a tunnel that is hollowed out of the petrous portion of the temporal bone (embryologically, both organs come from the same tunnel). The tunnel is divided into an outer perilymph-filled bony labyrinth and an inner endolymph-filled membranous labyrinth. In addition, as in the cochlea, the receptor cells of the vestibular apparatus are ciliated, and these cilia extend into a gelatinous matrix.

The 3 semicircular canals are oriented orthogonally or at right angles to each other. They can be thought of as lying in a bottom corner of a box. The horizontal (or lateral or external) canal is in the plane of the bottom of the box, and the anterior-vertical (or superior) and posterior-vertical (or posterior) canals are in the planes of the 2 sides of the box. In humans, the entire canal complex is tilted upward about 30°. In the physiologic position, the head is bent forward about 30° from the earth’s horizontal plane; therefore, the 30° upward tilt puts the horizontal canal in the horizontal position under everyday conditions. The superior and posterior canals are oriented in vertical planes that form an angle of approximately 45° with the sagittal head plane. Each semicircular canal lies parallel to one of the canals in the opposite vestibular labyrinth. Thus, the right horizontal canal is coplanar with the left horizontal canal, whereas the right superior and posterior canals are coplanar with the left posterior and superior canals, respectively.

The sensory epithelia or cristae of the semicircular ducts are located in enlarged areas, referred to as ampullae, at one end of each duct. The nonanampullated ends of the vertically oriented superior and posterior ducts connect to form the common crus. The bony vestibular aqueduct originates in the vestibule, that is, the entrance to the inner ear, and connects to the cerebrospinal fluid space medially. Within the vestibular aqueduct is the fibrous endolymphatic duct that establishes a route between the membranous vestibule and the cranial meninges, where the duct ends in the endolymphatic sac. The utriculosaccular duct, connecting the utricle and saccule, permits communication between the saccule and endolymphatic duct. Although there is no agreement concerning the site of endolymph absorption, it is likely that the K⁺-rich fluid is absorbed in the endolymphatic sac.

Figure 41A shows the anatomy of the crista. It is a saddle-shaped mound of tissue, attached to the ampullar wall at right angles to the long axis of the ampulla. The hair cells are on the surface of the crista. The ampullar nerve fibers travel through the center of the crista to synapse at the hair cell bases. The hair cell cilia protrude from the surface of the crista into the fan-shaped cupula, a gelatinous structure consisting of mucopolysaccharides within a keratin framework. The cupula partitions the semicircular duct by covering the top of the crista and extending to the opposite ampullar wall.

The saccus and utriculus are 2 sacs in the membranous labyrinth, located in the vestibule. Their receptor organs, called maculae, can be seen in Figure 41B, as patches of epithelium on the membranous labyrinth walls. The utricular macula lies on the floor of the utricle approximately in the plane of the horizontal semicircular
240 Type I hair cells are flask-shaped and have "chalice"-type afferent nerve endings that surround all but the hair-bearing end. Efferent nerve terminals synapse with the afferent calyx near its base. Type II hair cells have a cylindrical or test tube shape and have several small bouton-type nerve endings that represent both afferent and efferent innervation only at the cell's base. Type I hair cells are concentrated in the central apex of the crista and the central part of the macula; type II hair cells are more numerous toward the peripheral region of the end-organ.241 Although significant amounts of filamentous actin occur at the apical surfaces of both the sensory cells and the supporting cells in the hair cell-containing regions of the vestibular organs,242 motile properties such as the fast rates of lengthening and shortening, which have been observed for cochlear OHCs, have not been shown for vestibular hair cells. However, there is some evidence that slow motility is exhibited by type II hair cells.243 The electron microscope has also demonstrated 2 types of cilia: stereocilia and kinocilia244–246 (Figure 43B). Each hair cell has only 1 motile kinocilium and a bundle of 60 to 100 stereocilia.

Stereocilia are relatively rigid, club-like rods, varying systematically in length in a "pipe organ" fashion that extends at the apical end of the hair cell, from a dense cuticular plate that consists of actin and myosin.59 They are not homogeneous, as was originally thought. Rather, they contain longitudinally oriented microfilaments composed of actin.41 The membrane enveloping the stereocilia is a thickened continuation of the hair cell cuticular membrane.247 The stereocilia are constricted at their base and, when deflected, move like stiff rods pivoting around the basal constricted area.49 Interconnections between stereocilia via fibrils or tip links have been demonstrated.248

Kinocilia end in basal bodies, located just beneath the hair cell membrane. Within each kinocilium, there are 9 peripherally arranged double-tubular filaments, positioned regularly around the 2 centrally located tubular filaments. This 9-plus-2 tubule pattern is found in many motile cilia, for example, respiration epithelia, oviduct epithelium, unicellular flagellates.249 Stereocilia are coupled to the kinocilium and to each other so that during deflection, all cilia are stimulated as 1 bundle.66

On each hair cell, the single kinocilium is located to 1 side of the bundle of stereocilia. In both maculae and cristae, hair cells in the same area tend to have kinocilia on the same side of the stereocilia bundle. Thus, the vestibular sensory epithelium has a morphologic directional polarization that is determined by the direction of the cilia alignment. Figure 43C illustrates the directional polarization of the utricular macula. The kinocilia all tend to point toward a line of demarcation called the striola, or linea alba, running across the approximate center of the macula. In the saccule, the kinocilia point away from the striola. In the horizontal duct crista, kinocilia point toward the utricle, whereas in the pair of vertical cristae, they point away from the utricle. Thus, vertical and horizontal cristae are morphologically polarized in opposite directions.241

Transduction and Coding

Mechanical Events. As in the cochlea, the final mechanical event in vestibular transduction is the bending of the hair cell cilia. Figure 44 illustrates transduction by the macula. When the macular surface is tilted, the heavy otoliths tend to slide downward, carrying the gelatinous membrane and attached cilia with them.

The 6 semicircular ducts consist of a circular, narrow-bore tube in the temporal bone filled with fluid called endolymph. The tube originates from and returns to a reservoir (the utricle), but each duct may be thought of, for practical purposes, as a fluid ring. When the head undergoes an angular acceleration, the fluid is left behind because of its inertia. This causes the endolymph to flow relative to the duct and to push on the
flow. Consequently, the above equation can be integrated to give a velocity output.\(^{259}\)

Similarly, with the macular afferents, accurate coding by discharge rate of the head's position relative to gravitational vertical can be demonstrated in all species. The more complex orientation of the macular hair cells makes directional correlates more difficult to establish than for semicircular duct afferents. However, Fernandez and Goldberg\(^ {258}\) studied large populations of saccular and utricular neurons and were able to demonstrate neural "sensitivity vectors" among the neuronal populations that corresponded to the relative orientations of the saccular and utricular maculae.

Central Vestibular Pathway

Anatomy. Primary Afferent Connections. The vestibular system functions primarily as an afferent reflex input to the motor system. In general, vestibular pathway-mediated reflexes involve 3 muscular systems, including the extrinsic oculomotor, cervical, and antigravity pathways. As might be expected, the semicircular ducts, or the rotation sensors, connect primarily with the extrinsic oculomotor and cervical muscles, that is, the muscles that compensate for head rotation, whereas the otolithic organs, or position sensors, connect primarily with the antigravity muscles.

When the head rotates, causing cupular displacement and a stimulatory deflection of hair cell cilia, the semicircular duct afferents change their discharge rate above, in response to hair cell depolarization, and below, in response to hair cell hyperpolarization, the resting rate depending on the direction of rotation.\(^ {258}\) When the head rotates sinusoidally at velocities encountered during normal function, the ampullar nerve discharge rate varies sinusoidally, as shown in Figure 46. The phase relationship between head position and head velocity, which displays a phase lag of about 90°, is such that the maximum discharge rate occurs at the head's 0 crossing, that is, at the head's maximum velocity. Thus, the ampullar afferent discharge rate codes head angular velocity. The adequate stimulus is actually angular acceleration, but the hydrodynamics of the semicircular duct system are such that the head's acceleration is integrated to give a velocity output.\(^ {259}\)

Thus, the discharge rate, which is proportional to cupular deflection, carries a signal into the central nervous system proportional to head velocity, not acceleration. In other words, a constant head acceleration applies a constant force on the endolymph, causing it to flow at a constant velocity.

**Figure 45** Motion transduction by vestibular hair cells. (A) At rest there is a resting rate of action potential discharge in the primary vestibular afferents (center). Shearing forces on the hair cells cause either depolarization (right) or hyperpolarization (left), depending on whether the stereocilia are deflected toward or away from the kinocilium (indicated by longest cillum, with beaded end), respectively. This modulates the discharge rate in the vestibular nerve as shown below (action potential). (B) Vestibular nerve discharge rate \(R_v\) is 90 spikes/s at rest \(R_v\) in the squirrel monkey and changes approximately linearly with cupula deflection \(c\). When the latter is expressed in equivalent head velocity \(H\), the slope of the line \(S_v\) is about 0.4 (spikes/s)/(deg/s) for the average vestibular afferent fiber. (Part A reproduced with permission from reference 255; Part B reproduced with permission from reference 256.)

Consequently, cupula position, the integral of flow, must be proportional to head velocity, that is, the integral of head acceleration.

In the squirrel monkey, the typical resting discharge rate is 90 spikes/s.\(^ {254}\) The discharge rate increases for deflection of the cupula in 1 direction and decreases in the other. On the abscissa of Figure 45B, \(B (dh/dt)\) may be substituted for \(c\), in which case the slope of the linear line \(S_v\), for the average fiber is 0.4 (spikes/s)/(deg/s).\(^ {253,256}\) Thus, the signal sent from the duct to the brainstem on the average fiber for most normal head movements is 90 + 0.4 \(H (dh/dt)\).

Response of Primary Vestibular Neurons. Microelectrode studies in higher mammals have demonstrated the following characteristics of primary vestibular neuron activity. For example, most of the primary vestibular neurons called regular units exhibit a high (~100/s) and remarkably uniform spontaneous discharge rates.\(^ {257}\) When listening to such spikes on a loudspeaker, the neurons make a characteristic motorboat sound. There is also a small population of irregular neurons with a lower rate and less regular spontaneous discharge. The high-rate regular units have small diameter, slowly conducting axons that predominantly innervate the periphery of the end-organ, that is, the type II hair cell region of the crista, whereas the low-rate irregular neurons come from the center of the crista, where most type I hair cells are located.\(^ {229}\) The high, regular spontaneous firing rate of the primary neurons permits the bidirectional sensitivity of the vestibular hair cell receptors.

When the head rotates, causing cupular displacement and a stimulatory deflection of hair cell cilia, the semicircular duct afferents change their discharge rate above, in response to hair cell depolarization, and below, in response to hair cell hyperpolarization, the resting rate depending on the direction of rotation.\(^ {258}\) When the head rotates sinusoidally at velocities encountered during normal function, the ampullar nerve discharge rate varies sinusoidally, as shown in Figure 46. The phase relationship between head position and head velocity, which displays a phase lag of about 90°, is such that the maximum discharge rate occurs at the head's 0 crossing, that is, at the head's maximum velocity. Thus, the ampullar afferent discharge rate codes head angular velocity. The adequate stimulus is actually angular acceleration, but the hydrodynamics of the semicircular duct system are such that the head's acceleration is integrated to give a velocity output.\(^ {259}\)

Similarly, with the macular afferents, accurate coding by discharge rate of the head's position relative to gravitational vertical can be demonstrated in all species. The more complex orientation of the macular hair cells makes directional correlates more difficult to establish than for semicircular duct afferents. However, Fernandez and Goldberg\(^ {258}\) studied large populations of saccular and utricular neurons and were able to demonstrate neural "sensitivity vectors" among the neuronal populations that corresponded to the relative orientations of the saccular and utricular maculae.

Central Vestibular Pathway

Anatomy. Primary Afferent Connections. The vestibular system functions primarily as an afferent reflex input to the motor system. In general, vestibular pathway-mediated reflexes involve 3 muscular systems, including the extrinsic oculomotor, cervical, and antigravity pathways.

As might be expected, the semicircular ducts, or the rotation sensors, connect primarily with the extrinsic oculomotor and cervical muscles, that is, the muscles that compensate for head rotation, whereas the otolithic organs, or position sensors, connect primarily with the antigravity muscles. Figure 47 outlines these major central vestibular connections.\(^ {260}\)

Scarpa, or the vestibular, ganglia, in the internal auditory canal, within the vestibular portion of the eighth cranial nerve.
of the eighth nerve, contain the bipolar ganglion cell bodies of the first-order vestibular neurons. The vestibular nerve can be divided into superior and inferior divisions that innervate the sensory epithelia of the ducts and otolithic end-organs. The superior portion innervates the cristae of the superior and horizontal semicircular ducts, the utricular macula, and a small region of the saccular macula. The inferior division of the vestibular nerve innervates the crista of the posterior semicircular duct and the remaining part of the saccular macula. Centrally, all first-order vestibular neurons synapse in the vestibular nuclear complex, which occupies a considerable area beneath the floor of the fourth ventricle and lies across the pontomedullary boundary. On entering the brainstem, the vestibular axons bifurcate into the ascending rostral and descending caudal divisions.

The vestibular nuclear complex, as shown in Figure 47, consists of 4 distinct subnuclei: (1) the superior (Bechterew or angular), (2) lateral (Deiters), (3) medial (Schwalbe or principal or triangular), and (4) inferior (spinal or descending) nuclei. There is recent anatomic evidence that the nucleus prepositus hypoglossi, which is classically thought to relate to taste sensation, has strong efferent and afferent vestibulo-oculomotor connections, through the medial longitudinal fasciculus (MLF), and cerebellar projections. In addition, microelectrode recordings from awake monkeys have demonstrated that prepositus neurons fire in relation to both vestibularly and visually induced eye movements. Studies on the activity of ocular motoneurons in alert monkeys have shown that the neural commands for all conjugate eye movements (vestibular, optokinetic, saccadic, and pursuit) have both velocity and position commands.

The vestibular input to prepositus is disynaptic and reciprocally organized, that is, ipsilateral input is excitatory, whereas contralateral input is inhibitory. In addition, if cells in the monkey’s nucleus prepositus hypoglossi are lesioned with kainic acid, the monkey’s eye movements only reflect the velocity command. A great amount of neurophysiologic evidence indicates that the position command is obtained from the velocity command by the mathematical process of integration. That is, a neural network located in the nucleus prepositus hypoglossi integrates, in the mathematical sense, velocity-coded signals; thus, the prepositus is included in the diagram of the vestibular nuclear complex in Figure 47.

As indicated in Figure 47, each subnucleus has a unique set of connections with the periphery and with specific regions of the central nervous system including the spinal cord, cerebellum, and brainstem oculomotor nuclei (III, IV, VI). Most of the semicircular duct afferents terminate in the superior nucleus and rostral portion of the medial vestibular nucleus. Both of these nuclei, in turn, project to the oculomotor nuclei of the extraocular muscles via the ascending MLF. The superior nucleus projects only to the ipsilateral MLF, whereas the medial nucleus projects bilaterally. The medial nucleus, via the medial vestibulospinal tracts in the descending MLF, also sends bilateral descending projections to spinal anterior horn cells that control the cervical musculature. Thus, the input and output of the superior and medial vestibular nuclei provide a possible anatomic basis for the nystagmus and head-turning-reflex responses to semicircular duct stimulation (see below).

The otolith organs, particularly the utricles, project primarily to the inferior nucleus and caudal part of the lateral nucleus. Outputs from these nuclei, in turn, project downward to the ventral horn region throughout the length of the spinal

Figure 46 Peripheral vestibular neuron responses to sinusoidal rotation stimulation in the alert monkey. (A) A regular (high-rate) neuron. (B) An irregular (IR) neuron. Sinusoidal curve (H) plots head position. The records immediately below the sinusoidal traces show intervals between neuronal spikes. The height of vertical bars on these records is proportional to the interval between spikes. Because 1 of these bars occurs for every spike, their frequency reflects the frequency of the recorded spikes. (C) Response of unit in B averaged over 10 cycles; 0 is the phase lag (C) Response of unit in B averaged from reference 261.)

Figure 47 Diagram of major connections between primary vestibular neurons in the vestibular ganglia and the vestibular nuclei. Also shown are major outflows from the vestibular nuclei. Vestibulocerebellar connections are excluded. MLF = medial longitudinal fasciculus. (The primary afferent connections are modified from reference 261.)
cord via the lateral vestibulospinal tract. Thus, the afferent and efferent connections of the lateral vestibular nucleus provide a possible anatomic basis for antagonistic muscle responses in the limbs (extensors of the legs and flexors of the arms) to postural change. The otolith organs have relatively sparse connections to the extracerebellar muscles. These may be the connections that produce the ocular counter-rolling response to head tilt.266

**Efferent Innervation of the Vestibular System.** The vestibular organs in all vertebrates receive efferent innervation originating in brainstem nuclei. Although there are relatively few parent efferent neurons, their axons branch to innervate more than 1 end-organ and also ramify extensively in the neuropil of the individual neurons. By means of this divergent innervation pattern, efferent fibers provide a major source of synaptic input to type II hair cells, afferent calyces, and other unmyelinated afferent processes. In nonvestibular organs, efferent activation typically reduces afferent activity by hyperpolarizing the hair cell receptor. In contrast, efferent responses in vestibular organs are more heterogeneous. For example, in fish and mammals, there is an excitation of afferents, whereas in frogs and turtles, both excitation and inhibition are observed. In addition, there are variations in the efferent responses of vestibular afferents innervating different parts of the neuroepithelium, which differ in their responses to natural stimulation. Moreover, efferent neurons receive convergent inputs from several vestibular and nonvestibular receptors and also respond in association with active head movements. On the basis of the discharge properties of efferent neurons, one of their proposed functions is that they switch the vestibular organs from a postural to a volitional mode. For a more detailed review of the vestibular efferent system, see a recent summary by Goldberg.267

**Vestibulocerebellar Connections.** Primary Vestibular Fibers. Primary vestibular neurons project not only to the vestibular nuclei but also to the cerebellum. Most of these fibers are distributed to the ipsilateral flocculus and nodulus and the medially located uvula.268 Because of this innervation by primary vestibular fibers, these 3 cerebellar areas have been termed collectively the vestibulocerebellum. As discussed below, the primary vestibular input to the vestibulocerebellum appears to be important in controlling the vestibulo-oculomotor reflex (VOR). Moreover, the primary vestibular input to the vestibulocerebellum and the climbing fiber input from the inferior olive appear to be important in controlling the VOR.

Secondary Vestibular Fibers. The vestibulocerebellum receives secondary fibers primarily from the medial and inferior vestibular nuclei but also from the other divisions. In addition, the fastigial nucleus and the cortex of the vermis receive a strong, somatotopically organized projection from the lateral vestibular nucleus. Since this nucleus is the primary origin of the vestibulospinal tract, connections to it from the cerebellum are probably important in regulating antagonistic reflexes that help to maintain an upright body posture.269

**Projections to Cerebral Cortex.** Whether the vestibular system has a direct corticothalamic projection has long been a controversial question. The functional corollary to this question is whether we can consciously appreciate a sensation owing to vestibular stimulation. This question also has generated debate because most of the subjective sensations produced by vestibular stimulation, for example, vertigo, are secondary to motor reflexes or to autonomic responses, and it is difficult or impossible to separate a primary vestibular sensation from the secondary sensations.270

Experiments employing electrical stimulation of the vestibular nerve have demonstrated relatively short-latency localized cortical responses in both the cat and the monkey.271 The cat’s vestibular area is adjacent to both the auditory and the somatosensory fields, but in the monkey, and possibly in the human, it is located near the face area of the somatosensory field on the postcentral gyrus. Deecke and colleagues demonstrated that the ventroposteroinferior (VPI) nucleus is the thalamic relay for the vestibulocortical projection. The VPI nucleus lies adjacent to the thalamosomatosensory representation of the face. Prior to this study, the function of the VPI nucleus was unknown.

**Vestibular Influence on Postural Control.** The main unit for the control of tone in the trunk and extremity muscles is the myotatic reflex. These reflexes of the antagonistic muscles are under the combined excitatory and inhibitory influence of multiple supraspinal centers. Two of these supraspinal centers are facilitatory, that is, the lateral vestibular nucleus and rostral reticular formation, and 4 are inhibitory centers including the pericruciate cortex, basal ganglia, cerebellum, and caudal reticular formation. The balance of input from these different centers determines the degree of tone in the antagonistic muscles.

**Physiology of Vestibular Nuclei.** General Characteristics of Neuronal Responses. Microelectrode studies of responses of vestibular nucleus neurons to electrical stimulation of individual ampullary nerves and to “natural” stimuli, such as those involving rotation and tilt, have established the following general characteristics: (1) Neurons can be classified as tilt responders (otolith units) or rotation responders (duct units). (2) The locations of these 2 types correspond with that expected from the anatomic projections of otolithic and semicircular duct afferents to the vestibular nuclear complex. Thus, the tilt responders are found primarily in the areas innervated by the saccule and utriculus, that is, the inferior nucleus and caudal part of lateral nucleus, whereas the rotation responders are found mainly in the areas innervated by the semicircular ducts, that is, the superior nucleus and the rostral part of medial nucleus. (3) Among the rotation responders, pathways from individual ducts seem to be preserved. Thus, for example, a neuron that responds to vertical rotation or to electrical stimulation of a vertical ampullary nerve does not respond to horizontal rotation or to stimulation of a horizontal ampullary nerve and vice versa.

**Classification of Neuronal Response Types.** Both duct and otolithic vestibular nucleus units preserve the basic properties of the primary afferent input, but some respond in the same direction, for example, ipsilateral horizontal rotation increases firing rate; others respond in the opposite direction. A few of the vestibular nucleus neurons respond with either inhibition or facilitation in both directions. Table 2 outlines the characteristics of the duct units. The type I units, exhibiting a primary response pattern, are innervated by the ipsilateral labyrinth, whereas the type II units,

showing response patterns that are opposite to those of the primary units, are innervated by the contralateral labyrinth.

The analogous classification for otolith responders subdivides all types into (1) “a” units, which increase firing on ipsilateral tilt; (2) “b” units, which decrease firing on ipsilateral tilt; (3) “y” units, which increase firing in response to tilt in both directions; and (4) “o” units, which decrease firing by tilt in both directions. Analogous to the duct units, the relative populations of these units are a > b > y > o.272

Commissural Inhibition and Vestibular Compensation. Many of the contralateral (type II) semicircular duct responses listed in Table 2 are abolished when a midline dorsal brainstem incision is made that interrupts the vestibular crossing fibers. Thus, the “opposite-primary” type II responses are likely elicited by inhibitory input from type I neurons of the opposite labyrinth. Figure 48 summarizes the simplest of the probable neuronal interconnections responsible for this contralateral inhibition.255

The commissural inhibitory system is also important in the mechanism of compensation following labyrinthectomy. Thus, immediately after labyrinthectomy, the type I units on the labyrinthectomized side show no spontaneous activity and do not respond to rotation. However, within a few days, the deafferented type I units regain their spontaneous activity and, via inhibition from the contralateral pathway, also regain their normal response to rotation. The mechanisms by which this recovery process occur are unknown, but a contributing factor is the lowered threshold of the deafferented type I neuron for contralateral input.273 In animal studies, the course of compensation is affected by exercise,274 visual experience,275 and drugs.276 Thus, as a rule, stimulants accelerate and sedatives slow compensation.275 Fetter and Zee showed further that visual experience was not necessary for the acquisition or for the maintenance of this recovery process.275

Vestibulo-Oculomotor Reflex. Although there are neural connections between the maculae and the extraocular muscles, they are less important in humans, both functionally and clinically, than are the semicircular duct connections. This discussion of the VOR will therefore focus on the reflex connection between the semicircular ducts and the extraocular muscles.

An important function of the semicircular ducts is to provide afferent input to the VOR that generates eye movements that compensate for head movements by maintaining a stabilized visual image on the retina during rotation. Such eye adjustments are called compensatory eye

If a second labyrinthectomy is performed after compensation for the first labyrinthectomy, the animal again develops signs of acute unilateral vestibular loss with nystagmus directed toward the previously operated ear, that is, a condition referred to as Bechterew compensatory nystagmus.277 That is, the overall effect is as if the first labyrinthectomy had not occurred. Compensation after the second labyrinthectomy is slightly faster than the first but still requires several days. For a recent review on the molecular mechanisms underlying vestibular compensation, see the summary by Darlington and Smith.278
movements. Figure 49 diagrams the neural connections that stabilize gaze during head movement.

Anatomic Connections. The VOR is observed by a three-neuron pathway. That is, motions detected by the end-organ are transduced into neural impulses that are sent via the vestibular nerve to the vestibular nucleus and rostrally through the ascending MLF to the oculomotor nucleus of the extraocular muscles. Secondary vestibulo-ocular connections via the reticular formation have been described, but functionally these are less important than the "direct" three-neuron MLF vestibulo-ocular pathway.

Inhibitory crossed connections at the levels of both vestibular and oculomotor nuclei, which were described above, probably also participate in the VOR. The crossed inhibitory oculomotor connections subserve antagonistic extraocular muscles.279 These inhibitory interconnections are important in the formation of conjugate eye movements.

Functional Connections. A number of investigations have uncovered many details of the facilitatory and inhibitory interactions between neurons of the vestibular nuclear complex and motoneurons of the extraocular muscles. For a review, the reader is referred to Wilson and Melvill-Jones.272 However, in older experiments, the effect of mass stimulation of individual ampullary nerves on eye movements provided the clinician with the most useful integrative concepts of the functional organization of the VOR. The results of all of these ampullary nerve-stimulation experiments agree on the principle, illustrated by Figure 49, that stimulation of an ampullary nerve generates conjugate eye movements away from the side stimulated and in the plane of the duct stimulated.

This principle allows a straightforward description of the events leading from endolymph movement in the horizontal duct to the compensatory eye movement depicted in Figure 50: (1) Head movement to the left generates endolymph movement to the right in the left duct. This is toward the ampulla and therefore increases the ampullary nerve discharge rate. (2) The increased ampullary nerve output, according to the aforementioned rule, causes conjugate eye deviation away from the side stimulated, that is, to the right, which is opposite to the direction of head movement. (3) Similarly, head movement to the left generates ampullofugal movement in the right duct, which decreases neural output. (4) Decreased neural output inhibits the extraocular muscles, thus causing the eyes to deviate conjugately to the left, which provides a neural output that is synergistic to the conjugate right-eye deviation, generated by the output of the opposite duct. Figure 49 (upper right) depicts this sequence of events.

Functionally, the VOR provides more than a simple one-to-one transfer of information from the semicircular duct to the extraocular muscles. It should be recalled that the response of the ampullary nerves reflects head velocity, yet the ocular rotation, at the vestibular reflex output, reflects head position. Therefore, at some point in the transfer from vestibular input to ocular output, some form of neural integration must occur that converts the velocity signal at the input into the displacement signal at the output. The location of this integrator, as noted above, is the nucleus prepositus hypoglossi.264

Control of the Gain of the Vestibulo-Oculomotor Reflex. In studies of the VOR, the concept of gain is important. Gain of the VOR is simply the amplitude of eye rotation divided by amplitude of the head rotation. Generally, amplitudes of eye and head rotation are expressed as angles.

Because eye rotation is supposed to be equal and opposite to head rotation, that is, to compensate fully and leave gaze steady, it might seem at first that the ideal VOR gain would be −1. However, there are many real-life situations for which the ideal VOR gain is not −1. Functionally, such situations can be divided into long-term (ie, slow) and short-term (ie, fast) adjustments. The short-term or fast VOR gain adjustments occur in the course of visual tracking tasks, in which both the head and the eyes follow the fixation target at varying relative velocities. For example, in a tracking task in which the head and eyes must move in the same direction, the VOR must be completely suppressed. In the clinical test situation, this visual suppression of the VOR is observed as suppression of caloric or rotational nystagmus during visual fixation.

An example of functionally beneficial long-term VOR gain control is the situation in which a prescription for new glasses has been received. The change in magnification of the visual image changes the speed with which the visual image moves across the retina (for example, increasing magnification would increase the speed of movement of retinal images). Therefore, to maintain a stable retinal image after new glasses have been obtained, the VOR gain must be adjusted for the new magnification levels. Such adjustments have been demonstrated experimentally in humans by testing the VOR rotational response in the dark after long-term periods of wearing highly corrective lenses.280

An extreme example of the plasticity of the VOR gain is provided by adjusting to reversing prisms. Reversing prism glasses cause a normal visual image to be reversed right to left; hence, movement of the visual image, when the head or eyes are rotated horizontally, is exactly opposite of normal. Even in this extreme example, humans and other animals have been shown to function normally after a few days of wearing the prisms.281,282 Even in situations requiring visually controlled movements during head movements, for example, mountain climbing,283 Testing the VOR in humans after a few days of wearing reversing prisms has demonstrated actual reversal, that is, conversion of a negative to a positive gain, of the VOR.284

There is strong evidence that the vestibulocerebellum plays an important role in both short- and long-term control of the VOR gain. The strong primary vestibular afferent projection to the vestibulocerebellum and equally strong projection from the vestibulocerebellum to the oculomotor portion of the vestibular nuclear complex have already been described. There is also a strong input to the vestibulocerebellum from the retina by way of the inferior olivary climbing fibers. Most of these visual units detected in the vestibulocerebellum are "movement detectors."285 They are thus ideally suited to provide information on "retinal slip" of the visual image, which is needed to modify VOR gain control. The visual and vestibular inputs to the cerebellum converge on the Purkinje cells of the flocculus cortex. Furthermore, experiments on alert monkeys, in which rotation of the animal’s visual environment and its head were controlled independently, showed that visual and vestibular inputs modulate Purkinje cell outputs in ways exactly appropriate for the functionally useful control of the VOR gain.

Ablation experiments further support the role of the flocculonodular lobes in control of VOR gain. It has been demonstrated, for example, that removal of the vestibulocerebellum eliminates suppression of caloric nystagmus by visual fixation.286 An analogous failure of fixation suppression (FFS) of nystagmus is also observed in humans with cerebellar lesions.287 However, clinical data suggest that FFS can be produced by lesions in the brainstem and, less frequently, cerebral hemispheres, as well as the cerebellum.290

Robinson reported the results of a notable ablation experiment that demonstrates the role of the flocculus in causing long-term or plastic changes in VOR gain.287,288 Specifically, cats wore reversing prisms for several days, and VOR gain was measured each day by rotating the cats in the dark. After several days, as expected, VOR gain dropped from 0.9 to 0.1. When the vestibulocerebellum was removed, the VOR gain promptly increased to about 1.2. Furthermore, it proved impossible
to reinstate the VOR gain decrease by continued wearing of prisms after removal of the vestibulocerebellum. In addition, Miles and colleagues uncovered results in the monkey that implicated synaptic changes at other sites, especially in the brainstem. More recently, Lisberger provided further evidence that the modifiable synapses were located between vestibular primary afferents and those second-order and/or possibly third-order vestibular neurons that also received synapses from Purkinje cells. Finally, Luebke and Robinson reversibly silenced the flocculus of alert cats adapted to either high- or low-gain VOR. This reversible floccular shutdown did not alter the adapted VOR gain, yet the animals were subsequently unable to modify their VOR gain, while the flocculus was silenced.

**Clinical Considerations of Vestibular Reflexes**

**General Pattern.** It has been stated that the vestibular system functions primarily as an afferent input for motor reflexes and that, at rest, most primary vestibular neurons have high and remarkably regular spontaneous discharge rates. For the purposes of the following clinically oriented discussion, the spontaneous vestibular neuronal activity will be referred to as the resting discharge.

Normally, with the head at rest in the neutral position, the resting discharges in the 2 vestibular nerves are equal. Vestibulomotor reflexes are elicited when inputs from the 2 vestibular end-organs or their central projections are made unequal, that is, they are unbalanced. Such unbalancing can occur by an abnormality involving one side to a greater degree than the other. In this case, we term the resultant vestibular reflex spontaneous. Vestibular input from the 2 sides can also be unbalanced by stimulating 1 or both of the vestibular end-organs. In this case, the resultant vestibular reflex is termed "induced." When a vestibular input imbalance is unusually large or prolonged, a constellation of stereotyped responses occurs. These responses are head turning, falling (or swaying), past pointing, vertigo representing a sensation of rotation, and nystagmus involving a rhythmic back-and-forth eye movement, with alternate slow phases in one direction and fast phases in the opposite direction. These slow and fast eye movements are termed the slow and fast phases of vestibular nystagmus. The head turning, falling, past pointing, and nystagmus slow phase are all in the same direction, that is, away from the ear with the greater output. In this discussion, the reference is to the nystagmus slow or vestibular phase. The clinical convention is to designate nystagmus direction by the fast of central phase, presumably because these movements can be easily observed. Thus, the indicated reflex directions may be the opposite of those to which the reader is accustomed.

**Fast-phase nystagmus is in the direction of the angular acceleration.** The rotation sensation, or vertigo, may be referred either to the subject’s body, that is, subjective vertigo, or to the environment, that is, objective vertigo. If the body rotates, it is in the same direction as the nystagmus slow phase; if the environment rotates, it is in the opposite direction.

**Methods of Eliciting.** Vestibular responses can be generated by rotational, caloric, or galvanic stimulation of the vestibular periphery. The caloric and rotational responses are discussed in the following section. The galvanic vestibular response occurs when electrical current is applied to the head in the vicinity of the ear. Electrical current applied in this manner elicits the entire constellation of vestibular responses except vertigo. Interestingly, however, some subjects may report a slight sense of disorientation. If the current is positive, the nystagmus slow-phase, past-pointing, and body-sway responses are toward the stimulated ear; in contrast, if the current is negative, these responses are away from the stimulated ear.

Because the galvanic stimulus probably acts at a retro labyrinthine location, that is, either vestibular nerve, Scarpa ganglia, or a more central location, it has been suggested as a means of differentiating vestibular end-organ from vestibular nerve lesions. However, this procedure has not found widespread clinical acceptance, possibly because of uncertainty over the exact locus of action. For example, patients with their vestibular nerves sectioned intracranially still have a recognizable body-sway galvanic response, suggesting that at least part of the action of the galvanic stimulus is central to the vestibular nerve, that is, at the level of the brainstem or possibly cerebellum.

**Vestibular Nystagmus.** Vestibular nystagmus occurs when the semicircular duct system is overstimulated. For example, if the head is continuously rotated in one direction at an ever-increasing speed, the semicircular duct-initiated compensatory eye movement becomes repeatedly interrupted by rapid, snap-back movements and hence becomes a rotational nystagmus. Because the relatively slow compensatory eye movement phase of the nystagmus comes from the semicircular duct system, it is called the vestibular or slow phase of the nystagmus. Conversely, because the fast, snap-back eye movement comes from the brain, it is called the central or fast phase of the nystagmus. Caloric nystagmus is produced by a temperature change in the region of the vestibular apparatus.

In the clinical laboratory, this temperature change is usually produced by running cool or warm water into the external auditory canal. The temperature change is conducted through bone to the semicircular canals. Since the horizontal semicircular canal is closest to the irrigating water, it is the most affected; hence, caloric nystagmus is almost entirely in the horizontal plane.

**Figure 51 illustrates the generation of caloric nystagmus.** The subject is in the supine position, with his head elevated 30° to bring the horizontal canal into the vertical position. The cold caloric irrigation cools the endolymph in part of the horizontal duct. This cooled endolymph becomes slightly denser than the surrounding endolymph and thus falls, causing the eyes to rotate toward the irrigated ear. This vestibular eye movement is repeatedly interrupted by a compensatory rapid central eye movement in the opposite direction. A cold caloric nystagmus is thus created, with its slow phase toward and its fast phase away from the irrigated ear.

Although the slow phase is the vestibular phase of vestibular nystagmus, it is the clinical convention to designate the direction of the vestibular nystagmus by the direction of the fast phase. This convention, as noted above, originated because the fast phase is easier to observe than the slow phase.

**Neural Mechanisms of Nystagmus.** Figure 49 diagrams the neural mechanisms of different kinds of vestibular nystagmus. This Figure shows the physiologic rather than the anatomic form of the horizontal VOR system. It is drawn to reflect the fact that increased neural activity from a horizontal semicircular duct rotates the eyes horizontally away from the duct.

At rest, both ducts generate equal neural activity, which represents the resting discharge described above. Unbalancing the vestibular inputs from the 2 ears generates vestibular nystagmus if the imbalance is prolonged. Caloric and rotational stimuli unbalance the vestibular input via the normal transducer action of the semicircular ducts. Lesioning the labyrinth by surgery or disease causes a pathologic imbalance by eliminating or reducing the resting discharge on the involved side.

Inner Ear Drug Delivery and Gene Therapy

Anil K. Lalwani, MD
Nirmal P. Patel, MD

Over the past quarter century, there has been an expanding interest in directed therapy to address inner ear disorders as indirect, systemic therapy has shown limited success and significant morbidity. Intratympanic (IT) therapy has several potential advantages over conventional systemic therapy including increased therapeutic concentrations in the inner ear, reduced side-effect profiles, cost effectiveness by avoiding surgery, use when systemic therapy is contraindicated, and lastly as a salvage for failure of systemic therapy. Experimentally, as reviewed below, investigators have shown that intratympanic and intracochlear therapy is feasible and efficacious. In this chapter, the core of knowledge regarding delivery of material into the inner ear and its therapeutic consequences will be reviewed.

ROUND WINDOW MEMBRANE

The anatomy and physiology of the round window membrane (RWM) are covered in Chapter 1, “Anatomy of the Auditory and Vestibular Systems,” and Chapter 4, “Physiology of the Auditory and Vestibular Systems”; however, the aspects of the RWM that are relevant to intratympanic therapy are reviewed here.

Anatomy of the Round Window Membrane

The RWM is a three-layered structure that protects the inner ear from middle ear pathology and facilitates active transport. There is an outer epithelial layer that faces the middle ear, a central connective tissue layer, and an inner epithelial layer interfac ing with the scala tympani. The outer epithelial layer is continuous with the promontory. Mucoperiosteal folds from the neighboring epithelium can sometimes obstruct the round window niche, forming a “false” RWM. Other reactive changes, such as scarring from middle ear infections or surgery, may also lead to adhesions that obstruct the RWM. In a study of 202 cadaveric ears to determine the amount and nature of RWM obstruction, Alzamir and Linthicum identified RWM obstruction in one-third of ears.1 In their series, 21% had false RWMs, 10% had fibrous plugs, and 1.5% had fatty plugs. These obstructions may explain why a proportion of patients treated with intratympanic therapy have no beneficial effect or require multiple pharma-cotherapeutic courses to achieve treatment goals.

Permeability

A large range of substances are able to cross the RWM, including various antimicrobials, corticosteroids, antibiotics, water, ions, and macromolecules, including bacterial toxins. Several factors contribute to the RWM permeability, including size, charge, the morphology of the compound, and the thickness of the RWM. Size has proven to be a factor in permeability, as 1 µm spheres cross the RWM, but 3 µm spheres do not. Furthermore, substances with a molecular weight of less than 1,000 kD diffuse across the RWM fairly rapidly, whereas substances over 1,000 kD are transported by pinocytosis. Charge of the ion can also impact its ability to traverse the RWM; for example, it has been noted that cationic ferritin crosses the RWM, but anionic ferritin does not. Finally, increased thickness of the RWM will decrease permeability of substances. Whereas the average thickness of the human RWM is between 10 and 30 µm, its thickness can double in inflammatory conditions.

Kinetics

Delivery of therapeutic agents across the RWM displays a nonuniform distribution in the perilymph. Concentrations of the delivered agent are usually high in the basal turn in close proximity to the RWM and low in the apical turn. The permeability of the substance across the RWM and the rate of its clearance from the perilymph are the two major factors that determine the dispersion of substances in perilymph. Perilymph clearance includes a combination of clearance to blood, clearance to other scalae, uptake or binding by cells, or metabolism by cochlear tissues. Therefore, knowing the RWM permeability and clearance rates of a given agent will permit simulation of its perilymphatic distribution with reasonable accuracy.

Using these observations, Salt and Madeya described the development of a computer-simulated model of drug distribution in the perilymphatic space. A model of gentamicin kinetics in the perilymph closely approximates the data obtained from animal studies, providing a useful tool for predicting gentamicin concentrations and distribution in the perilymph. The model of gentamicin kinetics in the perilymph includes factors such as the volume of the scala tympani, the rate of its clearance from the perilymph, the permeability of the substance across the RWM, and the rate of its clearance from the perilymph. The model is useful for predicting gentamicin concentrations and distribution in the perilymph.

Delivery Methods

For a typical intratympanic injection, the patient lies flat with the affected ear facing the ceiling. Local anesthetic, such as 88% phenol, is then applied to the tympanic membrane. A myringotomy is necessary, as there should be a vent for air to escape the middle ear space as it is filled with fluid. The injection should be administered slowly and directed into the posterior half of the middle ear toward the round window, so that the solution pools around the round window niche. The patient should remain with the injected ear toward the ceiling for about 15 to 30 minutes. Some protocols call for multiple injections over a short period of time. Under these circumstances, it is useful to place a tympanostomy tube after the initial myringotomy.

Advances in microendoscopes may significantly increase the ease and accuracy of intratympanic drug delivery. Plontke and colleagues described the development of a 1.2 mm endoscope that incorporates a thin fiber optic, a working/laser channel (0.3 mm), and a suction/irrigation channel (0.27 mm). This new device allows several manipulations to occur at once, including direct observation of the RWM, lysis...
of adhesions (if present), and application of medications directly to the RWM.

Intratympanic injection is inherently inaccurate as the injected medication can leak down the eustachian tube, escape out of the external auditory canal, or be sequestered in the middle ear. Therefore, the amount of medication delivered potentially changes with each patient and each dose. In an attempt to address this problem, several static sustained release vehicles have been developed. For instance, a dry 2 × 3 mm Gelfoam (Upjohn, Kalamazoo, MI) pledget can be placed directly in the round window niche (Figure 1). The treatment compound can be injected directly onto the Gelfoam pad. Because of the slow dissipation of Gelfoam, this can be repeated several times. A Gelfoam slurry can also be used to suspend the medicine. A two-component fibrin glue system may also be used (Red Cross-Holland Laboratory, College Park, MD). The first component of the glue is deposited in the round window niche. The other component is mixed with the medicine. The two are mixed in situ and subsequently solidified, allowing the medicine to be slowly released from the glue onto the RWM. A final alternative as an inner ear delivery suspension is hyaluronic acid (Healon, Advanced Medical Optics Inc., Santa Ana, CA) which has been demonstrated to cause less ototoxic damage compared to fibrin or Gelfoam.²

The ultimate degree of pharmacokinetic control can be achieved with the use of mechanical sustained release devices. These devices allow researchers to manipulate inner ear kinetic curves reliably by changing the rate and amount of dose delivered to the RWM. There are two devices that are currently approved for use in humans and have been studied in clinical trials: the Silverstein MicroWick (Micromedics, Eaton, M N) and the IntraEar Microcatheter (Durect, Cupertino, CA). The Silverstein MicroWick is made of polyvinyl acetate and measures 1 × 9 mm long, small enough to fit through a tympanostomy tube (Figure 2). The wick absorbs medication which can be instilled into the external auditory canal by the patient at home and delivers it to the RWM. This device has been used to deliver corticosteroids and gentamicin in human clinical trials. The IntraEar Microcatheter consists of an electronic pump (Disetronics, Minneapolis, MN) connected to a catheter tip that is placed directly on the RWM. Implantation of the Microcatheter is more invasive and requires the elevation of a tympanostomy tube (Figure 2). The wick absorbs medication which can be instilled into the external auditory canal by the patient at home and delivers it to the RWM. This device has also been extensively tested in human subjects for both corticosteroid and gentamicin therapy to the inner ear.

**Figure 1** Routes of delivery for inner ear therapy. A variety of routes are available to introduce a drug or gene therapy vector to the cochlea. These include direct instillation of the agent through an intact round window membrane with a gelatin sponge (A), direct injection through the round window membrane (B), and infusion with osmotic mini-pump through cochleostomy (C). (Published with permission, copyright © 2007 Anil K. Lalwani, M.D.)

**Figure 2** Silverstein otowick. The wick is used in combination with a ventilation tube to deliver agents to the round window membrane.

Several new therapeutic agents, such as neurotrophins, require chronic or continuous application. This presents a serious challenge from a delivery point of view. In an attempt to address the need for a long-term delivery device, Praetorius and colleagues developed a fully implantable micropump system.⁶ The device is made from pure silicone and is designed for life-long implantation in humans. To place the device, a cavity is drilled in the mastoid bone to house the pump and reservoir system, a procedure that is similar to the one used to place cochlear implants or implantable hearing devices.

**Intratympanic Corticosteroids**

The two principal indications for intratympanic (IT) corticosteroids are sudden sensorineural hearing loss (SSNHL) and Ménière’s disease. The pathogenesis, pathophysiology, and diagnostic criteria for these indications are subject to controversy; furthermore, the mechanisms of action of corticosteroids in the inner ear are incompletely understood. Therefore, a comprehensive evaluation of the use of IT corticosteroids as a treatment for these conditions is exceedingly difficult. Table 1 summarizes the relative anti-inflammatory and sodium retention properties, relative to hydrocortisone duration and equivalent dose of various corticosteroids.

**Mechanism of Action.** Corticosteroids help mitigate the destructive processes caused by the immune response. Corticosteroids decrease the number of circulating blood leukocytes and inhibit the formation and liberation of inflammatory mediators, therefore, decreasing the damage from an inflammatory response, whether the response is secondary to mechanical, hypoxic, ischemic, infectious, or autoimmune causes. In addition to modulation of the immune response, corticosteroids are linked to several other biological effects in the inner ear, including ion homeostasis, functioning as apoptosis inhibitors, antioxidants, signal transducers in the neuroepithelial regions of the inner ear, and vasoactive agents that increase cochlear blood flow. To understand their various roles and potential target tissues, the presence and distribution of glucocorticoid receptors in the inner ear have been extensively studied. The distribution of corticosteroid receptors is not uniform, and this differential expression in the inner ear may explain, in part, their spectrum of functions.

**Pharmacokinetics.** IT administration yields much higher concentrations of corticosteroids...
in the inner ear than either intravenous (IV) or oral administration. Parnes and colleagues compared IV and IT administration of hydrocortisone, methylprednisolone, and dexamethasone (short-, intermediate-, and long-acting corticosteroids, respectively). While all the three corticosteroids successfully penetrated the blood-labyrinthine barrier, there was a much higher concentration of corticosteroids in inner ear tissues with IT administration. Methylprednisolone had the highest concentration and longest duration in perilymph and endolymph of the three compounds.

Systemic Corticosteroids

Currently, systemic corticosteroids are the treatment of choice for sudden sensorineural hearing loss and acute vestibular vertigo. IT corticosteroid delivery without controlled study may be premature as there may be certain biological effects that can only be achieved with systemic corticosteroids. For example, it is well established that corticosteroids decrease peripheral blood leukocytes. These cells enter the inner ear through the endolymphatic sac, the immunocompetent organ of the inner ear. Local administration may be incapable of stopping this system-wide process. Yang and colleagues developed a model of labyrinthitis induced by delayed hypersensitivity to keyhole limpet hemocyanin (KLH) that mimics a full scale, cell-mediated immune response. They found that IT dexamethasone was ineffective in reducing inflammatory infiltrate after KLH challenge. This situation represents the risk of using IT corticosteroids alone for inner ear disease, rather than in combination with oral or IV corticosteroids.

Sudden Sensorineural Hearing Loss

Systemic and IT corticosteroid therapy have been used for treatment of sudden sensorineural hearing loss (SSNHL). The major prognostic factors predicting response to treatment for SSNHL are initial severity of hearing loss and time between onset and treatment. There is a high spontaneous recovery rate of 30 to 60%, therefore treatment efficacy of any intervention has to be greater than the spontaneous recovery rate. Oral corticosteroid therapy within the first 2 weeks has shown recovery rates approaching 80% and decreasing with a greater interval between onset and treatment. Due to the high initial response to oral corticosteroids, few practitioners have attempted to use IT corticosteroids, and most IT corticosteroid trials enroll patients who have failed oral treatment. Dallan and colleagues reported results of a trial of IT corticosteroids for patients with SSNHL who had failed to improve after high-dose systemic corticosteroids. The protocol consisted of transtympanic injection of 62.5 mg/mL methylprednisolone for eight patients with no controls. The results showed a pure tone average improvement of 10 dB or greater in 75% of patients. The authors argue that while this improvement seems modest, this is in a cohort of patients who would otherwise be considered refractory to corticosteroid treatment.

Chandrasekhar and colleagues published results from a 10-patient series treated with IT dexamethasone. The dexamethasone concentration and number of IT injections varied among patients, and several patients were taking oral medications in addition to IT-administered corticosteroids, making outcomes difficult to assess. However, of the 10 patients treated, 6 experienced hearing improvements greater than 10 dB. Parnes and colleagues reported results from a similar series of 13 patients with sudden hearing loss treated with IT corticosteroids. Of the 13 patients treated, 6 showed hearing improvements of 10 dB or more.

Meniere Disease

Meniere disease is in some cases may be due to immune dysfunction, therefore corticosteroids are occasionally used in Meniere disease treatment protocols. Itoh and Sakata reported the first IT corticosteroid protocol in 1987, in which 4 to 5 weekly injections of 2 mg of dexamethasone were administered to 61 patients with unilateral Meniere disease. This protocol resulted in vertigo relief in 80% of patients and tinnitus reversion in 74% of patients. Subsequently, additional studies have used IT corticosteroids to treat Meniere disease, some with results more promising than others. Sungaroglou and colleagues placed tymanostomy tubes in 24 patients with Meniere disease with intractable vertigo and applied five drops of 1 mg/mL dexamethasone solution into the middle ear space every other day for 3 months, which was administered at home by the patient. This protocol resulted in a vertigo control rate of 72%, improved hearing in 17%, decreased tinnitus in 75%, and reduced aural fullness in 75%. To their credit, the authors acknowledge that their results may be confounded by a placebo effect secondary to the tymanostomy tubes.

Ariaga and Goldman presented short-term hearing results of Meniere disease patients who underwent an IT corticosteroid protocol with placement of Gelfoam and injection of an 8 mg dose of dexamethasone mixed with hyaluronate. The only parameter recorded was a 1-month postoperative audiogram. Results showed 33% improvement in hearing and 20% deterioration in hearing. The largest drop in hearing was a 20 dB loss with the speech discrimination score dropping from 88 to 24%. This patient also had severe Meniere disease symptoms during testing, including nausea, vomiting, and vertigo.

In a rare controlled trial, Silverstein and colleagues conducted a prospective, randomized, double-blind, crossover trial of IT dexamethasone and placebo in 17 patients with Meniere disease. All patients had stage IV Meniere disease by the Shea classification (they no longer had vertigo and had poor hearing and significant fullness and tinnitus). They received IT injection of either placebo or 0.2 to 0.3 mL of a 1:1 mixture of 16 mg/mL dexamethasone and sodium hyaluronate. This protocol was performed for 3 consecutive days. Three weeks after the initial treatment, the groups received their crossover treatment. The parameters recorded were audiometric data, ENG recordings, and tinnitus evaluations. The IT corticosteroids provided no significant benefit over placebo in any of the parameters recorded. However, a selection bias in this severely diseased patient population may not be present in other studies, leaving open the possibility that IT corticosteroids may be useful in less severe cases. Regardless, evidence is needed to support a role for IT corticosteroids in Meniere disease.

Dosing for Administration of Intratympanic Corticosteroids

The most widely used corticosteroid for IT protocols is dexamethasone, followed by methylprednisolone. IT dexamethasone preparations vary from as little as 1 mg/mL to as high as 25 mg/mL. Most IT methylprednisolone studies use a 62.5 mg/mL solution. The amount of solution injected (0.3 to 0.5 mL) is designed to fill the middle ear space.

Side Effects of Treatment

The side effects of long-term systemic corticosteroid use are well known and include compromise of the immune system leading to infections, osteoporosis, peptic ulcers, hypertension, myopathy, cataract formation, impaired healing, psychological effects, sleep impairment, and avascular necrosis. In contrast, IT corticosteroids are characterized by minor local morbidities.

Several preclinical studies have documented that IT corticosteroids cause no morphological or functional compromise in animal models. Human clinical trials have reported relatively benign side-effect profiles. There are several reports of decreased hearing in human clinical trials of Meniere disease patients, but it is unclear whether this is a side effect of treatment or part of the natural course of the disease. There have also been reports of tympanic membrane perforations and otitis media secondary to the perfusion process.16

**Conclusions on the Use of Intratympanic Corticosteroids**

There is currently no consensus on the mechanism of action of corticosteroids in the inner ear. Furthermore, there is insufficient experience with IT corticosteroids to advocate its routine use in autoimmune hearing loss, SSNHL, or Meniere disease. IT corticosteroids may prove to have a role in SSNHL unresponsive to oral corticosteroids or as an adjuvant to oral corticosteroids in acute settings.

**Intratympanic Gentamicin**

In 1957, Schuknecht published his work on IT administration of streptomycin for Meniere disease. Although loss of hearing was almost as common as the resolution of vertigo, his work sets the stage for the development of modern IT chemical ablation protocols. It was not until the mid-1970s that Beck and Schmidt described a low-dose strategy that departed from the goal of total vestibular ablation. They compared a high-dose ablative protocol with a low-dose, low injection frequency protocol, and found that while vertigo control was essentially the same, the hearing loss rate decreased from 58% to 15%. This improvement rekindled interest in IT gentamicin therapy.

**Mechanism of Action.** Despite the widespread belief that gentamicin is selectively toxic to vestibular hair cells, the literature does not fully support this assertion. Several researchers have shown that gentamicin and streptomycin cause parallel and dose-dependent damage to both vestibular and cochlear hair cells.17-20 The clinical finding of significant correlation between loss of caloric response and hearing loss following gentamicin exposure further betrays the notion of selective vestibular toxicity.

If there is no selective vestibular toxicity, how is it that clinicians have achieved good vertigo control with minimal hearing loss? In part, the answer may lie in pharmacokinetics. Hoffer and colleagues compared the kinetic profiles of IT injection versus microcatheter delivery of gentamicin and correlated these data to the functional changes.21 Despite the fact that the total dose in both methods was roughly equal, the resulting morphological changes were quite different. Intratympanic injection led to erratic changes, sometimes causing obliteration of auditory functioning within 4 hours, and in other cases showing significantly delayed ototoxic effects. In contrast, controlled perfusion by microcatheter caused predictable and uniform damage. Hoffer and colleagues explain that this may be due to two different patterns of hair cell loss which included a necrotic pattern associated with rapid and high-dose perfusion and an apoptotic pattern associated with slower or chronic perfusion.22 Therefore, in addition to the amount of gentamicin that accumulates in the perilymph over time, the nature of the distribution curve, timing of the peak, and total dose determine morphological and functional consequences of aminoglycoside exposure.

The alternative explanation for gentamicin’s selective vestibular effect is the proposal that gentamicin primarily affects secretory, rather than sensory cells: the “dark cell theory.” Vestibular dark cells are important in creating and maintaining ionic homeostasis in the inner ear since they transport potassium from extracellular environments to the endolymph. Several studies have documented that aminoglycosides induce structural and functional alteration of these dark cells.23 This damage is thought to alter the ionic homeostasis of the inner ear in such a way that it restores the ionic dysregulation of endolymphatic hydrops. Hilton and colleagues examined secretory and sensory cells in response to aminoglycoside challenge and found no significant changes in dark cells, despite extensive damage in both cochlear and vestibular hair cells.17 If dark cells are responsible for the selective effect of gentamicin, this has yet to be established in any preclinical models.

There is overwhelming clinical evidence that vestibular ablation is not required for vertigo control.24 These observations have caused a shift in strategy from vestibular ablation to “chemical alteration.” This term describes the clinical goal of balancing vertigo control and hearing loss.

**Pharmacokinetics.** Intratympanic gentamicin kinetics in the perilymph follows a one-compartment model. Gentamicin rapidly diffuses across the round window membrane (RWM); therefore, the kinetics of gentamicin in perilymph are largely determined by the method of delivery. IT injection has a faster absorption phase, demonstrates higher peak concentrations, and exhibits significantly more variability in all measurements than sustained release delivery methods. In pharmacokinetic studies, large value ranges and standard deviations are characteristic of IT injection delivery.

The pharmacokinetic data generated in animal models appear to fit what occurs in humans. Bcevarovskii and colleagues devised an in vivo human pharmacokinetic study by recruiting patients who were undergoing either translabyrinthine surgery or labyrinthectomy and exposed them to gentamicin intraoperatively through the facial recess.25 In these patients, there was rapid diffusion of gentamicin into the perilymph that peaked after 30 minutes. After this peak, concentrations were in a stable range until the limit of detection was reached after 4 hours. In summary, this study confirms that rapid diffusion of gentamicin across the round window occurs in humans. Furthermore, this study indicates that the elimination of gentamicin involves crossing the blood-labyrinthine barrier, since gentamicin was detected in the serum shortly after administration.

**Clinical Protocols.** There are three basic strategies used in IT gentamicin therapy: fixed, titrated, and sustained release protocols. Fixed protocols use a specific dose and number of injections in all patients. Titrination protocols adjust the total dose delivered to a predetermined end point, such as paralytic nystagmus, decreased tandem gait, subjective disequilibrium, or more simply relief from vertigo. The supposed advantage of fixed protocols is that each patient receives the same treatment, making outcomes easier to interpret across individuals. The flexible structure of titrated protocols supposedly allows for more control of the ototoxic effects of gentamicin, thereby decreasing the risk of hearing loss.

Much of the controversy in IT gentamicin therapy in the 1990s concerned a form of fixed protocol known as a “shotgun” protocol. The “shotgun” protocol was popularized by Nedelecky and colleagues in 1992.26 The protocol called for three daily injections for 4 consecutive days of 26.7 mg/mL gentamicin and resulted in a vertigo control rate of 94% and hearing loss rate of 26%. The main argument against the “shotgun” protocols is that they lead to higher rates of hearing loss that is often profound. Atlas and Parnes have pointed out that in “shotgun” protocols, the proportion of patients who experience hearing loss greater than 30 dB (10 to 24%) is much higher than the proportion seen in titration protocols (0 to 4%).27

Recently, “hybrid” protocols have been introduced. Quaranta and colleagues used a fixed schedule of two 0.5 mL IT injections of 20 mg/mL gentamicin solution spaced 1 week apart.28 Patients who did not achieve vertigo control after the first two doses were offered additional doses, up to a total of four doses. This was a prospective study with a control group who refused treatment. At the 2-year follow-up point, the vertigo control rate was 93% versus 47% for the nontreated group. Hearing loss was 7% for the treated group versus 47% for the nontreated group.

Microcatheter delivery method has been advocated to provide sustained gentamicin levels in the perilymph. Schoendorf and colleagues used a pump and microcatheter to deliver 40 mg/d of gentamicin to the RWM. The treatment was continued at this fixed rate until vestibular symptoms appeared (in essence, a titration protocol). While vertigo control was achieved in most patients, 8 of 11 patients treated became deaf.

In a study that epitomizes the microdose, slow perfusion rate strategy, Hoffer and colleagues reported the 2-year results of 27 patients who underwent microcatheter gentamicin therapy.21
known as acute chemical labyrinthine upset, Acute vestibular deafferentation syndrome, also and in this sense is not strictly a complication. The rate of untreated patients may represent an actual trial that significantly beats this 30% hearing loss interesting implication is that any IT gentamicin rates reported by most IT gentamicin trials. The study used a solution of 10 mg/mL, at 1 µL/ h for 10 days resulting in total dose of 2.4 mg. This strategy achieved vertigo control in 93% of patients, hearing loss in only 4%, tinnitus relief in 63%, and elimination of aural pressure in 74%. Surprisingly, 96% of patients had no decrease in vestibular function.

Practical Considerations. Delivery. The argument for using IT injections is that it is the simplest, most cost-effective, and least invasive method of delivery, and from published studies, it provides comparable vertigo control and hearing preservation rates to sustained release protocols. The argument for using sustained release mechanisms is that they may produce lower rates of hearing loss, allow for standardization across individuals, leading to more predictable and uniform results.

Dose. There is no minimum safe dose for IT gentamicin; the lowest documented IT gentamicin dose to produce hearing loss is 0.24 mg. Low-dose protocols use the pediatric formulation of gentamicin, a 10 mg/mL preparation. The adult preparation of 40 mg/mL is often diluted to 30 mg/mL. Comparing outcomes between 30 and 40 mg/mL IT gentamicin preparations has found that both cohorts had similar vertigo control and hearing loss rates, but the 40 mg/mL cohort required fewer injections to achieve these results.

Interval. The injection interval depends on the end point chosen for the study. There is increasing support for spacing the injections over a period of at least a week, primarily because of the delayed onset of gentamicin toxicity. The typical deafferentation syndrome only occurs 3 to 5 days after injection.

Complications. The complication of IT gentamicin treatment is hearing loss. Risk factors for hearing loss have been inconsistently identified across studies, partially due to the substantial differences in protocols. As noted above, Atlas and Parnes argue that “shotgun” protocols result in substantial rates of hearing loss greater than 30 dB (10 to 24%) whereas titration methods report low rates of substantial hearing loss (0 to 3.5%).

Hearing loss reporting in gentamicin trials does not distinguish whether the deficit is due to drug-induced toxicity or the natural consequence of Meniere disease. The long-term hearing outcome for untreated Meniere disease has been reported to be around 30% with medical therapy. This figure is close to the hearing loss rates reported by most IT gentamicin trials. The interesting implication is that any IT gentamicin trial that significantly beats this 30% hearing loss rate of untreated patients may represent an actual prevention of hearing loss.

A cute vestibular deafferentation syndrome should be an anticipated outcome of treatment, and in this sense is not strictly a complication. A cute vestibular deafferentation syndrome, also known as acute chemical labyrinthine upset, is the consequence of unilaterally injuring the vestibular apparatus. This phenomenon usually occurs 3 to 5 days after the injection, with symptoms including vertigo, nausea, oscillopsia, and disequilibrium. Patients can readily distinguish these symptoms from their typical Meniere disease-related symptoms. Gradual resolution occurs in 2 to 4 weeks in most patients.

**Indications and Contraindications.** The indication for IT gentamicin treatment is the cohort of patients with Meniere disease that have failed conservative therapy and have recurrent vertigo. Conservative therapy consists of a diuretic and diet restrictions (salt, caffeine) and is effective in 70% of cases. Most practitioners only begin to consider IT gentamicin therapy after conservative therapy has failed for at least 1 year. After this time, low-pressure pulse therapy, IT corticosteroids, IT gentamicin, and endolymphatic sac surgery are considered. Sennaroglu and colleagues argue that it is reasonable to try using IT corticosteroids before using IT gentamicin. In a prospective study that compared IT dexamethasone (n = 24) versus gentamicin (n = 16), they found that vertigo control rates were 72 and 75%, respectively. However, IT gentamicin was considerably more cochleotoxic than IT corticosteroids. Labyrinthectomy and vestibular nerve section are reserved for only the most severe and refractory cases.

Some practitioners recommend that elderly patients be treated with caution, as central compensation for peripheral vestibular loss is less effective in this cohort. Bilateral Meniere disease (incidence of 15 to 30%) is considered by some to be a contraindication for unilateral IT gentamicin treatment, because if hearing loss results from treatment, the remaining ear may be vulnerable to hearing loss as a natural course of the disease. Patients with no serviceable hearing in the problematic ear are generally considered candidates for labyrinthectomy, but it seems reasonable that the low-morbidity, low-cost IT gentamicin protocol be attempted in these patients before surgery is considered.

There is some debate as to whether otologic surgery is a contraindication to IT gentamicin treatment. Initial studies demonstrated poor vertigo control after endolymphatic surgery. However, more recent work has achieved the opposite effect with complete vertigo control and no effect on hearing outcomes in a cohort of five patients following endolymphatic surgery. The importance of this debate is that several practitioners advocate endolymphatic shunt procedures before resorting to IT gentamicin when treating intractable vertigo in Meniere disease patients.

**Conclusions on the Use of Intratympanic Gentamicin.** In a meta-analysis by Cohen-Kramer and colleagues of studies that used IT gentamicin as the only method of treatment and reported results according to American Academy of Otolaryngology-Head and Neck Surgery Foundation guidelines for Meniere disease, they found that, from an inclusion group of 15 studies, complete class A control was achieved in 74.7% of patients and complete or substantial class B control was achieved in 92.7% of patients. Furthermore, the success rate of vertigo control was not affected by treatment regimen (fixed vs titrated), and hearing level and word recognition scores did not seem to be adversely affected by either treatment regimen when compared to control groups. Similar analyses have found comparable vertigo control rates with increased deafness. Using these data, IT gentamicin using low dose with long inter-therapy intervals could justifiedly become the treatment of choice for medically recalcitrant Meniere disease, especially when hearing is poor in the affected ear.

**GENE THERAPY OF THE INNER EAR**

The simple and powerful objective of gene transfer technology is to introduce a “therapeutic gene,” for example, a normal version of the defective gene, into appropriate target cells of the affected individual. Expression of the exogenous “therapeutic gene” would alter the target cell and the clinical phenotype.

Both viral and nonviral vectors have been used to transfer and express genes in the inner ear of animal models. Individual virions represent a highly efficient means of introducing the viral genome into the nuclei of target cells followed by the use of the cellular machinery to express the viral genes. These viral agents have been adapted for the purpose of gene transfer by altering their genome so that they can no longer replicate within the transduced cell and lead to cellular lysis. These replication defective viruses are engineered to function solely to introduce the desired gene into the nuclei of target cells. Viral vectors have been developed from both DNA (eg, adenovirus, adeno-associated virus and herpes simplex virus) and RNA (eg, retrovirus and influenza viruses).

**Viral Vectors in Intracochlear Gene Therapy**

Feasibility of gene therapy for inner ear pathology was initially demonstrated through intracochlear transgene expression using the guinea pig as an animal model. A viral vector derived from the adeno-associated virus (A A V) was used to deliver a marker transgene to the cochlea via steady state infusion using an osmotic mini-pump. Based upon expression of the marker transgene encoding a bacterial enzyme β-galactosidase, the A A V vector was found to transduce the spiral limbus, spiral ligament, spiral ganglion, and the organ of Corti. Subsequent studies investigating intracochlear gene transfer have characterized a variety of different vectors for their efficacy and safety as well as their mode of introduction into the cochlea.

The adeno viral (A d) vector represents one of the well-characterized viral vectors used for intracochlear gene transfer. The attributes of the adeno viral vector for gene transfer include its capacity to carry large transgenes (8 kB), generating them at high titer in both dividing and
nondividing cells. The major disadvantage associated with the use of first generation Ad vector was the strong immune response that it elicited. Subsequent development of adenoviral vectors has generated attenuated viruses with complete deletion of viral protein sequences, leaving a vector with all the advantages and diminishing, if not eliminating, its immunogenicity.34

A lentiviral vector, based on the human immunodeficiency virus (HIV), can integrate into the chromosome of both dividing and nondividing or mitotically quiescent cells leading to a potentially stable, long-term expression of a transgene spliced into the viral vector. Thus, the postmitotic cochlea neuroepithelia and the spiral ganglion neurons (SGNs) represent suitable targets for a stable long-term transgene expression via lentivirus-mediated gene transfer. Restricted transduction of cell types confined to the periphery of the perilymphatic space by the lentivirus is ideal for stable production of gene products secreted into the perilymph (Figure 3).

Nonviral Vectors for Intracochlear Gene Transfer

In addition to viral vectors, cationic lipid vesicles or liposomes have also been used for intracochlear gene transfer. The liposome, coupled to the transgene integrated within a plasmid vector, binds to the plasma membrane of the target cells, releasing the DNA into the cytoplasm where it is eventually incorporated by recombination, so there is little risk of insertional mutagenesis. The drawback of liposome vectors is a low transfection rate compared with other vectors. The feasibility of inner ear gene transfer with liposome vectors has been demonstrated. The attributes of the vectors that have been used in intracochlear gene transfer are summarized in Table 2.

Suitable Animal Models for Gene Therapy of the Inner Ear

Preliminary studies in intracochlear gene therapy used the guinea pig as the animal model due to the relatively large size of its cochlea compared to mice and rats and the ease of surgical manipulation in this species. Subsequent studies are shifting their focus toward the mouse as the preferred model. The mouse genome is the most extensively characterized of all mammalian model organisms.

The intrinsic value of the mouse as a model in hearing research is seen in the availability of a number of mutant mice with inherited hearing loss. These mutant mice have been well characterized, and the genetic basis of their hearing loss is identified. Furthermore, established in vitro and in vivo rodent models for ototoxic sensorineural damage to the inner ear exist.

Delivery Modalities for Gene Therapy of the Inner Ear

Local biological transfer to the inner ear is feasible because of its relatively closed anatomy. However, developing a delivery method for genetic vectors/cells to the inner ear without causing local destruction and concomitant hearing loss is a significant obstacle. The general strategy behind these delivery modalities is to introduce the transgene-carrying vector into the inner ear fluid, enabling its diffusion to the surrounding tissues. Most of the delivery methods introduce the gene into the perilymphatic fluid. These methods include microinjection via the round window membrane, microinjection or mini-osmotic pump infusion following cochleostomy, and diffusion across the round window membrane after local Gelfoam placement (Figure 1). Gene transfer vectors have also been introduced into the endolymphatic fluid through injection into the endolymphatic sac or into the scala media following cochleostomy.

Histologically, introduction of viral vectors with a mini-osmotic pump was characterized by an inflammatory response and connective tissue deposition at the basal turn adjacent to the cochleostomy site, with associated increase in auditory brainstem response (ABR) thresholds at higher frequencies.35 Systemic dexamethasone-induced immunosuppression has also been shown to largely protect the inoculated ear from threshold shift and appears to improve Ad vector-based gene expression.36

A much less traumatic alternative to cochleostomy is microinjection through the round window membrane. Histologically, cochleae microinjected through the round window demonstrate after 2 weeks intact cochlear cytoarchitecture and an absence of inflammatory response with no hearing dysfunction.

To avoid potential hearing loss associated with the direct manipulation of the cochlea, gene transfer vectors and stem cells have also been delivered through the vestibular apparatus via a semicircular canal fenestration to the perilymph and through the endolymphatic sac to the endolymph. As a treatment for spiral ganglion neuronal damage, the direct delivery of vectors to the auditory nerve is feasible. A ccess to the auditory nerve is routinely achieved in the human patient for neoplasm removal and treatment of incapacitating vertigo. The modiolus and the auditory nerve have been successfully accessed in animal models.

The potential for surgical trauma, inflammation, and hearing loss associated with infusion or microinjection techniques has led to the investigation of a less invasive delivery method to the cochlea. The potential to deliver a variety of vectors across an intact round window membrane by leading vectors onto a Gelfoam patch has been explored. A denovirus and liposome vectors but not the AAV vector have successfully transfected cochlear tissues.

Preclinical Applications of Gene Therapy

The preclinical applications of gene transfer in the inner ear have focused upon four broad areas. The first application was to demonstrate the protective effects of various neurotrophins and growth factors in certain ototoxic circumstances. Secondly, gene therapy technology has been used to introduce antioxidant gene overexpression as a technique of ameliorating aminoglycoside-induced oxidative stress. Finally, gene transfer technology has been used to induce the differentiation of nonsensory organ of Corti cells toward hair cell fates, a preliminary step toward hair cell regeneration.

Certain neurotrophins and growth factors, including brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and glial cell line-derived neurotrophic factor (GDNF), have been expressed within the cochlea as transgenic products. These agents have served to protect sensory hair cells and the primary auditory neurons against atrophy and degeneration. Staecker and colleagues, in 1998, used a herpes simplex virus-1 (HSV-1) vector to deliver BDNF to the inner ear and assessed its protective effect against neomycin.37 This gene therapy group demonstrated a 94.7% salvage rate for SGNs, in contrast to a 64.3% loss of SGNs in control animals. Both in vitro and in vivo models have been used to test the protective effect of AAV-mediated BDNF expression.38 A significant survival of SGNs in cochlear explants transduced with AAV-BDNF and challenged with aminoglycoside relative to controls was observed. In the in vivo experiment, animals infused with AAV-BDNF with an osmotic mini-pump displayed enhanced SGN survival. The protection from AAV-BDNF therapy was region-specific; there was protection at the basal turn of the cochlea but not in the middle or apical turn. The authors proposed that this regional selectivity is a pharmacokinetic phenomenon.

NT-3-mediated protection against cisplatin-induced ototoxicity has been documented using an HSV-1-derived viral vector. The efficacy of the vector was established in an in vitro study, in which HSV-1-mediated transfer of NT-3 (demonstrated by production of NT-3 mRNA proteins and by reporter gene expression) conferred increased survival to cochlear explants after cisplatin exposure.39 These HSV-1 effects were confirmed in an in vivo model, in which HSV-1-mediated transfer of NT-3 to SGNs suppressed cisplatin-induced apoptosis and necrosis.

The efficacy of an Ad vector carrying the GDNF gene (Ad.GDNF) to protect against a variety of ototoxic insults has been established. When administered prior to aminoglycoside challenge, Ad.GDNF significantly protects cochlear and vestibular hair cells from death. Pretreatment with Ad.GDNF also provides significant protection against noise-induced trauma and transient cochlear ischemia.40–41 Finally, Ad.GDNF enhances SGN survival when administered 4 to 7 days after ototoxic deafening with aminoglycosides.

Antioxidants represent a potential therapeutic tool to counter the destructive effects of reactive oxygen species that are considered to be triggered by aminoglycoside-induced ototoxicity.42–43 Recently, inner ear gene therapy has been used to corroborate the protective effects of antioxidants against aminoglycoside-mediated ototoxicity.44 Catalase and superoxide dismutase (SOD2) were introduced into the cochleae of guinea pigs, which were subsequently challenged with kanamycin and ethacrylic acid. The catalase and SOD2-expressing animals preserved their auditory brainstem thresholds and had significantly less hair cell loss when compared to control animals.

Inner ear gene therapy has also been used to verify the molecular "switch" responsible for turning on the genetic program for supporting cell differentiation toward a hair cell fate. Math 1 is a basic helix loop helix transcription factor that is a master regulator gene in hair cell differentiation during cochlear development. To convert supporting, nonsensory cells phenotypically to hair cells Math 1 gene overexpression was used.45 Following Ad vector introduction, Math 1 transgene expression occurred mostly in supporting cells. Furthermore, 30 to 60 days following the transfer, auditory hair cells were identified with electron microscopy, and myosin VIIa was immunohistologically verified in ectopic locations near the organ of Corti. These "new" immature hair cells appeared to act as target sites for axon fibers that extended over a 50 μm range toward the newly formed ectopic hair cells. These results have been extended by introducing Math 1 into supporting cells of deafened guinea pigs through adenovirus transfection.46 Transfected animals showed phenotypically normal inner hair cells and a recovery of ABR levels to normal. These findings demonstrate the potential of gene therapy to cox a damaged mammalian ear toward regeneration via phenotypic transdifferentiation of nonsensory cells in the organ of Corti.

Risks and Limitations of Inner Ear Gene Therapy

Major risk factors associated with the introduction of either genes or cells into the inner ear are two-fold: damage to the cochlear structure and function as a consequence of the delivery modality and the relative safety of the biological material transferred. Delivery modalities that prevent damage to the cochlear structure and function have been described above. The safety of the gene transfer agent is determined by assessing its immunogenicity, toxicity, and unwanted dissemination of the therapeutic agent outside of the target region.

Utilizing AAV as the gene therapy vector, transgene expression within the contralateral cochlea of the AAV perfused animal has been observed, albeit much weaker than within the directly perfused cochlea.33 Expression of the transgene away from the intended target site, that is, within the contralateral cochlea, raises concern about the risks associated with dissemination of the virus from the target tissue. The appearance of the virus, distant from the site of infection, may be due to its hematogenous dissemination to near and distant tissues. However, this is unlikely due to the absence of the viral vector in near and distant tissues. Other possible explanations include migration of AAV via the bone marrow space of the temporal bone or via the CSF space to the contralateral ear.41 The perilymphatic space into which the virus was perfused is directly connected to the CSF via the cochlea aqueduct; transgene expression within the contralateral cochlea aqueduct has been demonstrated following introduction of the viral vector in the ipsilateral cochlea. Collectively, these results suggest that potential routes for AAV dissemination from the infused cochlea are via the cochlea aqueduct or by extension through the temporal bone marrow spaces.

Conclusions on Gene Therapy in the Inner Ear

A critical step forward toward the eventual application of gene therapy for hearing disorders has been accomplished: viral and nonviral vectors have been shown to be able to introduce and express exogenous genes into the peripheral part of the auditory system. Future refinements will include the development of newer hybrid vectors that assimilate the infectivity and stability of the viral vectors and the safety of liposomes. The hybrid vectors will largely replace the current generation of vectors. The preferred mode of introduction of gene therapy vectors will be those that minimize tissue damage and hearing loss, such as microinjection or application of the vector at the RWM. Safety concerns, specially regional and distant dissemination of the therapeutic agent, will have to be monitored and minimized.

Hair Cell Regeneration

Ricardo Cristobal, MD, PhD
Paul Popper, PhD
Fred A. Pereira, PhD

Hearing loss is a disability that affects approximately 1.7% of children under age 18. The incidence increases with age: approximately 31% of people over the age of 65 and 40 to 50% of people 75 years and older have hearing loss. According to World Health Organization estimates from 2005, approximately 278 million people worldwide have moderate to profound hearing loss. In a large majority of cases, hearing loss is the result of degeneration and death of hair cells and their associated spiral ganglion cells. This can result from accumulated or acute exposure to excessive noise, including loud work environments, increased use of portable electronic devices, and other loud noises, such as gunfire or explosions. Other common causes include infections and the use of ototoxic drugs. Hearing loss can impose a heavy social and economic burden on individuals, families, communities, and countries.

Children with hearing impairment often experience delayed development of speech, language, and cognitive skills, which may result in slow learning and difficulty progressing in school. In adults, hearing impairment and deafness often make it difficult to obtain, perform, and keep employment. As a result of hearing impairment, both children and adults may suffer from social stigmatization and isolation. The cost of special education and lost employment due to hearing impairment can also impose a substantial economic burden. Furthermore, loss of hair cells in the vestibular end organs of the inner ear can lead to balance disorders with significant associated morbidity and change in quality of life, particularly in the elderly.

Ultimately, the treatment of sensorineural deafness will require maintenance, repair, or regeneration of the structures involved. In a simplified model, restoration of inner ear function requires anatomical restoration of the hair cells of the sensory epithelia and associated structures and the formation of new, functional, and meaningful connections between hair cells and afferent and efferent neural elements. For some time it was thought that the vertebrate inner ear sensory epithelium lacked the ability to regenerate. However, over the past 25 years this concept gradually changed as studies in several different vertebrate species demonstrated various degrees of hair cell regeneration following acute loss of preexisting hair cells. In general, the term regeneration is used to describe mitotic division of progenitor cells within the tissue and their differentiation into mature specialized cells capable of restoring normal function. Yet in certain tissues such as peripheral nerves, the term regeneration refers to regrowth of neuronal axons without an intervening cell division. In the inner ear, sensory epithelia hair cell regeneration refers to restoration of the hair cell population and is thought to result from various mechanisms, individually or in combination: (1) proliferation of hair cell progenitors through mitotic division; (2) transdifferentiation of surrounding supporting cells; (3) repair of partially damaged hair cells; and (4) migration and differentiation of nonsensory epithelial cells.

Multiple experimental protocols have been designed to investigate the biological processes of hair cell origin, proliferation, and differentiation following the destruction of preexisting hair cells. In in vivo models, hair cells have been damaged with laser beams (fish lateral line organ hair cells), ototoxic drugs (vestibular and auditory hair cells), or with sound trauma (auditory hair cells). These experiments provided information about the existence and degree of hair cell regeneration in the normal adult vertebrate under physiologic conditions. In in vitro organ culture experiments, hair cells have been damaged with laser beams or with ototoxic drugs, and the process of regeneration has been evaluated directly, with time-lapse video microscopy, or indirectly, in histological preparations of organs fixed at different times after treatment. One characteristic of organ culture conditions is that the relative contributions to new hair cell formation of systemic factors such as inflammation cells and mediators are eliminated. But, in a third group of experimental protocols, the sensory epithelia of adult and developing ears were dissociated and dispersed cells were cultured, minimizing the effects of the normal physical and chemical interactions that occur between contiguous cells in the putative tissue. In all 3 experimental paradigms, mitotic tracers have allowed quantification of the process of cell division and subsequent differentiation. Newer lines of hair cell regeneration research have focused on the identification of genes that trigger the cellular program of hair cell development. Research on inner ear development has produced considerable information regarding extracellular soluble molecules that regulate the process of cell differentiation, cell–cell contact proteins that regulate patterning of the sensory epithelia, and intracellular signaling pathways and transcription factors that control the cell cycle. This information has proved invaluable in understanding hair cell regeneration in the adult animal. Progress also has been made in understanding the mechanisms that govern hair cell survival and repair. Atenuation of hair cell death has been achieved with the application of neurotrophic factors, antioxidants and antiapoptotic agents. The immune system has also been shown to play an important role in this process.

Studies in the last few years have demonstrated that the inner ear sensory epithelium of adult mammals contain stem cells capable of dividing indefinitely and of generating multiple cell types. This has raised hopes for restoring damaged inner ears by stimulating these cells in the putative epithelium or by transplanting these cells into the damaged ear to replace lost hair cells. This exciting and promising discovery also affords new avenues for investigating the molecular mechanisms that govern hair cell formation. This chapter reviews the field of hair cell regeneration as it has evolved over the past quarter century. A large body of literature has been produced during this time period.

VERTEBRATE INNER EAR ANATOMICAL ORGANIZATION

The inner ear of vertebrates contains vestibular organs capable of sensing gravitational pull, vibrations of the ground, linear and angular acceleration of the head and auditory organs that detect sound pressure waves. Both the auditory and the vestibular end organs have specialized patches of neurosensory epithelia that transduce mechanical stimuli into chemical signals, which are ultimately conveyed to the brain through the afferent innervation. The general organization of the vestibular sensory epithelia is common to all vertebrate organs and consists of sensory hair cells, supporting cells, afferent and efferent nerve
birds and mammals and has different structural organization\(^5\) (Figure 2). In humans, the auditory epithelium contains 3 rows of outer hair cells and 1 row of inner hair cells. The supporting cells surround the hair cells and fluid-filled spaces in a more intricate arrangement. Structural and possibly molecular differences among classes may account for the capability of spontaneous regeneration of the avian but not the mammalian auditory epithelia. While the hair cells and afferent neurons have been the subject of intense investigation for many years, the supporting cells have been assumed to play mostly a structural role and have received little attention. Recent studies on hair cell regeneration have suggested that supporting cells contribute to the generation of new hair cells in the adult vertebrate ear, and this has raised the level of interest in this cell type.

HAIR CELL REGENERATION

Fish and Amphibians

For many years, it was believed that vertebrates were born with the full complement of inner ear hair cells, and that those lost throughout the life of the animal were never replaced. However, quantitative studies performed in 1981 demonstrated that 80% of the inner ear hair cells in adult sharks are produced in the postnatal period.\(^6\) The majority of the new hair cells are produced in a germinal zone at the edges of the epithelia. This original study sparked a great deal of interest in the production of hair cells beyond the embryonic period. Cell division and postnatal production of new hair cells in the peripheral growth zone of the inner ear sensory epithelia was documented next in amphibians by demonstrating the incorporation of mitotic tracers into dividing epithelial cells and the subsequent localization of the tracer in newly formed hair cells.\(^7\) The natural next step was to investigate the possibility of hair cell regeneration following loss of preexisting ones.

Fish and amphibians have a specialized organ along the sides of their bodies termed the lateral line, which is stimulated by water currents and micromovements around their body (Figure 3). Immediately beneath the skin are hair cells that are similar to their inner ear counterparts. This organ provides an optimal model for direct visualization of hair cell formation in live animals. Time-lapse videomicroscopy of the lateral line was carried out following selective ablation of hair cells with a laser microbeam.\(^8\) This provided the first direct evidence of an increased rate of supporting cell division and subsequent differentiation of the progeny into supporting cells and new hair cells. Other in vivo studies delivered gentamicin to the bullfrog perilymphatic space and established a dose that induces complete hair cell regeneration following loss of preexisting ones.

Figure 1 Graphic representation of the general organization of the vertebrate vestibular sensory epithelia. Supporting cells rest on the basal membrane with their nuclei basally oriented and aligned. Their cytoplasm spans the full thickness of the epithelium. Hair cells rest on the supporting cells. Type I hair cells are flask shaped and are surrounded by chaliceal afferent nerve endings. Type II hair cells are cylindrical and receive bouton-type afferent nerve endings. Efferent nerve endings are bouton-type endings that contact both chaliceal endings and type II hair cells. Gel matrix rests over the kinocilia.

Figure 2 Depiction of the mammalian auditory organ. (A) The cochlear sensory epithelium is coiled around an axis, the modiolus, which contains the neuronal cell bodies. (B) The cochlear hair cells form 1 row of inner hair cells that receive the majority of the afferent innervation and 3 rows of outer hair cells. The inner and outer hair cells are separated by supporting cells and fluid-filled tunnels.

Figure 3 Representation of the lateral line of fishes. (A) The lateral line spans the length of the animal body (dark line). (B) Magnified cross section of 1 canal, illustrating the structure of the sensory organ, composed mainly of hair cells, supporting cells, afferent nerves, and a gelatinous cupula overlying the epithelium. This organ is sensitive to sound pressure waves and to movement of the surrounding fluid.
cell destruction with minimal disruption of other components of the sensory epithelium. A after a time there was recovery of the hair cell number and restoration of vestibular afferent response to stimuli, suggesting that new functional connections do indeed form between afferent neurons and the regenerated sensory hair cells. In parallel studies, vestibular sensory epithelia of bullfrogs were microdissected, and cells dissociated and placed in culture. The in vitro preparation allowed direct microscopic documentation of supporting cell division and asymmetrical differentiation of the progeny into hair cells and round cells. This demonstrated that vestibular sensory epithelia of adult animals contain precursor cells capable of generating new hair cells and that mitotic division is a mechanism for new hair cell formation in vitro.

Birds

Avian Vestibular System. The avian vestibular system is an easy model to work with and has remarkable similarities in structure and function to its mammalian counterpart. Unlike fish and amphibians, the vestibular sensory epithelia of adult birds lack a peripheral area of growth. Early regeneration studies in the avian vestibular epithelium demonstrated in vivo continuous production of new hair cells at a low rate in all regions of the intact sensory epithelium. Similarly, formation of both supporting cells and hair cells was demonstrated in organ cultures of normal postnatal chicken utricles. In another study, the degree of cell proliferation was shown to increase in damaged sensory epithelia. Young chickens treated with streptomycin injections to induce hair cell damage underwent a significant increase in the rate of supporting cell proliferation, which was followed by complete anatomical restoration of the epithelium. In a subsequent study, sheets of sensory epithelia were isolated from the utricles of chicks and cultured in serum-free and serum-containing media. The proliferation of epithelial supporting cells was assayed using the mitotic tracer bromodeoxyuridine. Similar levels of supporting cell proliferation were observed in epithelia maintained in serum-free and serum-containing media, suggesting that the vestibular epithelium of birds contain all the mitogens necessary for the continued proliferation of epithelial supporting cells.

Recovery of function was investigated in vivo in 4- to 8-day-old chicks treated with intramuscular streptomycin for 5 days. Within 1 week, the vestibular hair cell density decreased to 40% of normal, and there was no measurable vestibulo-ocular reflex (VOR) gain. In the subsequent 2 weeks, the average hair cell density increased along with the average VOR gain and phase. By 8 to 9 weeks after the ototoxic insult, the hair cell density and the VOR parameters had returned to normal values. The VOR recovery correlated better with the rise in type I than type II hair cell density. Furthermore, when comparing hair cell density within the control and treated organs, this study found that epithelia with similar hair cell density had a range of VOR gains. The study suggested that several factors, such as degree of repair of stereocilia, efficacy of hair cell synapses on afferent fibers, and the extent of compensation by central vestibular pathways also contribute to the recovery of VOR gain.

Avian Auditory System. The auditory peripheral organ of birds, the basilar papilla, evolved independently from its mammalian counterpart and is structurally different. In chickens, this organ contains a long spatula-shaped strip of epithelium bearing supporting cells and hair cells. Its sensory cells have been classified into tall hair cells, which have elongated morphology and are arranged along the superior neural side of the epithelium, and short hair cells, which are wide and short and are located along the inferior abneural side of the epithelium (Figure 4). As in the mammalian inner ear, there appears to be a division of labor between these 2 cell types, with the tall hair cells receiving predominantly afferent innervation and the short hair cells receiving efferent innervations. The characteristics and the innervation patterns of these 2 cell types suggest that they are analogous to the inner and outer hair cells, respectively, of the mammalian cochlea. The supporting cells rest on the basilar lamina and have narrow, elongated cytoplasm in between the hair cells. Unlike the mammalian cochlea, there are no tunnels or spaces within the avian auditory sensory epithelia.

In vivo auditory hair cell regeneration studies in birds have focused on the restoration of the inner ear sensory epithelia following acoustic trauma or ototoxic drug administration. Excessive pure-tone stimulation results in hair cell damage that follows a tonotopical or frequency-specific distribution. In general, the short hair cells in the inferior or abneural portion of the epithelium of the respective frequency-sensitive area were preferentially damaged. As the duration of the noise exposure increased, the position of damage shifted to the neural portion of the epithelium containing the tall hair cells. In animals treated with a mitotic tracer, new hair cells bearing the mitotic marker were observed at later time periods, demonstrating that mitotic division of precursor cells contributed significantly to the process of regeneration.

Hair cell regeneration in the avian cochlea has also been studied following ototoxic damage. With lower doses of ototoxic agents, the hair cells in the proximal or basal region of the epithelium, representing high frequency pitch location, were most affected. Larger doses of the drug or longer administration periods affected progressively lower frequency hair cells. The anatomical and/or physiological causes for this differential sensitivity remain unclear. A diminishment of a mitotic tracer allowed demonstration that only the cells in the damaged region of the epithelium entered the S phase of the cell cycle and underwent division. A reliable organ culture preparation of the chick basilar papilla has been developed, and this allowed confirmation of these findings under direct microscopic observation.

It is encouraging that following noise-induced trauma or ototoxic auditory epithelia damage, there is recovery of auditory thresholds in association with restoration of the normal organ structure. Pure-tone-induced trauma results in threshold shifts of 50 to 70 dB in the frequencies around the stimulus. Ultrastructural studies revealed that the localized lesion induced by pure-tone exposures resulted in damage to the tectorial membrane, changes in surface organization of the papilla, and loss of short hair cells. In chickens, the threshold shift recovered to 9.4 dB hearing loss on average by only 3 days after exposure. While many new hair cells reappear within these 3 days, their immature stereocilia are still not coupled to the restored tectorial membrane. Thus, the initial recovery has been attributed to restoration of the tectorial membrane overlying the unaffected tall hair cells, allowing it to couple to and stimulate the cells. This is not surprising since nearly all the afferent innervation of the basilar papilla is associated with the tall hair cells. A low degree of recovery continued over the subsequent 10 days, up to a final permanent threshold shift of about 5 dB. Further measurements of threshold sensitivity and frequency selectivity in the nucleus magnocellularis correlated recovery of function with structural recovery of the basilar papilla, suggesting that the source of the threshold shift was restricted to the cochlea. Behavioral studies, which reflect a response to an acoustic signal and which are considered a more sensitive measurement of recovery, agreed with the findings and the time course of recovery of earlier-evoked potential studies.

Otoxicity studies allowed evaluation of recovery of auditory function without the confounding factors of damage to the tectorial...
membrane and selective hair cell subtype sensivity inherent in acoustic trauma studies. Following aminoglycoside administration, both tall and short hair cells from the basilar papilla are affected, with a predilection for the basal aspect of the papilla, as described earlier. One study measured the cochlear nucleus evoked potential thresholds in neonatal chickens after gentamicin treatments. There was immediate isolated high frequency threshold shift with progression over the ensuing 5 weeks to involve the entire frequency range tested (0.25 to 5 kHz). Hearing loss correlated well with the time course of hair cell damage. Early loss of hair cells in the basal or high frequency aspect of the cochlea also progressed in the apical direction over the following weeks in a pattern that matched the threshold shift across frequencies. Sixteen to 20 weeks after treatment, robust recovery of thresholds was found for low and mid-frequencies, with a significant residual high frequency hearing loss. The pattern of functional recovery matches the structural recovery of hair cells in the basilar papilla of hatching chickens and was slightly faster in Bengalese finches. The hair cell density was found to be normal in the long term. The residual high frequency shift was associated with disorganization in the basal cochlea, residual regenerated hair cell functional immaturity, and shortcomings in the synaptic reconnections of nerve fibers with the regenerated hair cells.

In summary, the avian inner ear has the capability to regenerate hair cells following acoustic trauma or ototoxic damage. Furthermore, there is recovery of function of the auditory organs. The slower recovery of auditory function after gentamicin exposure when compared to acoustic trauma is thought to be related to the fact that hair cell loss is prolonged and the newly regenerated tall hair cells need to be reconnected with the afferent nerve fibers.

Mammals

In mammals, the vestibular epithelia are morphologically similar to those of the lower vertebrates, leading to speculation that hair cell regeneration could take place in the mammalian vestibular end organs as well. In a seminal in vivo study from 1993, mature guinea pigs were treated with gentamicin. Scanning electron micrographs and thin section histological preparations demonstrated loss of utricular hair cells. Four weeks after completion of the treatment, a large number of cells with immature hair bundles in multiple stages of development were identified in the epithelia. The lost type I hair cells were replaced by cells with the morphological appearance of type II hair cells. This study demonstrated an unexpected capacity for hair cell regeneration in vivo in the mature mammalian inner ear. In parallel studies, explants of the utricular maculae of guinea pigs and of humans (this was the first regeneration study in human inner ear sensory epithelia) were placed in culture and treated with aminoglycoside antibiotics at doses that killed the hair cells. Supporting cell proliferation was documented under these conditions. After 4 weeks in culture, the epithelia contained new cells with some phenotypical characteristics of immature hair cells. Multiple studies investigating hair cell formation in the mammalian vestibular end organs followed. In the normal untreated adult guinea pig, utricle cells carrying immature-appearing stereocilia were identified, representing 0.7% of the utricular hair cell population. This study suggested that some degree of hair cell replacement may be an active process in the vestibule of adult mammals. In the chinchilla, administration of gentamicin to the perilymphatic space resulted in direct damage to the hair cells. This was followed by postmitotic formation of new hair cells and complete restoration of the hair cell density 8 weeks after treatment. In another study gentamicin was injected trans tympanically in guinea pigs, and the epithelia were evaluated with scanning electron microscopy up to 10 months after treatment. A significant degree of hair cell loss, predominantly type I, was found in the first 4 weeks after treatment. Only limited long-term recovery of mature hair bundles was found, and it did not result in complete restoration of the epithelium. Type I hair cells were found to be more susceptible to ototoxic damage than type II hair cells. In summary, studies agree that the vestibular sensory epithelia of mammals have some regenerative capability, albeit low.

Recovery of vestibular function in mammals following damage to the hair cells was documented in two additional studies. In one study, guinea pigs were treated with streptomycin until postrotatory nystagmus response was eliminated. The response was completely reestablished within 22 days along with recovery of the expression of a hair cell marker. A study in humans reported return of vestibular function after treatment with streptomycin for Ménière disease although the anatomical basis for this remained unclear, and incomplete penetration of the drug as well as recovery of neural structures may have contributed.

In the mammalian cochlea, the potential for hair cell regeneration in embryonic and neonatal mouse organs of Corti maintained in vitro has also been examined. Small numbers of hair cells were killed by laser microbeam irradiation, and the subsequent recovery processes were monitored by direct differential interference contrast microscopy combined with continuous time-lapse video recordings. Replacement hair cells were observed to develop in lesion sites in embryonic cochleae and, on rare occasions, in neonatal cochleae. In embryonic cochleae, replacement hair cells developed from preexisting cells that changed from their normal developmental fates without any intervening mitosis. In neonatal cochleae, epithelial lesions were created with a laser beam resulting in an average of at least 3 damaged hair cells per lesion. Of 245 lesions analyzed, only 11 apparently regenerated hair cells and a single hair cell labeled by a mitotic tracer were observed. The results indicated that the organ of Corti can replace lost hair cells during embryonic development. The ability to generate new hair cells in the neonate was only anecdotal.

In vivo, hair cell regeneration in the mammalian cochlea was investigated in 9-day-old rat pups. The animals received amikacin injections for 7 consecutive days and were sacrificed at intervals up to 90 days postinjection. At 21 and 35 days after treatment, atypical cells bearing tufts of microvilli and resembling immature hair cells were observed in the outer hair cell region. The cells in the inner hair cell area lacked stereocilia but had afferent and efferent innervations. The study suggested that the cochlea only regenerates incompletely and does not reach the mature morphology.

In summary, in mammals there is evidence for only partial recovery of hair cells in the vestibular system. Only 2 reports of associated recovery of function are available. The evidence for spontaneous hair cell recovery in the cochlea is, thus far, unclear. Recent studies, though, have been successful at stimulating new cochlear hair cell formation through modification of the expression of the Math 1 transcription factor genes, as will be reviewed later in the chapter. The ability to regenerate the inner ear of different vertebrate species is summarized in Table 1.

### MECHANISMS FOR HAIR CELL RECOVERY

The origin of the recovered hair cells is still debated, and multiple mechanisms for hair cell regeneration have been proposed. Several experimental protocols have been designed and demonstrated partial or complete recovery of hair cell density through precursor cell proliferation, supporting cell transdifferentiation, haircell regeneration, and other processes. A summary of these mechanisms is presented in Table 1.

| Table 1 Hair Cell Regeneration in Vertebrate Species |
|-----------------|-----------------|-----------------|-----------------|
| Species and Organ | Continuous Hair Cell Formation | Proliferation after Damage | Spontaneous Hair Cell Regeneration | Recovery of Function |
| Fish and amphibian Inner ear and lateral line | + | + | + |
| Bird vestibular organs | + | + | + |
| Bird auditory organs | - | + | + |
| Mammalian vestibular organs | - | + | +/- |
| Mammalian auditory organs | - | - | +/- |
cell repair, cell migration, and a combination of the above.

Supporting Cell Proliferation
This mechanism consists of proliferation of supporting cells and differentiation of the progeny into hair cells and supporting cells (Figure 5). A avian inner ear regeneration studies have demonstrated upregulation of supporting cell proliferation around the region of hair cell loss under multiple conditions: in vivo in the chick utricle following ototoxic damage,52 in organ cultures of the basilar papilla after laser ablation,25 and in the basilar papilla in vitro,51 and in vivo after ototoxic damage.54 In mammals, cultures of guinea pig and human utricles treated with neomycin in the presence of the mitotic tracer tritiated thymidine led to the appearance of labeled nuclei in the basal aspect of the epithelium 2 to 6 days after treatment.33 By 4 weeks some labeled cells had migrated to the apical aspect of the epithelium. A number of these apical labeled cells went on to develop immature hair bundles, demonstrating postmitotic hair cell formation. Uregulation of supporting cell proliferation has also been demonstrated in the chick utricle following ototoxic damage.25

Supporting Cell Transdifferentiation
Another proposed mechanism for new hair cell formation is the conversion of the phenotype of supporting cells to hair cells without intervening mitosis (Figure 6). A bundant evidence supporting this mechanism is available. In vivo studies investigating morphological changes in the chick basilar papilla suggest that otoxicity leads to an initial wave of hair cell formation through transdifferentiation, followed by a second, slower wave of mitotic new hair cell formation.33 In other in vivo studies, chicks were treated with an ototoxic drug followed by the mitotic blocker Ara-C. This was followed by formation of immature new hair cells, suggesting a direct change of the supporting cell phenotype.54 In mammalian studies, guinea pigs received a transtympanic injection of gentamicin and a mitotic tracer. Soon after treatment, light and scanning electron microscopy techniques allowed demonstration of a variable degree of hair cell loss, while the supporting cell density remained constant. Subsequently, a small number of cells in the supporting cell region incorporating the mitotic tracer were identified, indicating a low degree of cell proliferation. Also, new immature hair cells without the tracer were noted to emerge, suggesting that new hair cell formation during this time period was due to supporting cell transdifferentiation rather than proliferation.41

Hair Cell Repair
The hair cell repair theory proposes that hair cells are only partially damaged following an insult. The damaged hair cells become sequestered below the reticular lamina and are internalized among the supporting cells. These cells may then remain dedifferentiated or regrow a apical process that regains contact with the surface of the organ (Figure 7). Direct videomicroscopic documentation for this mechanism was obtained in cultures of bullfrog saccule following ablation of hair cells with a laser pulse.55

In cultures of neonatal rat utricles, destruction of hair cells by ototoxic agents was followed by recovery of the hair cell number. While the supporting cell number remained constant, the degree of cell proliferation was limited and far below the number of recovered hair cells, suggesting that other mechanisms besides proliferation led to hair cell regeneration.43 Furthermore, this study presented ultrastructural evidence for hair cell repair and regrowth of the stereociliary tuft. Other morphological studies have demonstrated hair cell repair in the mammalian cochlea.56,57 In organ cultures of the newborn mouse organ of Corti, hair cells damaged mechanically or with a laser pulse: (1) lost their stereocilia but survived at the surface of the organ; (2) retained contact with the reticular lamina but were overgrown by the processes of the supporting cells; or, (3) became internalized among the supporting cells and either remained dedifferentiated or resurfaced with newly formed apical processes.

Cell Migration
In the basilar papilla of chickens, localized destruction of both hair cells and supporting cells with severe acoustic trauma was followed initially by replacement of the lost cells by a layer of flattened epithelial cells.58 These cells are thought to derive from the hyaline cells or cuboidal cells normally located along the inferior abneural edge of the basilar papilla.59 Thus, hyaline cell migration may be involved in maintenance or repair of the severely damaged cochlea (Figure 8).

REGULATION OF HAIR CELL FORMATION: MOLECULAR ASPECTS
During mammalian embryogenesis, cochlear hair cells and supporting cells have common cellular precursors.60-63 The formation of a cellular mosaic of sensory hair cells and nonsensory cells is a highly regulated developmental event involving cell fate decisions, coordinated cell division, pattern formation, and differentiation.64 Much of the research in regeneration revolves around the identification of master, regulatory genes that control the processes of patterning and hair cell formation, as have been shown in other systems. Controlled manipulation of these genes may lead to hair cell recovery.

Extracellular Signals
Research has focused on signaling mechanisms that regulate the decision to commit to mitotic division or to remain quiescent.

Soluble Factors. Multiple growth factors and hormones that might promote hair cell formation have been investigated. When intact basilar papillae are co-cultured with aminoglycoside-damaged papillae, the intact papillae experience increased rates of incorporation of the mitotic tracer, tritiated thymidine, suggesting that a diffusible factor is released by the injured papillae that stimulates cell proliferation.64 In dissociated cell culture preparations of the bullfrog, supporting cells express receptors for brain-derived neurotrophic factor (BDNF), and basic fibroblast growth factor (bFGF).59 In the same preparation, bFGF induces cell proliferation early after dissociation, while BDNF exerted its effect only at a later time and contributed to promoting hair cell differentiation and survival. In the chick vestibular epithelium, insulin-like growth factor 1 stimulates DNA synthesis in a dose-dependent manner.66 Retinoic acid and bFGF have also been implicated in the control of the cell cycle in the avian sensory epithelium.65 In mammals, transforming growth factor alpha (TGFα) and epidermal growth factor (EGF), in the presence of insulin,
stimulate cell proliferation in adult mouse vestibular epithelial cultures. Receptors for heresulmin, a member of the EGF family, are widely expressed in vestibular and auditory sensory epithelia in neonatal and adult mouse inner ears. Heresulin-α, however, stimulates cell proliferation in organotypic cultures of neonatal, but not adult, mouse utricular sensory epithelia. Thus, this factor may play a role in growing/developing but not in differentiated/quiescent epithelia. Studies evaluating the role of BDNF in the utricle of the chinchilla ear after ototoxic damage suggested that it may be involved in the maintenance of the vestibular ganglia and contribute to neurite outgrowth to new and repaired hair cells. A variety of other trophic factors regulating the cell cycle in the developing and mature inner ear have been described.

Cell–Cell Contact. Cell–cell contact interactions are crucial for cell cycle regulation in the sensory epithelia. In cultures of small pieces of chicken utricular epithelia, the degree of cell proliferation was inversely related to local cell density. N-cadherin is a protein belonging to a family of transmembrane molecules that mediate calcium-dependent intercellular adhesion. Cadherins are involved in controlling morphogenetic movements of cells during development and regulating cell surface adhesion. In cultures of chicken inner ear sensory epithelia, binding of microbeads coated with a function-blocking antibody to N-cadherin inhibited ongoing cell proliferation. The growth of epithelial cells was also affected by the density of extracellular matrix molecules. Notch and its ligands, Delta, Serrate, and Jagged, are cytoplasmic membrane proteins that mediate cell–cell contact interactions. The Notch pathway mediates 3 types of developmental processes: (1) lateral inhibition between neighboring cells; (2) lineage decisions (determination of cell fate between two daughter cells); and (3) boundary formation (such as between sensory and nonsensory epithelia). Transient administration of Notch ligands to the adult rat brain resulted in expansion of the stem cell population. In mice, genes encoding the receptor protein Notch1 and its ligand, Jagged-2, are expressed in alternating cell types in the developing sensory epithelium. Genetic deletion of Jag2 results in a significant increase in sensory hair cells, presumably as a result of a decrease in Notch activation. More recent studies suggested that the Notch pathway not only mediates lateral inhibition but also participates in the control of cell proliferation during ear development. Multiple studies involving genetic mutations, overexpression, or ectopic expression of specific Notch signaling cascade protein genes in the inner ear sensory epithelium demonstrated formation of supernumerary hair cells and/or supporting cells. In these models, new cells arose from expansion of the precursor cell pool, secondary division of the precursor cells, proliferation and transdifferentiation into hair cells, or the recruitment and transdifferentiation of adjacent nonsensory cells. In summary, cell density, cell–cell contact signaling and the composition of the extracellular matrix are essential factors in the regulation of hair cell formation.

Intracellular Signaling Pathway

Downstream from the processes above, the intracellular signaling pathways regulate cell proliferation and differentiation in the sensory epithelium.

Cell Cycle Regulation. Cell cycle regulation requires the appropriately coordinated activities of various cyclins and cyclin-dependent kinases, which are tightly regulated by multiple effector proteins. One family of regulator proteins is the Cip/Kip family of molecules (cyclin-dependent kinase inhibitory protein/kinase inhibitory protein). This family includes the protein p27kip1, which was recently discovered in supporting cells of the organ of Corti. p27kip1 plays a critical role in cell cycle arrest and in maintaining the differentiated phenotype of sensory epithelial cells during development and is the first known marker for the patch of epithelial cells destined to become the sensory epithelium. Interestingly, developing hair cells downregulate p27kip1 while supporting cells continue to express it. Mice that lack p27kip1 continue to develop hair cells and supporting cells beyond the normal period. Moreover, supporting cells in mice lacking p27kip1 can generate new cochlear hair cells after acoustic trauma-induced hair cell loss. Thus, release of the inhibition of the cell cycle induced by these molecules in a controlled fashion may allow the regeneration of hair cells in the adult auditory sensory epithelia. In a recent study, supporting cells from the adult mouse cochlea were purified and cultured in vitro under conditions that support growth and differentiation. Some supporting cells downregulated the cell cycle inhibitor p27kip1 and transdifferentiated into hair cells, suggesting that this gene may be important for repressing regeneration in the adult mammalian cochlea.

Another gene involved in cell cycle control, the retinoblastoma (Rb) gene, is required for cell-cycle exit and to prevent reentry into cell cycle of embryonic mammalian hair cells. However, the role of the Rb gene in postnatal hair cells is unknown. In mice with deletion of the Rb gene, hair cells continue to divide and can transduce mechanical stimuli in the early postnatal period. However, in adult life these mice exhibit progressive degeneration of the organ of Corti with profound hearing loss but only partial loss of vestibular function. Targeted deletion of another cyclin-dependent kinase, Ink4d, also leads to reentrance of hair cells into the cell cycle and hair cell death, with subsequent hearing loss. The mitogen-activated protein kinase (MAPK) intracellular signaling pathways transduce a large variety of external signals, leading to a wide range of cellular responses, including growth, differentiation, inflammation, and apoptosis. Studies in birds demonstrated that MAPK pathway plays a crucial role in regulating cell cycle in the avian inner ear. In the developing rat organ of Corti, inhibition of cyclin-dependent kinases resulted in differentiation of precursor cells without an intervening mitosis, suggesting their participation in normal development of the organ of Corti.

Hair Cell Differentiation. Math1 is a transcription factor that is expressed in the developing sensory epithelia of the inner ear at early embryonic stages. In a recent study, Math1–null mutant mice were generated and had complete lack of hair cells and supporting cells. This study suggested that Math1 is required to initiate inductive signals that regulate the overall formation of both hair and supporting cells from the sensory epithelium at the very early stages of development, and that it is necessary for hair cell formation. In another study, neonatal rat cochlear organ cultures were transfected with the Math1 gene; overexpression of this factor in nonsensory cells adjacent to the sensory epithelia led to their differentiation into hair cells. Similar findings were obtained in vivo in the normal adult guinea pig cochlea following Math1 gene transfer, demonstrating that Math1 expression is sufficient for hair cell differentiation. Newly formed hair cells resulted in improved hearing thresholds. However, the morphology of these regenerated or transdifferentiated hair cells was at a poor level, suggesting that better control of Math1 expression (timing and level) during delivery may be critical. Moreover, other pathways may be involved and require simultaneous regulation. A nodule transcription factor, Hes1, has been shown to negatively regulate hair cell differentiation by antagonizing Math1. Taken together these studies demonstrate that forced expression of Math1 in the mammalian adult inner ear may lead to differentiation of supporting cells into hair cells. Effective regeneration of the cochlea, however, is likely to require the generation of new supporting cells as well as hair cells. Co-transfection experiments in postnatal rat explant cultures show that overexpression of Hes1 prevents hair cell differentiation induced by Math1, further supporting the role of Math1 in hair cell formation.

Other factors important for hair cell formation have also been discovered and may represent important targets for hair cell regeneration genetic therapies. The transcription factor Brn-3.1 is expressed in the inner ear hair cells throughout life and is necessary for their development. Mice with mutation of both copies of the Brn-3.1 gene had complete deafness due to no identifiable cochlear hair cells and greatly reduced numbers of spiral ganglia cells. In mice with a mutation of only 1 copy of the Brn-3.1 gene, the remaining intact copy of the gene is sufficient to maintain a normal cochlea. A mutation in the human homologue of this gene has been shown to be related to adult-onset sensorineural hearing loss.

In summary, studies to date have unveiled multiple signaling pathways involved in hair cell formation. They highlight the importance of
coordinated expression of all genes involved in the cell cycle control, including those that regulate patterning of the epithelium and those that inhibit cell proliferation, as well as those that enhance it.

**NEW LINES OF RESEARCH: STEM CELLS**

As stated earlier, only anecdotal evidence of hair cell regeneration in the mammalian cochlea has been produced to date. This has led to the search for new ways to restore the hair cell population in damaged auditory organs. In 1998 human embryonic stem cell lines were isolated and expanded for the first time. This generated a tremendous amount of interest in embryonic and adult stem cells and their potential for treating diseases involving the loss of specific cell types, including hair cell loss in the inner ear sensory epithelia. The use of this technology has resulted in great progress in our understanding of the process of hair cell formation in the developing and regenerating ear.

**Definition and Properties of Stem Cells**

Stem cells are primitive, undifferentiated cells that are defined according to functional criteria: they must have the ability to self-renew and the ability to differentiate into more than one cell type. During stem cell division, at least 1 of the daughter cells must remain a stem cell to maintain the lineage, while the other daughter cell may differentiate or remain as a stem cell.

Stem cells can be found in embryonic and adult tissues. During development, as the divisions progress from the fertilized oocyte, the cells become progressively restricted in the cell types that they can produce and in their ability to proliferate. Initial totipotent cells formed from the first postfertilization cleavages are able to develop into complete new animals. In mammals, this capacity is lost as the early morula matures to form the late morula and blastula. The latter has an outer layer of cells, the trophoectoderm, and an inner layer of cells, the inner cell mass. Pluripotent embryonic stem cells (ESCs) can be established from the inner cell mass and are used extensively in stem cell research (Figure 9). The cells from the inner cell mass are capable of generating cells from all 3 layers of the embryo: the endoderm or inner layer, the mesoderm or middle layer, and the ectoderm or outermost layer. The latter gives rise to multiple tissues including skin and adnexa, neural tissue and the inner ear epithelia and associated nerve supply. Inner cell mass cells placed in culture and exposed to the proper biochemical signals are able to divide indefinitely and to generate the different cell types in the body, which makes them great candidates for developmental and regeneration research. Other fetal tissues including umbilical cord and placenta have been used to obtain fetal stem cells that develop into various organs. Stem cells are also found in adult tissues. As development proceeds, cells go through a series of restrictions in potency until they become committed to different cellular fates. As they do, rare cells are set aside in specific tissues that maintain a high proliferational and developmental potential, the so-called somatic stem cells (SSCs) that are found in embryonic and adult tissues and organs. The number of adult stem cells in tissues may be extremely small. In addition, adult stem cells proliferate at fairly low rates compared to ESCs, making expansion of these cells more challenging. Progenitor cells (PCs) are cell types intermediate between the stem cells and mature cells. They are in transit and amplifying stages that have multilineage differentiation capacity but lack the ability for unlimited self-renewal. The highest burden of cell division is placed on the PCs.

Cell differentiation has traditionally been regarded as a one-way avenue, and SSCs and PCs were thought to be restricted in the cell types they can produce. However, several recent reports have concluded that committed progenitor cells can actually transform to generate cell types of further stem cell systems. Cultured murine neuronal stem cells from embryonic and adult brains have been shown to repopulate the hematopoietic system of irradiated mice and produce a variety of blood cell types and, when injected into blastocysts, to generate multiple other tissue cells. However, unexpected spontaneous fusion of embryonic stem cells with hematopoietic stem cells has also been observed, making it possible that the observed cell products are, in fact, the result of fusion. Multiple other examples supporting the hypothesis of stem cell plasticity have recently been published.

**Figure 9** Representation of the formation of the inner cell mass as the fertilized oocyte divides multiple times to form the morula. Next the blastula is formed. This hollow sphere contains the inner cell mass (shaded cells). Human cells from this region are used for embryonic stem cell research.

**Stem Cell Research in the Vertebrate Inner Ear**

Many important issues regarding stem cell research and inner ear hair cell regeneration remain incompletely understood, including: (1) the existence of stem cells in the inner ear; (2) our ability to direct stem cells from the inner ear or from a different source to differentiate into the hair cell lineage in vitro; and (3) the presence in the damaged inner ear of cues capable of inducing stem cell differentiation (either with stem cells from the inner ear or from another source).

To date, these questions have been addressed in multiple studies. In a recent study, utricular sensory epithelia of adult mice were dissociated and cells were cultured in vitro at low density. Within a few days, spheres of cells containing stem cells were identified in the preparation. Although stem cells were not identified directly in the inner ear of adult mammals in this study, it demonstrated that some cells within the vestibular end organs have the ability to behave as stem cells following dissociation and culture. Furthermore, these stem cells were induced to express multiple hair cell markers in vitro under the appropriate conditions. While these results are encouraging, the degree to which these new hair cells are able to fully mature phenotypically and functionally remains unclear. In another study utricular organ cultures of rats were treated with gentamicin and rat otocyst stem cells were added to the media. These cells integrated into the utricular epithelia and expressed the hair cell marker calretinin, suggesting that the damaged utricle may contain or release the cues required for inducing the incorporation of stem cells and their differentiation into hair cells. In in vivo studies, cultured spheres of neural cells containing stem cells were transplanted into intact neonatal rat cochleas. This resulted in significant cell migration along the cochlea; expression of differentiation markers

---

**Stem Cell Research**

Mouse ESCs have been used for research for nearly one-quarter century and have enabled greater understanding of basic principles of stem cell biology. They have also led to the new common technique of “knockout mice,” which are mice genetically engineered to eliminate the expression of a particular gene.

In the inner ear, ESCs provide a unique opportunity to study in vitro the genetic and molecular nature of cell fate and the environmental cues that induce specific cell fate commitment and differentiation. Understanding these processes may allow us to manipulate hair cell regeneration in vivo by means of the application of soluble factors or by activating specific gene expression programs through gene therapy. Furthermore, stem cells could be transplanted into the inner ear, where damaged sensory epithelia may provide the proper signals to trigger incorporation of stem cells into the epithelium and new hair cell formation.

Certain caveats must be kept in mind in designing and interpreting stem cell research. In general, in vitro exposure of cells to factors that mimic in vivo conditions has been thought to exert similar effects and allow identification of signals that trigger progression through the cell cycle and differentiation. However, in reality, the putative conditions and endogenous signals converging in the damaged epithelia in vivo are much more complex and may themselves lead to changes in transplanted stem cells. These transformed stem cells may respond differently to the exogenous or endogenous signals and undergo uncontrolled division and tumorigenesis. Also, the efficacy of new stem cell–derived treatments may depend on the degree of damage and amount of tissue scarring, which may be a function of the length of time elapsed between the time of injury and the treatment.

---

**CHAPTER 6 / Hair Cell Regeneration**
of neurons, astrocytes and oligodendrocytes; and incorporation of a few cells into the sensory epithelia with acquisition of differentiating hair cell phenotype. Such results were unexpected since no damage was induced to the epithelia prior to transplantation and differentiation cues might be absent. Furthermore, neurospheres may be a poor model for predicting stem cell attributes since they consist of heterogeneous populations of cells, and only a small proportion of these are truly "stem-like." On the other hand, the fact that efficiency of hair cell formation was poor in a neonatal ear argues against the efficiency of transplanting stem cells from a different lineage and led the authors to propose that it may be more reasonable to use stem cells originating from the cochlea, rather than from the hippocampus, to replace hair cells in the inner ear.

The early otic placode possesses extensive autonomy and does not require additional external signals to form all major inner ear cell types. In a recent study, Li and colleagues proposed that ESCs could be induced to differentiate into hair cell progenitors at a stage equivalent to the otic placodes. ESCs were cultured in the presence of EGF, insulin-like growth factor and bFGF. New cells expressing otic placode and otic vesicle markers were generated. Next, the growth factors were withdrawn from the culture media, and the cells were further induced to differentiate into hair cell-like cells expressing a variety of markers including M ath 1, Brn-3.1 and myosin VIIA, and supporting cell-like cells expressing the marker p27kip1.

The aforementioned studies suggest the presence of stem cells in the adult mammalian vestibular organs. In the cochlea, on the other hand, the existence of such cells was demonstrated in small numbers. The exact origin has been attributed to the lesser epithelial ridge of the postnatal rat cochlea and to the pillar and Hensen cells of the adult mouse.

**Challenges of Stem Cell Therapy**

Currently, severe to profound hearing loss as a result of hair cell loss is treated with cochlear implantation. When considering stem cell transplant, the advantages and disadvantages over cochlear implantation must be carefully weighed.

**Cochlear Implantation Considerations.** Cochlear implantation has the advantage of providing the ability to stimulate the auditory neurons directly in a tonotopic fashion. The device can be reprogrammed over time should auditory sensitivity or function change. A great wealth of information is available on the outcomes of the surgical procedure and the auditory performance of implanted patients, with more than 59,000 people worldwide having received cochlear implants. On the other hand as Raz points out, this treatment is far from ideal. Cochlear implantation is discussed in Chapter 32, "Cochlear and Brainstem Implantation," and Chapter 33, "Cochlear Implant Coding Strategies and Device Programming."

**Stem Cell Technology Considerations.** The ability to restore the natural tissue by transplanting stem cells would eliminate many of the concerns related to cochlear implantation, including risks, costs, and performance. Multiple challenges must still be overcome.

**Tumorigenesis.** The fact that tumors may often originate from stem cells has led to concerns regarding uncontrolled proliferation of transplanted stem cells incorporated into the damaged epithelium, as well as those that get incorporated into other nondamaged areas of the inner ear. Tumorigenesis can occur early after transplantation or, conceivably, several years later. Due to their shorter lifespan, this possibility cannot be evaluated in animal models. Furthermore, as pointed out in studies demonstrating fusion of stem cells with other cell types following transplantation, the cell products of fusion may have altered cell cycle control and undergo uncontrolled proliferation. A possible strategy to overcome uncontrolled proliferation is to predifferentiate stem cells along the hair cell or neuronal pathway prior to transplantation, thus decreasing their proliferative capability and ensuring that transplanted cells acquire the desired phenotype. Predifferentiated cells, however, have lesser ability to migrate and integrate into tissues and may not be as effective in replenishing lost hair cells. Cell proliferation in stem cells could possibly be regulated by inserting suicide genes into the stem cells under the control of a promoter that can be turned on with pharmacotherapy. Another concern is that transplanted cells could migrate out of the inner ear into adjacent structures, such as the brain, and fail to differentiate, disrupting the local tissues.

**Graft-versus-Host Disease.** The use of nonautologous human ESCs also raises the question of HLA incompatibility and graft-versus-host disease. This would require lifetime immune suppression therapy, which also carries significant risks of infection and tumor formation. An alternative would be to use autologous stem cells from cord-banked blood or autologous adult stem cells if, and when, these become available. Other alternatives include the use of nuclear transfer techniques, in which the nucleus of a somatic cell is transferred into a blastocyst cell to create embryonic stem cells with the genetic information of the host. Finally, another option is the creation of stem cell banks with human leukocyte antigen-types cells.

**Biological Contamination.** Mice ESCs have been routinely grown on a layer of mouse embryonic fibroblasts, which inhibited cell differentiation. However, recently the use of the cytokine leukemia inhibitory factor (LIF) has eliminated the need for the feeder layers. In human ESC cultures, it remains unclear whether LIF can replace the feeder layers. This raises serious concern regarding cross-contaminating human cells with mouse pathogens by growing the human cells on mouse feeder layers or with culture media conditioned by mouse cells.

**Genetic Mutations.** The transplanted ESCs must be carefully genetically screened, and the presence of mutations in genes pertaining to deafness or any other disorder must be ruled out before any type of transplantation can take place. A standard of test protocol must be in place before cell transplantation can be routinely performed.

**Transplantation Issues.** Different approaches have been proposed for the delivery of cells to the damaged inner ear. The endolymphatic space can be accessed through a transmastoid approach to the endolymphatic sac or the semicircular canals. The cells delivered through these approaches would have to travel a fair distance to reach the target, the damaged cochlear epithelium. The endolymphatic space could theoretically also be accessed through the basilar membrane, either through a transmastoid transfacial recess approach to the cochlea, similar to cochlear implantation surgery, or through the external auditory canal, tympanic membrane and round or oval window. This route would require the development of appropriately designed precision tools. So far, the incorporation of the cells into the damaged regions of the sensory epithelium in experimental models, has had poor efficiency.

The endolymph is so rich in potassium ions that it is toxic to the nerve endings on the basolateral membrane of the hair cells. When a hair cell dies in response to trauma, 2 of the 4 surrounding supporting cells undergo rapid expansion of the apical cytoplasmic domain while sealing the reticular lamina against a leak of fluids. This prevents mixing of perilymph and endolymph and is essential for maintaining the endocochlear potential. In these conditions, survival of transplanted cells in this environment and migration through the apical surface of the epithelium may be diminished. Finally, neural stem cells delivered intravenously have been used successfully in animal models to target tumors with little accumulation in normal tissues demonstrating that stem cells can migrate following gradients of cytokines or other soluble molecules. However, to date, our understanding of the molecules that bring about this process in the ear is poor.

**Ethical Issues.** Human ESCs are derived at a point when the fertilized zygote has developed into a hollow sphere of cells, the blastocyst. The process of deriving the stem cells thus destroys a developing embryo. While the potential for medical benefits deriving from stem cell technology is theoretically tremendous, no clinical benefit has derived to date. This research has generated strong opinions for, or against, this technology, based on differing cultural, moral, and religious beliefs. Politicians worldwide have adopted different approaches allowing (with or without funding) or prohibiting such research. Parallel research currently focuses on the development of stem cell lines from adult tissues, bypassing ethical concerns dealing with experimentation on embryonic tissue. In a recent study, functional neural stem cells were derived from adult bone.
marrow, indicating the great potential for this technology as well.110

**OTHER LINES OF RESEARCH: MOLECULAR GENETICS**

A great deal of research effort has recently been focused on elucidating the genes for cell cycle regulation molecules, cell surface receptors, and transcription factors that participate in hair cell formation and patterning of the inner ear sensory epithelia. These studies have taken advantage of global gene expression profiling techniques, the development of immortalized cell lines of inner ear epithelia at different stages of differentiation, and gene therapy techniques.

**Global Gene Expression Profiling Technology148,40,120**

The Human Genome Project has been the most significant undertaking in recent molecular biology. This project focused on enumerating the basic components of human biology (such as genes, genomes, and proteomes) and describing rudimentary aspects of behavior in an attempt to deconstruct the biological processes into their molecular components. Such essential information will provide the basis for mapping gene activity into biological and physiological processes, thereby shifting the focus from lists of genes to pathways, networks, molecular machines, organ-elles and eventually, the cell itself as a unit of work. The development of microarray and other high throughput technologies has made it possible to measure the relative abundance of mRNA from thousands of genes per experiment. These technologies have allowed comparison of gene expression differences in regenerating versus nonregenerating avian papillae121–125 and the identification of multiple genes that may be targets for pharmacological upregulation of the process in vivo. In a recent study, laser capture microdissection of individual hair cells and supporting cells in vivo. In a recent study, laser capture microdissection of multiple genes that may be targets for ear sensory epithelia.126 Furthermore, techniques have been developed that allow labeling of dissociated hair and supporting cells precursors from the embryonic cochlea and purification with flow cytometry.124 These new technologies should enable substantial progress to be made in understanding the process of hair cell formation.

**Gene Therapy**

In a recent study, adult guinea pigs were deafened with systemic administration of ototoxic drugs, leading to complete loss of hair cells in the high- and mid-frequency regions of the cochlea. The gene for M ath 1, a transcription factor that regulates hair cell formation, was delivered using adenoviral vectors infected into the cochlea. This resulted in new hair cell formation with substantial restoration of hearing thresholds, demonstrating that delivery of crucial genes for hair cell formation may induce restoration of auditory organ structure and function.128 For further information on gene therapy, see Chapter 5, “Inner Ear Drug Delivery and Gene Therapy.”

**CONCLUSIONS**

Studies over the past quarter century have produced extensive evidence of hair cell regeneration in nonmammalian vertebrate vestibular and auditory organs and generated a wealth of knowledge on the mechanisms that regulate the process. Although regenerations occurs to a modest degree in the mammalian vestibular sensory epithelia, no evidence, to date, of spontaneous hair cell regeneration has been produced in the mammalian cochlea sensory epithelia. However, recent stem cell and gene transfer research has resulted in hair cell formation and auditory threshold recovery in the damaged auditory epithelia. Although multiple essential questions remain unanswered, the large advances in this field over this short period of time may well lead to successful strategies for anatomical and functional restoration of the organ of Corti. Clinical applications of this technology will surely follow. Other lines of research are currently needed, such as the development of therapies to increase resistance of hair cells to damage and to enhance the repair of injured hair cells in the organ of Corti.

OVERVIEW: BIOPHYSICS AND THE INNER EAR

Physics deals with matter and energy and the interaction between the two. This chapter describes the biophysics underlying energy transduction by cochlear hair cells. Transduction is the conversion of one type of energy to another. The cochlea converts sound-evoked vibrations into neural information that is transmitted to the brain via the auditory nerve. The cochlea can detect mechanical movements at the eardrum that are less than the size of a hydrogen atom, and encodes the temporal features of those movements with a precision that allows us to discriminate which ear receives the sound first to within 20 microseconds. The conversion of acoustic energy to neural (electrochemical) energy occurs in the hair cells. The mechanical vibration of hair cell stereocilia results in a change of hair cell transmembrane electrical potential and ultimately leads to the secretion of an excitatory neurotransmitter that activates an eighth nerve fiber. Outer hair cells (OHCs) have both sensory and motor functions. Sensory receptor potentials are produced by the bending of the stereociliary bundle. The receptor potentials are converted directly into mechanical force by the membranes of the outer hair cell lateral wall. This electromechanical force counteracts viscous-damping forces within the fluid-filled environment of the inner ear, and it provides the basis of the cochlear amplifier that enhances sensitivity and frequency selectivity. One side effect that can be measured clinically is otoacoustic emissions.

High-Frequency Force Production in the Ear

Sound waves arriving at the external ear pass through the ear canal and displace the tympanic membrane. The sound vibrations are transmitted through the bones of the middle ear and create pressure differences in the cochlea. The pressure differences between cochlear compartments produce a traveling wave along the elastic basilar membrane (Figure 1). Auditory nerve fibers at a given location in vertebrate hearing organs respond most vigorously to sounds at a specific frequency. Systematic differences in geometry, elastic properties, and mass of the basilar membrane and cochlear partition result in a frequency mapping along the length of the cochlea. The topographic mapping of best frequencies is called “tonotopic” and is retained in the central nervous system (CNS) auditory structures. Factors that impose limits on the frequency at which inner ear structures can vibrate set the frequency limits of hearing.

Vertebrate hearing organs are fluid filled, and fluids impose a damping force on vibrations. Fluid or viscous damping is directly proportional to the velocity of the vibrating structures so that the damping force resisting differential movements (such as the bending of stereocilia) increases proportionally with frequency. It becomes more difficult for animals to hear as frequency increases unless there is a mechanism to counteract viscous damping. Diverse strategies to mechanically counteract fluid damping and increase the upper frequency limit of hearing are found in animal ears and involve the production of a “negative damping” force. It is likely that force production by the stereociliary bundle was the negative damping strategy used for the relatively low-frequency hearing of early vertebrates. When mammals appeared over 220 million years ago, they adopted a different mechanism associated with the lateral wall of their cylindrically shaped OHCs. The ability of the OHC to counteract viscous damping is referred to as the cochlear amplifier. The amplification is a function of the magnitude of the vibration, operating with the greatest gain for low-intensity sounds. The result is a compressive nonlinearity that improves the sensitivity and frequency selectivity of hearing.

HAIR CELLS

Hair cells are polarized epithelial cells that get their name from the stereociliary bundle on their apical surface (Figure 2). The stereocilia are giant microvilli arranged in three rows that increase in length toward the side of the cell located away from the central axis (the modiolus) of the cochlear spiral (Figure 3). Stereocilia have a dense inner core of tightly packed actin filaments that send a bundle of rootlets into a matrix of cytoskeletal proteins known as the cuticular plate located at the base of the stereociliary bundle (Figure 4). Just lateral to the center of the tallest row and located in the cytoplasm adjacent to the cuticular plate is a basal body which is all that remains of a single kinocilium that was present during early development but is resorbed as the organ of Corti matures (see Figure 2). During development, the kinocilium is thought to establish the morphologic polarization of the stereociliary bundle. The morphologic polarization then determines the physiologic polarization.

Mechanoelectrical transduction (MET) channels located in the wall of the stereocilia are hypothesized to be tethered to adjacent stereocilia by “tip links” (see Figure 2). The deflection of the stereocilia toward the tallest row causes the tip links to pull on the MET channels and open them. Deflection in the other direction releases the tension of the tip links, causing the transduction channels to close. Thus bending the bundle in the direction of the tallest row leads to entry of K+ and Ca2+ ions from the endolymph into the hair cell. This causes depolarization of the hair cell. Bending the bundle in the opposite direction closes the channels and the hair cell hyperpolarizes. The stereociliary bundle has an axis of symmetry that runs through the basal body perpendicular to the rows (see Figure 4). Bending the bundle parallel to the axis modulates the flow of ions into the hair cell. Bundle deflection perpendicular to the axis of symmetry results in no change in membrane potential. The magnitude of the voltage change produced by a stereociliary
deflection toward the modiolus (which closes MET channels) is less than that of an equivalent deflection away from the modiolus (which opens MET channels). This nonlinearity results from the various voltage- and calcium-dependent ion channels in the hair cell’s basolateral plasma membrane that shape the relation between current and voltage.

**ORGAN OF CORTI**

The sensory epithelium of the cochlea is called the organ of Corti. It consists of hair cells supported by an elegant matrix of cellular and acellular structures (see Figure 3). There are 3 rows of OHCs and a single row of inner hair cells (IHCs). The IHCs are located nearer the central axis of the cochlear spiral while the OHCs are further away. Both inner and outer hair cells are mechanoreceptors, but only IHC receptor potentials trigger afferent nerve activity sending signals to the brain. The fact that more than 10 afferent nerve fibers receive information from a single inner hair cell tells us that there is ample redundancy and added security for information transfer to the CNS. OHCs have the specialized role of enhancing the micromechanical tuning of the basilar membrane. They do this by generating a mechanical force in response to the receptor potential changes produced by bending the stereociliary bundle. The force alters the vibrations of the organ of Corti and refines the stimulation of the IHCs, thereby enhancing the perception and discrimination of the high-frequency sounds. There are about 12,000 hair cells (3,000 IHCs and 9,000 OHCs) in a normal human cochlea. This is a small number of cells when compared to the hundreds of millions of sensory cells found in the sensory epithelia of the retina, nose, or skin. Physics helps to understand the reason for the much smaller number of hair cells. The auditory system must detect small mechanical vibrations. Newtonian mechanics tells us that detecting a small force requires that the detection mass must be as small as possible. Similar considerations suggest that the benefits of small mass for the detection of rapid, low energy mechanical events may scale to the molecular level where assemblies of smaller molecules would be favored.

**TECTORIAL MEMBRANE**

The stereociliary bundles of the OHCs are embedded in the tectorial membrane (see Figure 3). The tectorial membrane is an extra-cellular matrix, which contains at least 3 types of collagen and the noncollagenous glycoproteins: α-tectorin, β-tectorin, and otogelin. The organization of these proteins within the tectorial membrane is anisotropic in that they project radially away from the central axis of the cochlea. Within the body of the tectorial membrane, a laminated striated sheet matrix is formed from 7 to 9 nm diameter filaments. The lower fibrous layer near the hair cells (Kimura membrane) consists of collagen organized in bundles of straight 20 nm diameter filaments. The marginal band at the lateral edge of the tectorial membrane and the cover net bundles on the top of the tectorial membrane contain anastomosing networks of thick collagen fibrils. Alpha- and beta-tectorin are thought to play a role in cross-linking collagen fibers. The role of otogelin is unclear at this time.

The development of the tectorial membrane occurs in concert with the development of the organ of Corti and differentiation of hair cells during embryogenesis. The greater epithelial ridge begins to give rise to inner hair cells and the lesser epithelial ridge begins to give rise to outer hair cells. The tectorial membrane matrix is secreted by supporting cells within the greater and lesser epithelial ridge. Eventually, the inner sulcus cells under the medial aspect of the tectorial membrane resorb, leaving it attached medi ally only to the spiral limbus and stretching across the surface of the organ of Corti. Once the cochlea has fully developed, the tectorial membrane is thought to remain inert with little protein turnover.

Hair cell stereocilia deflection is coordinated by the tectorial membrane. The tips of OHC stereociliary bundles are embedded in the tectorial membrane. When sound is transmitted to the inner ear, the organ of Corti vibrates up and
containing 3 full and 2 partial von Willebrand domains is due to alterations in cochlear endothelial cells. The von Willebrand factor (vWF) is an example of a protein that is highly expressed in the inner ear. The vWF domains tend to cause progressive, high-frequency hearing loss; some are autosomal dominant, and others are autosomal recessive. Mutations in the vWF protein are associated with moderate hearing loss. The vWF domain of the vWF protein is located in a region of the protein that is highly conserved across species. These mutations can cause a reduction in the amount of vWF that is produced by the endothelial cells of the cochlea. This can impair the formation of a functional tectorial membrane, which is necessary for normal cochlear amplifier function.

While OHC stereociliary movements can be directly linked to movements of the cochlear partition, the movements of the IHC stereocilia are not as straightforward. IHC stereociliary bundles are not directly connected to the tectorial membrane, but they are in close proximity to it. As a consequence of this anatomy, the fluid space around the stereociliary bundles (the subtectorial space) is constrained, and the fluid movement makes a major contribution to IHC stereociliary deflection. Current models include the fact that OHC electromotility may act to "pump" fluid back and forth within the subtectorial space.

Mutations that affect the tectorial membrane cause hearing loss. Most tectorial membrane mutations have been found within the gene for alpha-tectorin (Tecta). Alpha-tectorin is a large modular protein composed of an N-terminal entactin G1-like domain, a central region containing 3 full and 2 partial von Willebrand factor (vWF) type D repeats, and a C-terminal zona pellucida (ZP) domain. To date, 9 different mutations in Tecta that cause hearing loss have been identified. All are point mutations and cause nonsyndromic sensorineural hearing loss; some are autosomal dominant, and some are autosomal recessive. Mutations in the ZP domain are associated with moderate hearing loss in the middle frequencies that tends to remain stable over time, while that of a cookie-bite audiogram. On the other hand, mutations in the vWF domains tend to cause progressive, high-frequency hearing loss.

Hearing loss due to tectorial membrane protein mutations is due to alterations in cochlear biophysics. Changing the proteins that constitute the tectorial membrane changes its shape and mechanical properties, and this produces cochlear dysfunction. For example, if the mutant tectorial membrane does not interface with the OHC stereocilia, loss of the cochlear amplifier will occur. This will lead to elevated auditory brainstem response (ABR) thresholds, widened tuning curves, and reduced distortion product otoacoustic emissions (DPOAE). On the other hand, if the tectorial membrane interfaces with the OHCs, but is farther away from the IHC stereocilia than normal, there will be elevated ABR thresholds but normal DPOAE responses and normal tuning curve sharpness.

Little is known about age-related or other degenerative processes affecting the tectorial membrane. Ultrastructural studies in aged rats have shown a reduced number of collagen fibers in the tectorial membrane associated with progressive hearing loss. Another study has shown that aged rats have a distorted tectorial membrane that is detached from the organ of Corti. Therefore, it appears as though age-related degeneration of the tectorial membrane can occur in mammals. However, the extent to which this causes clinically relevant hearing loss is unknown.

**OUTER HAIR CELLS**

OHCs have a cylindrical shape (see Figures 3-5). They vary in length from approximately 12 µm at the basal or high-frequency end of the cochlea to >90 µm at the low-frequency end. Their diameter at all locations is approximately 9 µm, which is slightly larger than the diameter of a red blood cell. Their apical end is capped with a rigid cuticular plate which anchors the stereocilia. Their synaptic end is a hemisphere containing the nucleus along with synaptic structures. Each of these 3 regions (the apical stereociliary bundle, middle cylinder, and hemispheric base) has a specific function. The top and the bottom of the OHC perform functions that are common to all hair cells. The stereociliary bundle at the top of the cell is responsible for converting the mechanical energy of sound into electrical energy. Afferent and efferent synaptic structures are found at the base of the OHC. While the function of the OHC afferent synapse is unknown, the efferent synapse modulates the cochlear amplifier. The elongated cylindrical portion of the outer hair cell is where electrical energy is converted into mechanical energy. This function is unique to the OHC. No other hair cell (nor any other kind of cell) is able to change its length by internal pressure in response to electrical stimulation. This electromotility can be greater than 1% of the cell's original length if the electrical stimulation is large.

**The Outer Hair Cell Is Pressurized**

In contrast to the other cells in the body which have a cytoskeleton to maintain their shape, the OHC is a hydrostat. A hydrostat is a mechanical structure in which an elastic shell is inflated by a pressurized fluid core. The OHC cytoplasm is slightly hyperosmotic relative to the cochlear fluids, and the resulting osmotic pressure inflates the cell. A rigid internal skeleton such as that found in other cells would impede electromotility, so it is not surprising that no long-chain polymerized proteins exist within the axial core of the OHC. The turgidity of the OHC renders it mechanically strong enough to transmit force to the rest of the organ of Corti. Pressurized cells are common in the plant kingdom but are rarely found in cells of the animal kingdom. Plant cells, such as those found at the base of a tree, are highly pressurized. This allows the cells to hold the weight of the tree and still be flexible enough to bend and not shatter in a wind. Most of the cells in our body will not tolerate internal pressure because the membrane that encloses them would rupture. The OHC membrane is reinforced with a highly organized actin-spectrin cytoskeleton just underneath the plasma membrane (see Figures 4 and 5). This cortical lattice determines the cylindrical shape of the OHC when it is inflated by the hyperosmotic fluid core. The nature of the osmolytes is unknown at this time.
The Lateral Wall

The lateral wall of the OHC is about 100 nm thick and contains the plasma membrane, the cortical lattice, and an intracellular organelle called the subsurface cisterna (SSC). Electron microscopy reveals the presence of hexagonally packed particles within the lateral wall plasma membrane. The composition and function of the particles has not been identified. Cortical lattice actin filaments are oriented circumferentially around the cell and are cross-linked by spectrin molecules. Actin is less compliant than spectrin. This is why OHC length changes are greater than diameter changes. Pillars tether the actin-spectrin network to the plasma membrane, but their molecular composition has not yet been identified. The plasma membrane may be rippled between adjacent pillar molecules (Figure 6).6

The SSC structurally resembles endoplasmic reticulum, but it can be stained with both endoplasmic reticulum and Golgi body markers. It does not belong to the plasma membrane-endoplasmic reticulum-Golgi membrane pool but instead appears to be a part of a membrane pool that includes the canalicular reticulum (see Figure 4), a structure that occurs in ion-transporting epithelia. The membranes of the canalicular reticulum are contiguous with those of the SSC as well as the outer membrane of mitochondria. The molecular composition of the SSC (its phospholipid composition and complement of integral membrane proteins) and the content of the narrow approximately 20 nm lumen lying between the inner and outer SSC membranes have not been identified. The SSC partitions the cytoplasm into two domains, the axial core and the extracisternal space. The axial core is the larger of the compartments, and it contains only a few structures, such as most of the cell’s complement of mitochondria, which are located adjacent to the lateral wall. This partitioning may help to maintain the OHC’s cytoskeletal organization.

The Outer Hair Cell Membrane Motor Involves Prestin and Intracellular Chloride

OHC electromotility involves a membrane-based motor mechanism in the plasma membrane of the lateral wall. The mechanical force generated by the plasma membrane is communicated to the ends of the cell both hydraulically and via the cortical lattice. The motor mechanism is piezoelectric-like in that mechanical deformation of the membrane changes the transmembrane potential (direct piezoelectric effect) while electromotility is comparable to converse piezoelectricity.7

The protein prestin and intracellular chloride ions are required for optimal performance of the membrane motor. Prestin (Slc26A5) is a necessary component of the membrane-based motor that underlies outer hair cell electromotility. It was discovered by subtractive cloning to identify proteins that were expressed in the OHCs but not in the IHCs (which are nonmotile).8 Prestin is a member of the Slc26A family of anion transporters with up to 12 transmembrane helices. The family member with the closest sequence similarity is pendrin Slc26A4. Pendrin is expressed in the tissue forming the membranous labyrinth where it may be involved in the maintenance of the unique endolymphatic fluids (Figure 7). When prestin is in a membrane, a displacement charge movement into and out of, as opposed to through, the membrane can be measured. The prestin-associated charge movement is the accepted electrical signature of electromotility. Intracellular anions such as chloride and bicarbonate appear to be the charge carrier. The involvement of anions is consistent with prestin’s membership in the SLC26A family of anion transporters. Computational (informatic) analysis of the amino acid sequence of prestin and close family members indicate those regions of the proteins that are highly conserved in the prestins from different mammals. These include 2 sets of residues at the extracellular ends of transmembrane helices 1 and 2. Membrane electromotility and prestin-associated charge movement are blocked by single point mutations in these residues.

The dependence of electromotility and the prestin-associated charge movement on the material properties of the membrane has long been known. Changes in membrane tension shift the voltage dependence of both electromotility and the charge movement. The membrane nature of the motor mechanism is highlighted by altering the lipid profiles of cell membranes. The voltage charge movement function can be shifted over a 100 mV range by adding or depleting cholesterol in the membrane while the total amount of charge moved is not affected. Reduction of membrane cholesterol in the living cochlea eliminates DPOAEs while cholesterol enrichment results in a small (~3 dB) increase followed by the elimination of DPOAEs. The nature of these lipid-protein interactions requires further exploration and may be related to gender differences in hearing sensitivity and cochlear amplification.

STRIA VASCULARIS

The energy required for OHC mechanoelectrical and electromechanical transduction is provided by the stria vascularis (see Figure 7). This structure forms the outer wall of the scala media and is located within the spiral ligament. It is
STRUCTURE AND FUNCTION

OUTER HAIR CELL SYNAPTIC STRUCTURE AND FUNCTION

The importance of the OHC’s motor role is reflected in the afferent and efferent synapses found at the cell’s basal pole. The few afferent synapses found at the base of an OHC do not appear to excite the auditory nerve fibers that they contact while the efferent synapses are capable of modulating OHC force generation.

Afferent Synapses

Presynaptic dense bodies (synaptic ribbons) touch presynaptic thickenings of afferent synapses and are surrounded by synaptic vesicles (see Figure 2). There are fewer synaptic ribbons in OHCs than in IHCs; and, in some species, they are missing in adult OHCs. There is no evidence that the OHC afferent synapses activate the eighth nerve fibers they contact. There is only one study in which an eighth nerve fiber was reconstructed after intracellular recording and found to terminate on an OHC. The fiber did not fire action potentials in response to acoustic stimuli. The absence of acoustically evoked activity in nerve fibers coming from the OHC is consistent with the absence of evidence for vesicle membrane recycling at the OHC afferent synapse. Those afferent eighth nerve fibers that innervate OHCs may communicate information to the CNS but it is unlikely to be encoded in spike train activity.

Efferent Synapses

The OHC synaptic pole is dominated by efferent synapses. Postsynaptic cisternae are found in the cytoplasm adjacent to the postsynaptic thickening of efferent synapses. Most of the efferent endings originate from neurons located in the contralateral medial olivary complex. The end result of stimulating the efferent fibers is to decrease the sensitivity of afferent nerve fibers from the IHCs. Since these efferent fibers innervate the OHCs and not the IHCs, they perform their function indirectly through an effect on OHC force production. The synapse is cholinergic and cell shortening was observed when acetylcholine (ACh) was iontophoretically applied to isolated OHCs. It was later found that ACh modulates the magnitude of the OHC’s electrically evoked movements.

The novel heteromeric nicotinic receptors at the efferent synapse contain both α9- and α10-subunits, which may activate cell-signaling pathways that alter mechanical properties of cytoskeletal proteins in the OHC lateral wall. A family of small guanosine triphosphatases (GTPases) regulates the polymerization and depolymerization of cytoskeletal proteins, and studies that have biochemically dissected the action of several of these GTPases, specifically Rac, Rho, and Cdc42, suggest that signaling triggered by the nicotinic receptor at the efferent synapse may regulate the mechanical properties of the OHC lateral wall.

ACTIVE PROCESSES IN HEARING

Enhanced Frequency Selectivity

OHC electromotility is important in overcoming viscous damping and allowing the ear to hear high frequencies. It also enhances frequency selectivity. The mechanical tuning of the cochlea based only on passive mechanical properties such as mass and stiffness cannot explain the exquisite frequency selectivity of human hearing or the frequency selectivity that can be measured from individual auditory nerve fibers. OHC electromotility allows the human ear to discriminate between sounds that are very close in frequency. The reason for this can be understood by considering a simple mechanically tuned system, the playground swing. The frequency at which a swing vibrates is determined by the length of the rope. Its tuning may be appreciated when attempting to push it at a frequency other than the natural frequency of the swing. When pushed at a different frequency, the system requires considerably more energy to affect movement at that frequency.

A child sitting passively on a swing is an example of a passive, in contrast to an active, system. To understand what is meant by an active system, one need only recall one’s own early experiences on a swing. After a short time, one learned how to make the swing go higher and higher by pumping energy into the system through a combination of kicking your legs and tilting your upper body. Not only could one make the swing go high, but one probably experimented with kicking at a frequency other than the natural(911,833,911,835) best frequency. When one did, one found that the magnitude of the swing was rapidly attenuated. The “active” system with one pumping had become effectively more narrowly tuned than the original system in which one just sat on the swing. Narrow tuning is also a feature of the inner ear where the active pumping of the OHCs greatly improves the mechanical tuning of the inner ear vibrations. Not only is the amplitude of the vibrations enhanced at the best frequency, but they are suppressed for frequencies near best frequency.

Otoacoustic Emissions

One consequence of having an active, nonlinear ear system is that oscillations can occur even when no energy is coming into the system from the outside. This happens in the cochlea, and the resulting sound vibrations can be measured in the
ear canal. These are called spontaneous otoacoustic emissions and are only observed in living ears. Other types of otoacoustic emissions can be measured as well, including distortion product otoacoustic emissions and transient-evoked otoacoustic emissions. These can be triggered as needed by playing certain types of sound stimuli into the ear and are, therefore, more useful clinically than the measurement of spontaneous otoacoustic emissions. Measuring otoacoustic emissions has become an important diagnostic tool for determining if OHCs are working, particularly in newborn hearing screening.

Sensorineural hearing loss is a common clinical problem and has many different causes, including noise exposure, ototoxicity, and age-related hearing loss (presbyacusis). The common site of pathology for all of these conditions within the inner ear is the OHC. The attachments of OHC stereocilia to the tectorial membrane can be broken, even with mild noise exposure. This reduces the ability of OHC electromotility to provide positive feedback, leading to a temporary hearing loss. With further damage, the actin core of the OHC stereocilia can fracture. With enough trauma, hair cell death occurs and a permanent hearing loss results because mammalian cochlear hair cells do not regenerate. After OHCs begin to degenerate, additional structures within the cochlea die as well, including IHCs, supporting cells, and auditory nerve cells.

A low level of trauma that produces disarray of both inner and outer hair cell stereocilia proportionally elevates tuning curve thresholds. When OHCs are lost, only the sharp peak of the tuning curve is lost. Loss of IHCs produces a dramatic elevation in tuning curve thresholds. OHC damage blocks the cochlear amplifier, but the passive tuning properties of the cochlea are retained. In contrast, IHC damage reduces cochlear function overall. In summary, OHCs are predominantly responsible for the cochlear amplifier while the IHCs are responsible for signal detection to provide afferent input.

**CONCLUSIONS**

Throughout this chapter simple physical principles have been used to explain the biophysics of the cochlea at the microscopic and molecular level. More sophisticated application of the same concepts leads to mathematical models that better approximate reality. These models may someday lead to improved hearing health.

Central Auditory Processing and Functional Neuroimaging

Charles J. Limb, MD
Marc D. Eisen, MD, PhD

INTRODUCTION

Whereas the structures that comprise the auditory apparatus, including the external auditory canal and cochlea, provide us with the ability to hear, it is the auditory cortex that enables us to understand what we hear, providing us with auditory cognition. In the hierarchy of neural processing centers for sound perception, it is the cerebral cortex that ultimately permits auditory cognition—the conscious awareness of the acoustic environment. The emergence of new functional neuroimaging techniques, especially functional magnetic resonance imaging (fMRI), has provided unprecedented access to the study of the brain, allowing researchers to delineate both neuroanatomical substrates and functional roles of auditory processing centers. This chapter reviews the key components of the network of central neural structures for sound processing and highlights critical data obtained through an array of novel methods.

METHODS OF INVESTIGATION

Anatomical Methods

Traditional methods of elucidating anatomical-functional correlates in the human central nervous system were based primarily on lesion studies of individuals with behavioral or cognitive deficits, typically after central nervous system damage (whether due to stroke, tumor, or trauma), with postmortem anatomical analysis. Part of the difficulty in elucidating the mechanisms of human auditory processing deals with the inherent interspecies variability, which makes comparisons between humans and animal models challenging. Compared to most other mammals, humans are sensitive to a relatively lower frequency spectrum and lack the specialized auditory abilities (e.g., echolocation) found in certain species. Hence, while animal research in auditory processing has flourished, the applicability of results from animal work to our understanding of human sound perception has been variable.

The development of anatomical imaging methods, including X-ray, computed tomography, and magnetic resonance, ushered in dramatic increases in the ability of physicians and scientists to study the human brain. Yet, these methods were anatomical rather than functional in nature—they provided static images of the brain at rest and required inferences and assumptions for one to make any functional correlations. The recent introduction of functional imaging modalities has truly revolutionized our ability to draw functional-anatomic correlations. By measuring neural activity, functional imaging has provided unprecedented access into the inner workings of the human brain.

Functional Methods: Positron Emission Tomography

Positron emission tomography, or PET scanning, was developed shortly after computed tomography scanning. In PET, radionuclides are coupled to a tracer agent introduced intravenously into a patient’s bloodstream concurrent with the acquisition of data. These radionuclides have a spontaneous emission of positrons, which annihilate with electrons present in the study subject, in a manner proportional to the pharmacodynamics of the molecule to which the radionuclide is attached, thereby allowing measurements of local blood flow or metabolic activity. The annihilation of positrons and electrons causes a release of energy in opposite directions, which is subsequently detected by scintillator/photomultiplier tubes arranged concentrically around the brain. Based on differences in timing of coincidence detection, it is possible to calculate the exact location from where the energy was emitted, thus localizing the putative neural event. It should be emphasized here that neural blood flow and neural activity are not necessarily the same. Herein lies one of the crucial limitations of both PET scanning and functional MRI methods which both rely on local increases in blood flow as a marker of increased neural activity. While the correlation between blood flow and neural activity is widely accepted, it is an acknowledged limitation of the methods that the measurement of neuronal activity is indirect rather than direct, and that the anatomic variance in vasculature can cause artificial differences between subjects as well as provide an absolute physical limit (i.e., the distance between the vessel and neuron) to the accuracy of activity measurement, since these methods typically detect metabolic activity within the nearest blood vessel rather than the nearest neuron. Furthermore, both neuronal inhibition and excitation require increases in local metabolism and blood flow, and therefore the two cannot be discerned with this modality.

There are several types of available radionuclide-tracer combinations, the most commonly used being 18-fluorodeoxyglucose (18FDG) and H215O, that have widely varying pharmacokinetics and thus provide widely differing types of data. 18FDG has primarily been employed as a marker of increased glucose consumption and, by extension, metabolic activity and is therefore useful for detecting regions of abnormally high uptake, such as the case of many cancers, including tumors of the head and neck. For auditory experiments, the most useful agent has been H215O, which involves the administration of a modified water molecule with a relatively short (123 seconds) half-life. During the roughly 2-minute time period of radionuclide stability, subjects typically undergo an imaging scan during which an experimentally controlled task or stimulus is introduced. The neural activity over the entire interval is accumulated during each acquisition period. Therefore, in H215O PET, the acquired functional images represent a condensation of neural activity over the preceding 2-minute interval. By inference, this half-life represents the limit in temporal resolution that can be achieved using this method. For auditory stimuli, which typically vary from millisecond to millisecond, the temporal limitations of PET must be considered in both experimental design as well as data interpretation.

Functional Methods: Functional Magnetic Resonance Imaging

Functional MRI (fMRI) is based upon a modification of traditional MRI methods, which measure intrinsic differences in magnetic properties between adjacent tissues, thereby providing a high level of anatomical detail that has been extremely useful for all medical disciplines. In MRI, subjects are placed within a high-strength magnetic field (typically 0.5 to 1.5 T), inducing magnetic alignment of protons within the body, and then an orthogonal magnetic field is applied, causing the magnetic dipoles to “flip” sideways. As the second magnetic field is extinguished, the flipped dipoles decay to their original aligned orientation with a decay constant that is tissue-specific and measurable, ultimately producing a high-quality MR image. Unlike traditional MRI methods,
functional MRI does not produce a high-quality anatomical image. Rather, it employs technology that allows extremely fast (~2 to 5 seconds) imaging throughout the entire brain. This speed is achieved through a method known as echo planar imaging (EPI), which is a process that quickly applies and diminishes the magnetic cross-field, measuring extremely small differences in decay. Using EPI, multiple series of brain images can be acquired in a relatively brief time period, allowing comparison of different neural responses to experimentally controlled stimuli.

In fMRI, no intravenous agent is typically administered. Rather, the method relies on an endogenous contrast agent. fMRI relies on the fact that deoxyhemoglobin is a ferromagnetic molecule, unlike oxyhemoglobin. Active neurons require greater amounts of oxygen and produce subsequently higher amounts of deoxyhemoglobin. However, it has been found that the relative increase in blood flow outweighs the relative increase in deoxyhemoglobin. Therefore, there is a net decrease in the local amount of deoxyhemoglobin in areas of heightened neural activity. By utilizing the magnetic properties of deoxyhemoglobin, it was determined that differences in deoxyhemoglobin related to changes in neural activity could be detected using MRI. This method, known as blood-oxygen-level-dependent (BOLD) contrast imaging, has been the cornerstone of functional MRI methods.

Because no ionizing radiation is administered (therefore removing the constraints of radiation exposure to subjects), no intravenous agent is required, the acquisition speed is extraordinarily fast (thereby improving temporal resolution), and the spatial resolution is very good (typically around 3 mm³ on average), fMRI has largely supplanted PET scanning as the dominant method of functional neural imaging.

Once functional imaging data are obtained, several processing steps are required prior to analysis of the data. While a detailed discussion of data processing methods in functional imaging is beyond the scope of this chapter, the reader should be familiar with the need to correct for head movement artifact, to normalize differences both within and between subjects (usually to a template brain), and to apply smoothing algorithms that improve our ability to identify clusters of neural activity. This process thus allows comparisons to be made between brains of different sizes and shapes and employs a standardized stereotaxic coordinate system to allow for accurate localization of regions of activity.

To construct useful functional neuroimaging maps, the method of subtractive analysis (typically referred to as contrast analysis) is employed, usually through the process of general linear modeling analysis. In the simplest type of contrast analysis, a baseline level of activity is measured with the subject at rest (or performing some other control condition) for an extended period of time, referred to as a block. During the same scanning session, images are also acquired with the subject exposed to an experimental condition (e.g., listening to an auditory stimulus). The images from the baseline condition are subtracted out from the images obtained during the experimental condition, presumably allowing identification of those regions of neural activity specific to the experimental task. Using variations on this methodology, researchers have been able to employ fMRI to both substantiate existing claims as well as derive new insights into the way the brain processes sound.

### Limitations of Functional Imaging Methods

Both PET scanning and fMRI have inherent practical and theoretical limitations. In PET scanning, a radionuclide must first be available for administration. Given the short half-life of H₂¹⁵O, this requires that the agent is produced on site, with the use of a cyclotron. The cost associated with this modality is therefore quite expensive. Because ionizing radiation is administered, PET scanning is less useful in children and for experiments in which repeated acquisition of data from a subject is required. Because the half-life is also fairly long (2 minutes), the spatiotemporal resolution of PET is relatively poor. fMRI is widely available, since it requires only a modification of existing MRI technology. However, fMRI is also an exceptionally noisy technology, with background scanner noise levels approaching 130 dB SPL. For auditory experiments, this noise level is a clear limitation and requires several assumptions to be made in the evaluation of auditory stimulus processing or the use of specialized data acquisition paradigms which can reduce the number (but improve the quality) of data sets acquired in a session. Also, the powerful magnetic fields employed by fMRI limit the use of indwelling devices, such as cochlear implants, thereby excluding this important patient population from participation in fMRI experiments.

### CENTRAL AUDITORY PROCESSING

It should be stated at the outset that our understanding of how sound is actually perceived in all of its complexity is quite limited. Although we have a good deal of information regarding the various processing stages that occur along the auditory pathways, it still remains a mystery how these signals ultimately produce an accurate percept that enables cognition. Functional imaging methods, however, hold the most promise in terms of identifying those areas of the brain that are actively engaged during these tasks and will hopefully continue to shed new light on this fascinating process.

Once sound enters the cochlea, the process of acoustic-to-neural conversion begins. That is, sound, which is composed of waves of vibrational energy, induces neural stimulation within the cochlea, leading to hair cell initiation of neurotransmission. From this point onward, the process of auditory perception ceases to be an acoustic phenomenon and is entirely neural. The central auditory system is responsible for analyzing these incoming neural impulses and then filtering, encoding, recoding, and distributing them to the appropriate neural centers (Figure 1). While much of auditory cognition per se takes place in the auditory cortex, many baseline processes required for complex perception take place in the brainstem, such as the encoding of multiple frequency channels and binaurally driven calculations needed for sound localization.

### Cochlear Nucleus

The peripheral auditory mechanism collects, filters, and disperses sound in a frequency-specific pattern known as tonotopy. This tonotopic arrangement that begins in the cochlea is maintained throughout the auditory system as it ascends through subcortical and cortical processing stages. The auditory brainstem is the first synaptic relay station of the central auditory pathway. The auditory nerve enters the brainstem at the pontomedullary junction, where its axons synapse within the cochlear nucleus. The cochlear nucleus is subdivided anatomically into two principal components, the dorsal cochlear nucleus (DCN) and the ventral cochlear nucleus (VCN). Each individual auditory nerve fiber branches within the cochlear nucleus and travels to the DCN and VCN in an orderly arrangement that preserves the tonotopic gradient established in the cochlea. The processing that occurs in the cochlear nucleus (and throughout the auditory brainstem) is dependent largely upon the cell type upon which each neuron synapses as well as upon the nature of the physical and physiological coupling between
presynaptic and postsynaptic neurons; different classes of recipient cells have intrinsically different neuronal response properties and therefore relay incoming auditory signals in varying fashion to upstream processing sites. The VCN contains large synapses that are tightly coupled with the postsynaptic recipient (the spherical bushy cells), thereby constituting a form of fail-safe synaptic transmission that is believed to be important in sound localization. The DCN receives fewer inputs directly from the auditory nerve than the VCN but is thought to be important in spectral tuning and is characterized by strong inhibitory influences among DCN neurons.

The effects of auditory deprivation on the cochlear nucleus are significant. It has been shown that primary synapses of the auditory nerve within the cochlear nucleus, especially the endbulb of Held, undergo an atrophy of their complex 3-dimensional structure that appears to limit the neural connectivity between the afferent auditory nerve input and the recipient cochlear nucleus (Figure 2). Furthermore, the few synapses that do exist appear to have undergone hypertrophy of their size upon examination via electron microscopy, perhaps to compensate for the limited neural connectivity that exists between these malformed neurons. In a landmark study attesting to the importance of cochlear implantation, Ryugo and colleagues showed that early cochlear implantation in the deaf white cat led to synaptic rescue, with a restoration of normal synaptic morphology following a period of sustained implant use. It has been also shown that synaptic development in the auditory brainstem takes place during early life and likely corresponds to a so-called critical period during which auditory synaptic connections may form and after which neuroplastic changes (including those responsible for proper sound transmission) are limited.

**Superior Olivary Complex**

One of the primary demands on the auditory brainstem is that of spatial sound source localization. This challenge is hampered by the fact that (unlike the visual system) there is no physical representation of 3-dimensional sound space within the auditory periphery. The superior olivary complex (SOC) is thought to be the first location in the ascending auditory pathway in which bilateral peripheral inputs converge, and this feature supports the notion that the SOC processes differences between binaural input, which are necessary for proper sound localization to occur. In simplified terms, the ability to localize sound is based on differences in both amplitude (or level) and timing between right and left ears. A sound that is closer to the right side than to the left side is called right ear dominance. An example of stimulus that elicits differential responses in the SOC is a long-duration tone presented to one ear. The SOC is ideally suited to perform the function of binaural comparison, allowing computations based on interaural timing differences (intensity level differences are likely calculated in the inferior colliculus). Certain neurons in the medial nucleus of the SOC have been found to serve as “coincidence detectors,” in which simultaneous binaural input is required to stimulate a neural response in the postsynaptic cell.

**Medial Geniculate Nucleus**

The medial geniculate nucleus (or body) is the portion of the thalamus that receives all incoming auditory input that has been integrated by the thalamus. Cells in the IC are ideally suited to perform the function of binaural comparison, allowing computations based on interaural timing differences (intensity level differences are likely calculated in the inferior colliculus). Certain neurons in the medial nucleus of the SOC have been found to serve as “coincidence detectors,” in which simultaneous binaural input is required to stimulate a neural response in the postsynaptic cell. This finding also sheds light as to why transection of the auditory nerve ordinarily does not relieve patients of their tinnitus.

**Inferior Colliculus**

The inferior colliculus (IC) plays an important, albeit less well-understood, role in the integration of auditory input and receives direct inputs from all of the nuclei in the auditory brainstem via the lateral lemniscus. The largest processing nucleus within the IC is called the central nucleus. The IC subsequently provides input to the auditory thalamus. Although the inferior colliculus has a relatively limited number of cell types, the neuronal response properties within the IC have been found to be quite diverse, including both excitatory and inhibitory interactions that modulate both ascending and descending activity, as well as activity to the contralateral IC. There is significant evidence to suggest that the IC plays a crucial role in spectral processing of sound, in addition to the calculation of interaural intensity differences. In a technically challenging functional neuroimaging experiment, Macher and colleagues studied the auditory brainstem activity within the IC of patients suffering from unilateral versus bilateral tinnitus (Figure 3). In this study, it was determined that patients with unilateral tinnitus had increased activity within the IC compared to patients without tinnitus, thereby suggesting a link between aberrant brainstem activity within the IC (triggered by peripheral deafferentation through hair cell loss or damage) and the development of tinnitus. This finding also sheds light as to why transection of the auditory nerve ordinarily does not relieve patients of their tinnitus.
THE AUDITORY CORTEX

Numerous organizational schemes have been used to describe the components of the human cerebral cortex. The organization scheme of Brodmann20 has been widely used to depict the parcellation of the brain into smaller functional units although functional imaging experiments have begun to reveal the oversimplified nature of these schemes, with an increasing trend away from relying upon Brodmann’s classification. Anatomically, the brain is divided into lobes (frontal, temporal, occipital, parietal), and it is also likely that discrete neural systems (e.g., limbic system) exist to serve specific functions. Of the cortical lobes, the temporal, occipital, and parietal lobes are all thought to subserve somatosensory functions, while the frontal lobe is thought to have an executive role in the coordination and control of activity within the somatosensory lobes. Indeed, it is the prefrontal cortex, more than any neural area, which demonstrates the greatest degree of expansion during hominid evolution. The auditory cortex is housed within the temporal lobe, much of it hidden within the Sylvian fissure (and seen only after lateral retraction of the temporal lobe). More specifically, the human auditory cortex is located along the superior temporal gyrus. As will be discussed, however, cortical areas outside the temporal lobe (e.g., inferior parietal lobe) are known to be critical in the cognition of complex auditory stimuli. Perhaps most importantly, it should be noted that our current understanding of the auditory cortex is limited by the fact that the cortex is divided into smaller functional units, and it is thought to be necessary for speech production. Closely related to this region is a portion of the inferior temporal lobes (primary core) that is likely to be primary in nature, as this region is consistent in other primates and humans.

Primary Auditory Cortex

The primary auditory cortex is the first cortical stage of auditory processing, found in all mammals (often referred to as A1). The primary auditory cortex receives inputs primarily from the medial geniculate nucleus of the thalamus (MGv), and it is thought to be located on the superior temporal plane, along the transverse temporal gyrus, also known as Heschl gyrus and Brodmann area 41 (Figure 4).

Figure 4 Axial view of anatomical T1-weighted MRI image at level z = +10 (Montreal Neurologic Institute coordinate system). The image shows the transverse temporal gyrus, or Heschl gyrus, highlighted in red bilaterally. This area contains the primary auditory cortex.

110 PART I / Otology and Neurotology

from the ventral component of the medial geniculate nucleus. Further, studies in primates have shown that the posterodorsal division of the medial geniculate nucleus is the primary input to the rostromedial area of the “belt” area of primary auditory cortex, whereas the anterodorsal division is the primary input to the caudomedial “belt” area.19 The primary auditory cortex also communicates in descending reciprocal fashion with the medial geniculate nucleus (ventral subdivision). The functional implication of these pathways is poorly understood.

Auditory Association Cortex

Once primary input to the auditory brain is processed and received by the core/belt/parabelt regions, it undergoes a secondary stage of auditory processing in areas known as auditory association cortex (also referred to as secondary auditory cortex) (Figure 5). The identification of functional roles of auditory association cortex has been controversial and challenging. However, it is generally accepted that this portion of auditory cortex lies along the superior temporal plane, posterior to Heschl gyrus, in an area known as the planum temporale (PT). The PT is thought to be involved in the processing of complex auditory stimuli, such as speech and music. These stimuli typically have both spectral and temporal components of complex, evolving patterns that change constantly. The PT is thought to provide the neural substrate through which the challenging calculations of spectrotimelar pattern identification and segregation (e.g., separation and tracking of competing sounds presented from multiple sources) are performed.21 In anatomical studies of the planum temporale in musicians with absolute pitch, which is the ability to identify a musical pitch without the use of a reference note, this region was found to demonstrate leftward asymmetry, ultimately determined to be the product of decreased PT size in those with absolute pitch.25 Studies such as these encouraged scientists away from the notion that the PT was an area dedicated to language processing and broadened the notion to include complex auditory stimuli of which language was one specific example. Although the diverse functions of the PT remain to be described, there may be a role for the PT in the temporal comparison of successive auditory patterns. The perception of sound, which is a continuum of energy presented over time, necessarily involves a certain amount of working memory to integrate the significance of successive events (e.g., the first syllable of a word must be remembered when heard for the second syllable to be interpreted meaningfully), and the PT may provide the computational means of accomplishing this demanding task.25

Persisylvian Language and Extratemporal Areas

In addition to the primary and secondary auditory areas of the cortex, there are additional extratemporal regions that also play critical roles in auditory processing (Figure 6). The most well-described of these areas is a focal portion of the left frontal operculum that was identified by Carl Broca in 1861, often referred to as Broca area, or Brodmann area 42 and classically considered to be necessary for speech production. Closely related to this region is a portion of the inferior
The main auditory processing areas are located.

The green line depicts the line of the Sylvian fissure as well as the superior temporal plane along which the superior temporal gyrus, and the green line depicts the line of the Sylvian fissure. The secondary auditory cortical regions are located within the belt and parabelt regions, along the STG. The right image shows a three-dimensional view of the brain with surface renderings of the primary and secondary auditory regions and Sylvian fissure. (Reprinted from reference 28.)

Although these regions are considered nonauditory, they are certainly critical for language perception.

Recent functional neuroimaging studies have revealed that the simple division of language processing into these subdivisions is overly simplistic, and that there are numerous areas of the brain involved in language production. In terms of cortical demands, it is likely that the primary and secondary auditory areas process the incoming auditory stimuli into identifiable temporal and pitch patterns that are relayed to extratemporal portions of the brain where the cognitive assessment of awareness and significance takes place. In addition, there are numerous connections between auditory and “nonauditory” portions of the brain, including the visual, motor, limbic, somatosensory systems, and prefrontal cortex. Although these regions are considered nonauditory in nature, it is highly likely that they play critically important roles in cognitive awareness of sound, particularly those of a complex nature, such as speech and music.

Hemispheric Lateralization

As suggested by the left hemispheric specialization for language processing, the neural processing of sound is not necessarily a symmetric process, even though the similar neural substrates are present in both hemispheres. In right-handed individuals, language processing clearly occurs in a left hemispheric dominant fashion, leading individuals to suggest the notion of a right-ear advantage for speech in right-handed individuals, given the contralateral routing of neural signals in the ascending pathway. It has also been shown that this asymmetry is even present within the primary auditory cortex. In a functional neuroimaging study of passive sound perception, individuals listened to auditory stimuli that varied in either spectral or temporal domains. The results of this study showed that primary auditory cortices were activated in both sides, but that there was relatively greater activity within the left primary auditory cortex for temporal variation and relatively greater activity within the right primary auditory cortex for spectral variation (Figure 7).

This study has been supported by other investigations using music as a complex auditory stimulus, which have shown that in right-handed individuals, processing for rhythmic (temporal) patterns is left-hemispheric dominant, whereas processing for melody (spectral) patterns is right-hemispheric dominant.

CENTRAL AUDITORY PROCESSING DISORDERS

Patients who demonstrate impairment of sound discrimination, localization, or comprehension in the face of normal cochlear and auditory nerve function are considered to have a central auditory processing disorder. The implication of such disorders is that the auditory nerve faithfully conveys all of the timing, spectral, and intensity information about the sound stimulus but that upstream deficits in the brainstem or cortex preclude adequate processing of the sound. A defective processing is required for language acquisition and comprehension. In addition, however, impairment in central auditory processing has been implicated in more global behavioral disorders.

Assessing Central Auditory Processing

Central auditory processing can be assessed with a complement of behavioral and electrophysiological testing. Behavioral tests can assess complex and subtle processing abilities but require intelligent, compliant patients for reliable testing. Behavioral tests of central auditory processing can be grouped into three types. One involves tests of binaural fusion, where stimuli to both ears need to be compiled. These include tests of sound localization, detection of sound level thresholds in one ear with concurrent masking noise presented to the other ear, and comprehension of speech stimuli alternating rapidly between the two ears. These tasks rely on brainstem auditory centers, and impairment implies brainstem lesions. A second type involves presenting distorted speech. Recorded speech is sped up (accelerated), slowed down (decelerated), or low-pass filtered and then presented to the subject. Deficits on these comprehension tasks are associated with temporal lobe lesions. A third type involves presenting different, conflicting (typically speech-like) acoustic stimuli simultaneously to the two ears, termed “dichotic” listening tasks. With conflicting sounds presented to the two ears, the sound contralateral to the dominant hemisphere is typically suppressed. With hemispheric cortical lesions, however, the contralateral ear is typically suppressed regardless of dominance. These central auditory processing behavioral tests can be complicated, however, by peripheral auditory impairment and, in the case of conductive or sensorineural hearing loss, need to be interpreted cautiously.

Auditory Evoked Potentials and Central Processing

Electrophysiological tests of central auditory processing have the substantial advantage of being free from the bias and criterion inherent in behavioral testing. Their limitation, however, is that interpretation of the tests tends to be difficult and relies to some degree on the test reader’s judgment. Potentials recorded from scalp surface electrodes evoked by auditory stimuli are typically grouped by their latencies as being either early, middle, or late.

Early potentials occur within 10 ms of the auditory stimulus and represent the auditory brainstem response (ABR). Waves I, III, and V are the most robust and are thought to reflect synchronous activity in the auditory nerve (I), the projection from the ventral cochlear nucleus to the superior olivary complex (II), and the contralateral lateral lemniscus or inferior colliculus (V).

Middle latency responses occur typically between 10 and 50 ms following the auditory stimulus. These responses are generated by both...
subcortical and primary auditory areas within the temporal lobe. Long latency responses occur between 50 and 500 ms after the auditory stimulus and are generated by the auditory cortex. Because the auditory cortex receives bilateral projections, only bilateral deafness abolishes these potentials. Changes in these potentials are thus diagnostic of central auditory pathology. One long latency response that is used is the P-300 (ie, latency of 300 ms). Its amplitude and latency correlate with attention to auditory stimuli and auditory cognitive processing.33

Recognizing differences in sound stimuli, that is, discrimination, is another component of central auditory processing. An electrophysiological measure of sound discrimination is the mismatch negativity response (MMN). When a simple stimulus is presented repeatedly in a series, the MMN is recorded when the frequency of the stimulus is changed.34–35 The MMN is elicited even when the subject is not attending to the stimuli.36 The MMN is therefore a useful tool for studying cortical auditory discrimination, even in patients who have difficulty undergoing behavioral testing.37

**Specific Central Auditory Processing Disorders**

Several fairly common neurologic and psychiatric disorders have been associated with deficits in central auditory processing.

**Schizophrenia.** Sensory gating refers to the suppression of central auditory processing to subsequent external sounds when previously presented sounds are being processed. Deficits of auditory sensory gating result in "sensory overload" and disruption of higher-order processing. An electrophysiological measure of auditory sensory gating is the P50 event-related potential. P50 is a middle-latency potential found in the auditory evoked response to a click stimulus. Suppression of the P50 amplitude occurs in normal subjects to clicks presented closely in time.38 Suppressed P50 has been demonstrated in schizophrenic patients and their relatives,39 suggesting that a deficit in auditory sensory gating underlies schizophrenia.

**Autism.** Autism spectrum disorder (ASD), is a phenotypically heterogeneous diagnostic category characterized by variable impairment in social interaction, communication, and the presence of restrictive or stereotyped patterns of behavior.40 A autistic subjects have shown superior pitch memory, discrimination, labeling, and tone from chord disembedding,41 but a failure to attend to the sounds, like speech, to which normal children favor. A interpretation of these studies is that autism is associated with abnormal sound discrimination and orienting function.

**Stroke.** Hearing complaints in stroke victims are typically overshadowed by more prominent complaints involving other neurological systems. Furthermore, the auditory deficits in hemispheric strokes are likely to be subtle. Nonetheless, stroke can certainly result in central auditory processing deficits, especially in elderly patients.42 Insular stroke is associated with temporal resolution and sequencing deficits in auditory processing.43

**Alzheimer’s Disease.** Patients with Alzheimer’s disease can demonstrate central auditory processing deficits that appear to be independent of cognitive decline and may even precede the onset of dementia diagnosis by many years.44

**CONCLUSIONS**

Central auditory processing is responsible for interpreting and integrating the “raw” data of sound stimuli from two ears into meaningful sensations of the sounds around us. Delineating human central auditory pathways and structures has its origins in correlating behavioral abnormalities with postmortem identification of brain lesions—an inherently low-resolution methodology. With technological advancements in PET scanning and MRI, however, we can “see” the brain in action in live human subjects and with much finer resolution. Such methods have been applied to the auditory system, and details about how we process sounds have begun to be decoded.

As we begin to understand how and where complex sounds are processed in the normal listener, we can begin to pinpoint abnormalities in the pathway that may be associated with auditory processing disorders. As such, we have seen that several common neuropsychiatric disorders may have central auditory processing abnormalities as their root cause. As functional imaging technology advances, researchers will undoubtedly gain tremendous new insights into the mysterious phenomenon of auditory cognition.

**REFERENCES**

Within the past quarter century, dramatic advances in technology and techniques have contributed to more powerful audiologic test batteries and more effective management options for pediatric and adult populations. With auditory brainstem response (ABR) and otoacoustic emissions (OAEs), newborn infants can be screened for hearing impairment within days after birth and managed audiologically within the next critical 6 months. New techniques and strategies for the assessment of auditory function in adults have also been introduced in recent years. Pure-tone audiometry, immittance measurements (tympanometry and acoustic reflexes), and calculation of word recognition scores continue to be important for hearing assessment, and the traditional audiogram remains useful in summarizing the results of basic audiologic assessment. Clinical audiology, however, now also includes other behavioral and electrophysiological test procedures. For example, electrocochleography (ECochG) can contribute to the diagnosis of Menière disease. ABR offers a readily accessible, and relatively inexpensive, means for identification of retrocochlear auditory dysfunction. A variety of speech and nonspeech behavioral measures and several cortical auditory evoked responses are available for clinical assessment of central auditory nervous system dysfunction and associated auditory processing disorders. Finally, OAEs, because of their unique sensitivity and specificity to cochlear dysfunction, have become the latest addition to the clinical audiologic test battery.

The otolaryngologist is in a pivotal position to identify children and adults at risk for hearing loss, work closely with audiologists in diagnostic hearing assessment, and contribute to timely and appropriate medical or surgical intervention. In this chapter, we summarize current techniques and strategies for hearing assessment of adults, with an emphasis on the application of a test battery approach that maximizes diagnostic accuracy and efficiency, while minimizing test time and costs. The chapter includes a review of current hearing instrument technology for management of hearing impairment when other medical interventions do not or cannot rectify the hearing impairment and is a summary of pediatric audiol-ogy habilitation approaches. At the end of the chapter, we define in a glossary common audiol-ogy terms and abbreviations.

**THE BASIC AUDIOLOGIC TEST BATTERY**

**Pure-Tone Audiometry**

Pure-tone audiometry, the most common hearing test, is a measure of hearing sensitivity utilizing sinusoid stimuli at octave frequencies from 250 up to 8,000 Hz, and usually two inter-octave frequencies (3,000 and 6,000 Hz). The normal hearing, young (under 20 years) ear responds to frequencies from 20 to 20,000 Hz. Test results are graphed on an audiogram. Two common audiogram versions are illustrated in Figure 1. All audiograms include, minimally, a graph for plotting hearing threshold levels (HTLs) as a function of the frequency of pure-tone signals, although the exact format and symbols may vary.
ears are plotted on the same graph, requiring a separate symbol system for each ear. The same audiometric findings (top portion) for pure-tone audiometry, (middle portion) for speech audiometry, and (bottom portion) for aural immittance measurement are shown in A are also plotted in B, producing less clear analysis. Masking is indicated by filled symbols. Findings for the right ear represent a typical sensorineural hearing impairment.

The unit of stimulus intensity is the decibel (dB), a logarithmic unit. The intensity of any sound is defined by its ratio of sound pressure to its reference sound pressure, or sound intensity. The reference sound pressure is the amount of pressure against the eardrum, caused by air molecules when a sound is presented that vibrates the eardrum and can just be detected by a normally hearing ear. Briefly, the relationship for sound intensity is described as dB = 10 log 10 (sound pressure/reference pressure). The reference sound pressure is defined as 0.0002 dynes/cm², which is the minimal detectable intensity for normal humans. A common unit for expressing sound intensity is dB sensation level (SL) which is intensity of the stimulus in dB above an individual person’s hearing threshold. For example, a word recognition test may be administered at an intensity level of 40 dB SL (40 dB above the patient’s pure-tone average).

In adult audiologic assessment, hearing thresholds for tonal or speech signals are measured separately for each ear with earphones (air-conduction stimulation). Insert earphones (ER-3A) are now the transducer of choice for routine audiologic assessment. They offer distinct advantages over the traditional supraaural earphones, including increased comfort, reduced likelihood of ear canal collapse, greater interaural attenuation, disposability (aural hygiene), and greater acceptance by young children. Pure-tone audiometry can also be performed with stimuli presented by a bone-conduction oscillator or vibrator placed on the mastoid bone. During pure-tone audiometry, all equipment meets American National Standards Institute (ANSI) specifications, and testing is carried out according to clinical adaptations of psychophysical methods.

For adults, the clinically normal region on the audiogram is from 0 to 20 dB HL. The normal region for children is more limited because even mild hearing loss can interfere with speech and language acquisition. Pediatric hearing threshold levels exceeding 15 dB may be considered abnormal. Thresholds in the 20 to 40 dB HL region constitute a mild hearing loss, 40 to 60 dB HL thresholds define a moderate loss, and threshold levels greater than 60 dB HL are considered a severe hearing loss. A reference intensity level of whispered speech close to the ear is less than 25 dB HL; conversational speech is in the 40 to 50 dB HL region, and a shouted voice within a foot of the ear is at a level of about 80 dB HL. The essential frequencies for understanding speech are in the 500 through 4,000 Hz region although higher frequencies also contribute to discrimination between certain speech sounds. Hearing sensitivity within the “speech frequency” region is traditionally summarized by calculating the pure-tone average, or PTA (hearing thresholds for 500, 1,000, and 2,000 Hz divided by three and reported in dB).

The validity of audiometric results depends on whether the patient’s responses result from stimulation of the test ear. If a sound of greater than 40 dB HL is presented to one ear via standard earphones with supraaural (resting on the outer ear) cushions, it is possible that the acoustic energy will cross over from one side of the head to the other and stimulate the non-test ear. The mechanism for the crossover is presumably bone-conduction stimulation caused by vibration of the earphone cushion against the skull at high stimulus intensity levels. The amount of sound intensity needed before the crossover occurs is a reflection of interaural attenuation, that is, the sound insulation between the two ears provided by the head. Interaural attenuation is usually about 50 dB for lower test frequencies and 60 dB for higher test frequencies (such as those contributing to the ABR). Interaural attenuation is considerably higher for insert earphones. With bone-conduction stimulation, interaural attenuation is very limited (at most 10 dB). Clinically, one must assume that interaural attenuation for bone-conducted signals is 0 dB. That is, any sound presented to the mastoid bone of one ear by a bone-conduction vibrator may be transmitted through the skull to either or both inner ears. A claustral perception of this bone-conducted signal will, of course, depend on the patient’s sensorineural hearing sensitivity in each ear.

Masking is the audiometric technique used to eliminate participation of the non-test ear whenever air- and bone-conduction stimulation exceeds interaural attenuation. An appropriate noise (narrow band noise for pure-tone signals and speech noise for speech signals) is presented to the non-test ear when the stimulus is presented to the test ear. With adequate masking, any signal crossing over to the non-test ear is masked by the noise. Selection of appropriate masking is sometimes difficult, especially when there is bilateral hearing impairment. The otolaryngologist should...
always attempt to verify that appropriate masking was used in interpreting audiologic results.

Comparison of the hearing thresholds for air versus bone-conduction signals is useful in classifying type of hearing loss, that is, whether a hearing loss is sensorineural (no air-bone gap), conductive (normal bone conduction and loss by air conduction), or mixed (loss by bone conduction with a superimposed air- vs bone-conduction gap). Configuration refers to hearing loss as a function of the test frequency. With the sloping configuration, hearing is better for low frequencies and poorer for higher frequencies. High-frequency deficit hearing loss is the most common pattern associated with a sensorineural hearing impairment. A rising configuration is typified by relatively poor hearing for lower frequency stimuli and better hearing for the high frequencies. The rising configuration can result from varied types of middle ear pathology. One exception to the typical association of conductive hearing loss with rising configuration is Menière disease, which is discussed in Chapter 28. "Menière Disease, Vestibular Neuritis, Benign Paroxysmal Positional Vertigo, Superior Semicircular Canal Dehiscence, and Vestibular Migraine." Menière disease includes cochlear pathology that produces a rising configuration. A flat audiometric configuration is often recorded from patients with mixed hearing loss, that is, when both sensorineural and conductive components are present.

Speech Audiometry

Speech audiometry measures how well a person hears and understands speech signals. Speech audiometry procedures are used routinely to measure hearing sensitivity (thresholds in dB) for words or to estimate word recognition, for example, speech discrimination, ability. Spondee reception threshold (SRT), also referred to as the speech reception threshold (SRT) or speech threshold (ST), is the softest intensity level at which a patient can correctly repeat words approximately 50% of the time. Spondees words, two syllable words with equal stress on each syllable, for example, airplane, baseball, cowboy, are presented to the patient monaurally via earphones. The technique is equivalent to the method for determining pure-tone thresholds described previously.

Because the PTA indicates hearing thresholds in the speech frequency region and ST or SRT is measured with a speech signal, close agreement between the PTA and the ST is expected. If the difference between PTA and ST exceeds ±7 dB, there is reason to suspect that one or both of the measures are invalid. An unusually good ST relative to the PTA, for example, ST of 5 dB and PTA of 45 dB should immediately alert the tester to the possibility of a nonorganic hearing loss, as in malingering. With cooperative adult patients, particularly if pure-tone hearing thresholds are within the normal range from 500 to 4000 Hz, there is probably little or no clinical benefit in measuring speech thresholds. Test time can be saved, with no loss of diagnostic information, by excluding speech threshold measurement from the test battery for such patients.

The common clinical approach for estimating a person’s ability to hear and understand speech is speech recognition for phonetically balanced (PB) words. Usually, a list of 25 or 50 single-syllable words is presented to the patient via earphones at one or more fixed intensity levels, and the percentage of words correctly repeated by the patient is calculated by the tester. One ear is tested at a time. Within the list of words, specific speech sounds (phonemes) occur approximately as often as they would in everyday conversation, that is, they are "phonetically balanced." Traditionally, these words were spoken into a microphone by the tester, while the level was monitored with a VU (volume unit) meter. Then, the words were routed to the patient through the audiometer after selection of the test ear and desired intensity level. This is, however, an outdated and poor clinical practice since it lacks standardization and consistency and increases the variability of test outcome. With adult patients, it is almost always possible and always preferable to use professionally produced and commercially available speech materials presented via compact disk player and an audiometer. Diagnostic speech audiometry utilizing more sophisticated materials, for example, spectrally degraded or temporally distorted speech, or speech in noise materials, is feasible for assessment of the central auditory system.

Immittance Measurement

Introduction. Aural immittance (impedance) measures are an important part of the basic audiometry test battery. Immittance is a term derived from the terms for two related techniques for assessing middle ear function (impedance and admittance), techniques which have been applied clinically since 1970. A detailed discussion of the principles of immittance measurement is not within the scope of this chapter; however, this has been reviewed by Hall and Mueller. Briefly, the external ear canal is sealed with a soft rubber probe tip. Connected to the probe tip is a device producing a tone which is delivered toward tympanic membrane. Middle ear impedance or admittance is calculated from the intensity and other physical properties, for example, phase, of the tone in the ear canal. A middle ear (tympanic membrane and ossicular system) with low impedance (higher admittance) more readily accepts the acoustic energy of the probe tone, whereas a middle ear with abnormally high impedance (lower admittance) due, for example, to fluid within the middle ear space tends to reject energy flow. Thus, impedance (admittance) characteristics of the middle ear system can be inferred objectively with this quick and noninvasive technique, and then related to well-known patterns of findings for various types of middle ear pathologies.

Tympanometry. Tympanometry is the continuous recording of middle ear impedance as air pressure in the ear canal is systematically increased or decreased. The technique is a sensitive measure of tympanic membrane integrity and middle ear function (Figure 2). Compliance (the reciprocal of stiffness) of the middle ear, the dominant component of immittance, is the vertical dimension of a tympanogram. Tympanometry is popular clinically because it requires minimal technical skill and less than a minute to perform. Because aural immittance measurement is an electrophysiologic (vs behavioral) method, it does not depend on cooperation of the patient. Importantly, it is a sensitive measure of middle ear function. Tympanometry patterns, in combination with audiogram patterns, permit differentiation among and classification of middle ear disorders.

James Jerger in 1970 described what has become the most clinically widespread approach for describing tympanograms. There are three general tympanogram types: A, B, and C. The normal, or type A, tympanogram has a distinct peak in compliance within 0 to –100 mm of water pressure (decapascals or daPa) in the ear canal (shown in Figure 2). To be classified as normal, the location of the compliance peak on the
The type A tympanogram is a variation of the type A tympanogram. The "s" stands for shallow. Peak compliance is below the lower normal limits of compliance. That is, middle ear impedance is abnormally high. The type A tympanogram also have a distinct peak in compliance (as with the type A), but the peak is within the negative pressure region below -150 mm H₂O decapascal (daPa). This pattern is usually found in patients with eustachian tube dysfunction and inadequate ventilation of the middle ear space, and often precedes the type B tympanogram in the development of otitis media.

The type A tympanogram is recorded from patients with disruption of the ossicular chain, including those with the diagnosis of otosclerosis. In contrast, with an unusually steep tympanometry procedure, high positive or negative pressure is introduced into the ear canal. This pattern is most often associated with fluid within the middle ear space, for example, 2 cm or more in an adult or a larger (2-3 cm) than those of the earlier responses because they reflect activity evoked from a greater number of neurons. The cortical responses have multiple generators and are calculated in milliseconds (ms). These latency data for each ear are assessed for symmetry and also compared to appropriate normative data. With regard to symmetry, ABR waves are calculated in milliseconds (ms). These latency data for each ear are assessed for symmetry and also compared to appropriate normative data. With regard to symmetry, ABR waves are calculated in milliseconds (ms). These latency data for each ear are assessed for symmetry and also compared to appropriate normative data. With regard to symmetry, ABR waves are calculated in milliseconds (ms). These latency data for each ear are assessed for symmetry and also compared to appropriate normative data. With regard to symmetry, ABR waves are calculated in milliseconds (ms). These latency data for each ear are assessed for symmetry and also compared to appropriate normative data.
waveform patterns are illustrated in Figure 3. A well-formed and clear wave I at a delayed latency value for the maximum stimulus intensity level is characteristic of a conductive or mixed hearing loss. When wave I is small and poorly formed, but interwave latency values are within normal limits (the wave I–V latency value is less than 4.60 ms), a high-frequency sensory (cochlear) hearing loss is suspected. Delayed interwave latency values are the signature of retrocortic cochlear dysfunction. A normal delays between the early wave components, for example, I–III, are consistent with posterior fossa lesions involving the eighth nerve and/or lower brainstem, whereas a prolonged III–V latency suggests intra-axial auditory brainstem dysfunction.

A primary goal in any diagnostic ABR is to record a clear and reliable wave I component. Wave I serves as the benchmark for peripheral auditory function. Subsequent interwave latencies offer indices of retrocorticotic (eighth nerve and brainstem) function that are relatively unaffected by conductive or sensory hearing loss. The likelihood that a wave I will be recorded is enhanced by the use of either ear canal (TIPtrode) or tympanic membrane electrode designs, along with alterations of the test protocol, such as a slower stimulus rate, rarefaction stimulus polarity, and maximum stimulus intensity level. Reports on ABR dating back to the late 1970s confirmed that waveforms evoked by high intensity yielded neurodiagnostic information on cochlear and retrocorticotic auditory function and could be applied in the identification of retrocorticotic disorders, for example, vestibular schwannomas, with a hit rate exceeding 95%. With the development of sophisticated neuroradiological techniques, such as computed tomography (CT) or magnetic resonance imaging (MRI) with enhancement, reports of normal ABR findings among patients with very small posterior fossa tumors have appeared in the literature. These are clearly false-negative ABR outcomes in patients at risk for retrocorticotic auditory dysfunction due, usually, to very small intracranial vestibular schwannomas. On the other hand, false-positive outcomes for CT and MRI have also been reported for patients with normal ABRs and no surgical evidence of tumor. ABR continues to be a readily available, relatively inexpensive, and reasonably sensitive procedure for initial diagnostic assessment of eighth nerve and auditory brainstem status in patients with retrocorticotic signs and symptoms. ABR is also valuable in electrophysiological monitoring of the eighth nerve and auditory brainstem function during certain neurotologic operations, for example, vestibular neurectomy, auditory brainstem implant placement, or posterior fossa tumor removal.

**Auditory Steady State Response**

The auditory steady state response (ASSR) is an electrophysiological technique that is useful for estimation of auditory thresholds in infants and young children. The ASSR is elicited with
pure-tone (steady state) signals that are rapidly modulated or changed in amplitude and, usually, frequency. Fast stimulus modulation rates, for example, >80 Hz, are utilized when the ASSR is recorded from children who are sedated or lightly anesthetized. As with ABR measurement, sedation or anesthesia is necessary in recording the ASSR from children to eliminate the deleterious effects on response detection of muscle or movement-related measurement artifact. ASSR measurement is now possible with commercially available evoked response systems used also for ABR assessment. The ASSR offers three potential advantages over the ABR for auditory assessment of young children. First, because the response is elicited with pure-tone (steady state), rather than transient (very brief) stimuli, it is possible to present stimuli with intensity levels up to 120 to 125 dB HL. Second, depending on the extent of the modulation, especially the frequency modulation, the stimuli used to elicit the ASSR can be rather frequency specific and valuable for electrophysiological estimation of the audiogram. Finally, the analysis of either the phase and/or the frequency content of brain activity elicited by the modulated pure-tone signals is fully automated and independent of the skills and experience of the tester. Clinical experience confirms that the ASSR complements the ABR in the electrophysiological assessment of auditory function of infants. Each technique has its advantages and disadvantages, but together the ABR and ASSR offer a powerful diagnostic duo for early assessment of hearing in children in the era of universal newborn hearing screening.

**Elecrocochleography**

For over 30 years, ECochG has been applied in the assessment of peripheral auditory function. Currently, ECochG is performed most often for intraoperative monitoring of cochlear and eighth nerve status and in the diagnosis of M eniere disease. Optimal ECochG waveforms are recorded from a small needle electrode placed through the tympanic membrane on to the promontory although tympanic membrane and, to a lesser extent, ear canal electrode locations are also clinically useful. Stimulus and acquisition parameters for recording ECochG have been well defined for decades. The three major components of the ECochG are the cochlear microphonc (CM), the summatring potential (SP), and the action potential (AP). The CM and SP reflect cochlear bioelectric activity, whereas the AP is generated by synchronous firing of distal afferent nerve fibers and is equivalent to the ABR wave I (Figure 4). The typical ECochG analysis technique in neurotology requires determination of the amplitude and frequency of the SP and the AP from a common baseline. Then, the ratio of the SP/AP is calculated and reported in percent. Normal SP/AP ratio ranges and cutoffs in percentage have been reported for each electrode type. A normal SP/AP ratio values are defined as >50% for the trans tympanic membrane electrode, and >30% for the transtympanic needle electrode type.\(^6\)

The characteristic ECochG finding in patients with M eniere disease is an abnormal enlargement of the relation between the SP and AP component amplitudes. With the tympanic membrane electrode technique, sensitivity of ECochG in the diagnosis of endolymphatic hydrops is reported as 57%, whereas specificity is 94% in a series of 100 patients.\(^7\) Only 3 out of 30 patients yielded false-positive findings. Thus, an abnormally enlarged SP/AP ratio is highly suggestive of endolymphatic hydrops according to these data. In this study, the likelihood of an abnormal ECochG SP/AP ratio was statistically higher as hearing loss increased and when the hearing loss fluctuated.

**OTOACOUSTIC EMISSIONS**

OAEs are low intensity sounds produced by the cochlea in response to an acoustic stimulus.\(^4\) A moderate intensity click stimulus, or an appropriate combination of two tones, can evoke outer hair cell movement or motility. Outer hair cell motility affects basilar membrane biomechanics, resulting in a form of intracochlear energy amplification, as well as cochlear tuning for more precise frequency resolution. The outer hair cell motility generates mechanical energy within the cochlea which is propagated outward, via the middle ear system and the tympanic membrane, to the ear canal. Vibration of the tympanic membrane then produces an acoustic signal, that is, the OAE, which can be measured by a sensitive microphone. There are two broad classes of otoacoustic emissions: spontaneous and evoked. Spontaneous OAEs (SOAEs), present in only about 70% of persons with normal hearing, are measured in the external ear canal when there is no external sound stimulation. A significant gender effect for SOAE has been confirmed with females demonstrating SOAE at twice the rate of males.

Evoked OAEs, elicited by moderate levels (50 to 80 dB SPL) of acoustic stimulation in the external ear canal, are generally classified according to characteristics of the stimuli used to elicit them or characteristics of the cochlear events that generate them. Stimulus-frequency OAEs (SFOAEs), which are technically difficult to record, are the least studied of the evoked otoacoustic emissions. Distortion-product OAEs (DPOAEs) are produced when two pure-tone stimuli at frequencies \(f_1\) and \(f_2\) are presented to the ear simultaneously (Figure 5). The most robust DPOAE occurs at the frequency determined by the equation \(2f_1-f_2\), whereas the actual cochlear frequency region that is assessed with DPOAE is between these two frequencies and probably close to the \(f_2\) stimulus for recommended test protocols. With all of the five FDA-approved instruments that are commercially available for recording DPOAE, amplitude as detected in the ear canal and described in dB SPL is plotted as a function of the frequencies of the stimuli in a DPgram, that is, a plot of the DPOAE as a function of frequency (see Figure 5). Transiently evoked OAEs (TEOAEs) are elicited by brief acoustic stimuli such as clicks or tone bursts. Although there are distinct differences in the methodology for recording DPOAE versus TEOAE, and the exact cochlear mechanisms responsible for their generation are also different, each type of evoked OAE is now being incorporated into routine auditory assessment of children and adults.\(^8\) Clinical applications of OAEs, along with their rationale, are summarized in Table 1.

When outer hair cells are structurally damaged or at least nonfunctional, OAE cannot be evoked by acoustic stimuli. A mong patients with mild cochlear dysfunction, OAE may be recorded but amplitudes are below normal limits for some or all stimulus frequencies. Importantly, some patients with abnormal OAE, consistent with cochlear dysfunction, will have normal pure-tone audiograms. An example is a patient with the symptom of tinnitus, yet a normal audiogram. A normal OAE is expected in the frequency region represented by the tinnitus. Up to 30% of a population of outer hair cells may be damaged without substantially affecting the simple audiogram. In such cases, however, abnormal OAE findings are invariably recorded. The noninvasive nature of OAE recording, coupled with their accuracy and objectivity in assessing cochlear, in particular outer hair cell, function suggests diverse potential clinical applications, ranging from auditory screening to the diagnosis of sensorineural hearing loss.

A mong the more important clinical contribution of OAEs in children is the identification and diagnosis of auditory neuropathy. First described regularly in the literature in the mid-1990s as clinical equipment for OAE measurement became widely available auditory neuropathy is hearing impairment secondary to eighth cranial nerve pathology that is not related to a tumor or other neoplasms.\(^9\) Since OAEs originate from the outer hair cells and are, therefore, "preneural," OAEs are typically normal in patients with auditory neuropathy, even with evidence of severe to profound hearing loss by the ABR or pure-tone audiometry. As detailed by Rapin and Gravel,\(^5\) early identification and appropriate diagnosis of auditory neuropathy, and its differentiation from serious sensory hearing impairment, are essential for appropriate patient management.

**INDICATIONS FOR DIAGNOSTIC AUDIOLOGIC ASSESSMENT**

**Children**

Hearing loss influences speech and language development of infants and young children, and these effects begin within the first 6 months of life.\(^10\) Even mild peripheral hearing deficits among preschool- and school-age children interfere with educational development. Therefore, early identification of hearing loss, coupled with timely and appropriate intervention and
Electrophysiological procedures were electrophysiological measures for diagnosis of APDs in school-age children include:

- Often APDs are related to central auditory nervous system that is specific to the auditory modality.

In addition to peripheral hearing impairment secondary to common causes, such as conductive hearing loss with otitis media or sensorineural hearing loss in ototoxicity, the otolaryngologist must also consider the possibility of auditory processing disorders (APDs) and advanced technological features, such as digital signal processing, that can significantly improve listening in noise. One noteworthy aspect of hearing aid design is that only a single disposable button-type battery of less than 1.5 V powers most units. A rechargeable life ranges between 10 and 14 sixteen-hour days.

Electronic hearing aids consist of three basic components: a microphone, an amplifier, and a receiver, with each component housed in a casing designed to fit behind or in the ear. The microphone is located externally and is activated by miniscule fluctuations in air pressure caused by the sound source. These vibrations are converted into an electrical impulse and delivered to the amplifier. At this stage, the signal is amplified and filtered. The altered signal is delivered to the receiver, which converts the electronic impulse into an acoustic signal. The amplified acoustic signal is delivered to the ear canal for reception of the signal by the wearer.

**Types of Hearing Aids**

Hearing aids are classified in two general ways. The first is by the style of the hearing aid, which usually refers to the size and location of the hearing aid and the hearing aid receiver relative to the ear. The second is by the technological features of the device.

**HEARING AIDS**

**Introduction**

A hearing aid is an assistive device that delivers an amplified acoustic signal into the ear canal. Some form of amplification has for centuries been used to overcome the deleterious effects of a hearing impairment on communication. The most simplistic “hearing aid” is easily made by cupping one’s hand behind the ear. This technique is effective because it helps channel the acoustic signal into the ear canal. A more modern means for improving the reception of an acoustic signal is to move closer to the sound source. When the distance between the listener and the sound source is doubled, the acoustic intensity is reduced by 6 dB at the listener. Similarly, a reduction in the distance by one-half increases the intensity by 6 dB. When the acoustic signal is an electronic device, such as a television or radio, reception can be easily enhanced by adjusting the volume control to make a more intense signal.

All of these methods enhance the reception of a particular acoustic signal and demonstrate that amplification is often an effective means of improving one’s ability to hear. A modification can be used to improve hearing in many forms of hearing impairment. Cochlear and auditory brainstem implants are discussed in Chapter 32, “Cochlear and Brainstem Implantation.”

Electronic hearing aids enhance the signal strength by amplifying the acoustic signals that reach its microphone. Hearing aid design has evolved rapidly with advances in electronics and miniaturization, becoming smaller, reliable, and more efficient. Some of today’s hearing aids are small enough to fit completely within the ear canal, and some have advanced technological features, such as digital signal processing, that can significantly improve listening in noise. One noteworthy aspect of hearing aid design is that only a single disposable button-type battery of less than 1.5 V powers most units. A rechargeable life ranges between 10 and 14 sixteen-hour days.

Electronic hearing aids consist of three basic components: a microphone, an amplifier, and a receiver, with each component housed in a casing designed to fit behind or in the ear. The microphone is located externally and is activated by miniscule fluctuations in air pressure caused by the sound source. These vibrations are converted into an electrical impulse and delivered to the amplifier. At this stage, the signal is amplified and filtered. The altered signal is delivered to the receiver, which converts the electronic impulse into an acoustic signal. The amplified acoustic signal is delivered to the ear canal for reception of the signal by the wearer.

**Types of Hearing Aids**

Hearing aids are classified in two general ways. The first is by the style of the hearing aid, which usually refers to the size and location of the hearing aid and the hearing aid receiver relative to the ear. The second is by the technological features of the device.

**Hearing Aid Styles**

The most commonly used hearing aid styles (although other types do exist) are the behind-the-ear (BTE), open-fit in-the-ear (ITE), in-the-canal (ITC), and completely-in-the-canal (CIC) hearing instruments. Figure 6 shows a hearing aid representing each of these major styles.

**Behind-the-ear hearing aids** are aptly named because the body of the hearing aid lies on the posterosuperior aspect of the auricle. The receiver is coupled to the ear canal by a piece of acoustic tubing attached to a custom-made ear mold, as
BTE device. A defective unit can be replaced by configuration of hearing loss can be managed with a BTE hearing aid. BTE style is the open-fit mold described below. Due to the amount of available material varying in density from hard (lucite) to soft (silicone). The choice of ear mold material can significantly add to the comfort and flexibility of the instrument. A disadvantage of the BTE instrument, however, is the location of the microphone. The ideal location of a microphone would be deep in the ear canal using the natural resonance of the auricle and ear canal. However, the microphones of BTE instruments are generally located above the auricle and oriented anteriorly. The loss of natural cues must be compensated by the hearing aid. One advantage of this microphone placement is the availability of directional microphone, a technology further discussed in a later section of this chapter. Because of the acoustic, and perhaps cosmetic, advantages of open-fit BTE hearing aids, and further advantages associated with the open-fit design, market

* The crosscheck principle in pediatric audiology is that the results of any single audiologic test should not be relied on without independent corroboration or crosscheck from another audiologic test.

A adapted from reference 8. ABR = auditory brainstem response.
Examples of major hearing instrument styles. The five types of hearing instruments are: (A) behind-the-ear (BTE); (B) open-fit; (C) in-the-ear (ITE); (D) in-the-canal (ITC); and (E) completely-in-the-canal (CIC).

**Figure 6** Examples of major hearing instrument styles. The five types of hearing instruments are: (A) behind-the-ear (BTE); (B) open-fit; (C) in-the-ear (ITE); (D) in-the-canal (ITC); and (E) completely-in-the-canal (CIC).

The body of the hearing aid, completely filling the concha, contains most of the electronic components, including the battery and a volume control. The anterosuperior portion of the ITE hearing aid fits into the helix of the auricle inferior to the triangular fossa and functions primarily to keep the instrument in place. The microphone is frequently located within this portion of the instrument. The medial portion fits partially in the ear canal and contains the receiver. ITE hearing aids are completely self-contained, with no tubing or ear mold assembly. The hearing aid is essentially built into the ear mold. Properly fit ITE hearing aids are appropriate for mild to severe losses of hearing. The location of the microphone close to the level of the ear canal is an advantage of the ITE style. Additionally, an ITE hearing aid can include directional microphones. Despite these advantages and its cosmetic appeal, the ITE hearing aid style does have at least three disadvantages. First, the size of the instrument within the auricle minimizes the use of the natural acoustic resonance of the external ear. Second, when the instrument must be repaired or replaced at an off-site facility, that is, the manufacturer, the patient must get by without the hearing aid for a number of days. A BTE loaner may be provided when coupled with a temporary ear mold, but this is usually not an acceptable alternative. Finally, ITE hearing aids may be difficult for some patients to insert and remove, especially for individuals with decreased manual dexterity skills.

In-the-canal hearing aids fit primarily into the ear canal (Figure 6D). Only the faceplate of the hearing aid is visible in the concha of the ear. A properly fitted ITC hearing aid may accommodate up to a moderately severe hearing loss. The location of the microphone is at the opening of the ear canal taking advantage of the acoustic properties of most of the auricle. Also, these devices are inserted deeper within the external ear canal than ITE hearing aids, producing an increase in gain of about 5 dB. Some ITC hearing aids can include directional microphones. However, the availability of this desirable feature depends on the size of the faceplate of the hearing aid. Although the size of the ITC instrument is an acoustic advantage, there are a couple of disadvantages. Since the hearing aid casing making contact with the ear serves to hold the hearing aid in place, the smaller ITC device more easily becomes dislodged and lost. The small size of ITC hearing aids makes them more difficult to insert and remove, hindering use by those with manual dexterity limitations.

Completely-in-the-canal (CIC) hearing aids are the smallest of the hearing aid styles and, therefore, often the most cosmetically appealing (Figure 6E). CIC hearing aids are inserted deeply into the external ear canal by the patient and are essentially invisible to the casual observer. With the CIC hearing instrument design, the receiver is located past the second bend of the ear canal, and the medial end of the assembly typical of traditional BTE hearing instruments. A cone- or dome-shaped piece rests in the ear canal just before the second bend of the ear canal (Figure 6B). This earpiece has an open design and deep insertion allowing some sounds to enter the ear naturally while maximizing the natural resonance of the concha and auricle. The earpiece connects to a slim tube and ear hook assembly connected to the BTE device. Some benefits of the open-fit design include more pleasant perception of one’s voice because it can be heard more naturally through the open design earpiece, and gain is not inappropriately applied to the low frequencies. Open-fit hearing aids tend to be cosmetically appealing because the BTE case is often much smaller than the traditional BTE case, and the tube and earpiece used are small and deeply inserted making them much less conspicuous (Figure 6B). One drawback of this style of hearing aid is a fitting range that is limited to high-frequency hearing loss.
hearing aid is within 5 mm of the tympanic membrane. A CIC hearing aid has a nylon fish line-type cord attached to its lateral surface to aid in retrieval of the instruments from the ear canal. Because of its size and microphone location, these devices have a number of advantages. These advantages include a reduction in the occlusion effect, ease of use on the telephone, no problems with wind noise on the microphone, an increase in gain by as much as 15 dB, and enhancement of the acoustic effects of the auricle and ear canal. Unfortunately, CIC devices are not without disadvantages. Practical drawbacks include problems obtaining and maintaining a good seal with the external ear canal and associated acoustic feedback, increased repair problems related to blockage with cerumen, difficulty inserting and removing the device from the ear canal, increased expense, reduction in the number of advanced technological features, and an inability to provide adequate amplification for persons with severe hearing losses. A nother disadvantage of this hearing aid style is that its small size prevents the use of directional microphones as the microphone ports require a certain amount of space between them to achieve directionality. There is simply not enough space for multiple microphones on the faceplate of a CIC hearing aid.

**Hearing Aid Technology.** Within the past decade, hearing aid technology has advanced tremendously. Hearing aids today have many advanced components and features. We will now review briefly some of the more important developments in hearing aid technology. In addition, there are many published and internet sources of current hearing aid technology.

Disposable and instant fit hearing aids are a relatively recent development to emerge on the hearing aid market. These devices have attracted increased attention because they can be fit immediately while the patient is in the office, without the need to ship ear mold impressions to a laboratory or the manufacturer. The products are available in a wide range of sizes, from BTE to CIC instruments. An advantage of these devices is their significantly reduced price in comparison to custom-made products. The disposable hearing aids have an added benefit in that there is never a need to replace the battery, since the entire hearing aid is replaced after 40 days. However, these devices may only be appropriate for milder degrees of hearing impairment, rendering those individuals with severe and profound hearing losses ineligible for this technology.

Conventional or analog hearing aids are the least technologically sophisticated of the custom-made hearing aids. An analog hearing aid receives the acoustic signal from the microphone, converts it into an electrical signal, amplifies and filters it according to the individual’s hearing loss, and reconverts it into an acoustic signal that is delivered to the ear canal. With this type of technology, the audiologist selects a matrix for the hearing aid, which determines its overall gain, slope, and maximum output. Relatively few adjustments can be made directly by the physician, hearing aid dispenser, or audiologist. These minor adjustments may be made by screwdriver controls known as “trim pots.” Typically, these devices provide linear amplification, although some do provide some form of compression. Linear amplification in hearing aids produces the same amount of gain regardless of the input signal. As the input signal increases in intensity, so does the resulting output of the hearing aid, until the hearing aid maximum output limit is reached. At this point, signal distortion occurs. Compression, on the other hand, helps eliminate the problem of distortion created by linear hearing aids. With a hearing aid containing compression circuitry, the amount of gain provided by the hearing aid depends on the intensity of the incoming signal. Since at greater intensity levels are amplified less than those with lower intensities. This reduction in gain decreases distortion as the signal approaches the maximum output provided by the hearing aid. Typically, these instruments have a volume control that may be adjusted by the user.

Programmable hearing aids provide increased flexibility and options for the wearer. Just as in conventional hearing aids, these instruments have analog amplifiers. However, unlike the conventional hearing instruments, programmable devices can be modified in the audiologist’s office via a computer or hand-held programmer. The programming allows for increased flexibility in shaping the frequency response, output limitations, compression characteristics, and enhanced features provided by the hearing aid. Additionally, many of the programmable devices offer multiple memories or programs. The utilization of these multiple programs allows the patient access to different settings that may be more appropriate for various listening environments, for example, quiet versus noisy. The multiple programs may be accessed via a remote control or a switch on the hearing instrument.

Digital hearing aids are the most popular hearing aid technology available today, and the market share continues to increase. A digital hearing aid processes the acoustic signal differently than an analog instrument. In digital processing, the acoustic signal is converted into a digital or binary code, minimizing the possibility for distortion of the signal. The signal is then amplified and converted back to an acoustic signal that is delivered to the ear canal through the receiver. Digital devices offer a number of advantages, including increased flexibility of shaping the frequency response of the instrument, feedback suppression capabilities, improved sound quality, decreased battery drain, and less internal circuit noise. Like programmable hearing instruments, digital devices may have multiple memories and can be adjusted via a computer or hand-held programmer. The memories may be accessed via a remote control or a switch on the hearing instrument. Most manufacturers currently market advanced hearing aids that change the program automatically based on the noise levels in the environment. These hearing aids also usually have some form of noise reduction technology to reduce sounds such as wind noise that may otherwise be unnecessarily amplified. The goal of noise reduction technology is to reduce unwanted sounds and increase the speech signal. To achieve this goal, the device must acoustically sort out the speech signal from a background of noise.

The major complaint of persons with sensorineural hearing loss is the inability to hear in background noise. Currently, directional microphones provide the individual with hearing impairment the best opportunity for understanding in noise. In its simplest form, this microphone arrangement allows the wearer to differentiate sound originating from the front, which is where the sound source is usually located, from sound coming from the rear, which is usually where noise is located. Multiple microphones may result in 5 to 8 dB of improvement in signal-to-noise ratio (SNR) in comparison to standard, omnidirectional microphones. The improvement in SNR may result in improvement in speech recognition by as much as 60%. Directional microphone technology is available in conventional, programmable, and digital hearing aids. However, the performance of the directional hearing aid is better in the advanced, that is, digital devices. Additionally, directional microphone technology is available in BTE instruments through half-shell ITE instruments. However, the improvement in noise is greater in the larger styles. In some advanced hearing aids, adaptive directionality is available, allowing the hearing aid to analyze the direction of speech versus noise signal sources with automatic appropriate adjustment of the hearing aid.

**Indications for Amplification**

Hearing aids are indicated whenever it can be demonstrated that the patient’s ability to communicate will be significantly improved through the use of amplification. A hearing aid is not recommended under the following conditions:

- Effective medical treatment can be implemented to restore normal hearing
- Hearing aid use would exacerbate pathology or interfere with treatment for it
- A hearing aid fails to improve the ability of the patient to communicate

A common myth is that amplification is of no benefit in the case of sensorineural hearing loss. While there is no evidence correlating the use of a hearing aid with restoration or treatment of the impaired auditory system, hearing aids are routinely used to offset the negative effects of sensory hearing impairment. Sensory hearing loss accounts for 90% of all types of hearing loss. More than 95% of all hearing aids are purchased by patients with sensorineural hearing loss. Amplification is an effective means of improving the communicative abilities of individuals with sensory hearing impairment, as attested by hundreds of research articles published in the last 50 years.

Amplification is an extremely effective means of improving the hearing of patients with conductive hearing loss. A hearing aid is clearly
not an acceptable alternative to effective medical treatment of a pathological condition, but it may be utilized after the course of treatment to offset residual hearing impairment. Residual conductive hearing loss is commonly present following placement of an ossicular prosthesis, for example. In this case, a hearing aid is often an effective means for further improving hearing sensitivity. In contrast, a hearing aid is rarely of benefit for patients with retrocchlear (neural or central) auditory disorders. In some cases, amplification may actually exacerbate the effects of the disorder. The use of amplification must also be carefully evaluated in all cases of central impairment. However, there are alternatives for these patients. Perhaps the most common approach is the recommendation of an assistive listening device, like an FM system, for improvement of speech understanding by significantly enhancing the speech signal in relation to background noise. FM technology can be effective in the management of persons with hearing impairment and also as a treatment option for children with auditory processing disorders. Representative types of FM technology are shown in Figure 7. With any type of FM device, the primary objective is to increase the SNR for the listener. That is, the speaker’s voice is enhanced in comparison to background sounds. A personal FM device (see Figure 7A and B) is most effective for an individual person, for example, a single child with APD in the classroom. However, classroom FM systems (Figure 7D) provide benefit to many children at minimal cost. Even modest improvements in the signal-to-noise ratio, for example, 5 dB, are associated with large improvements in speech perception and communication.

Benefits of Amplification

It is readily apparent that the utilization of amplification can significantly improve the communicative ability of an individual with hearing impairment. However, recent research has revealed additional benefits in psychosocial and functional health measures. These studies have shown that individuals utilizing amplification reported less depressive feelings, richer social relationships, and less anxiety and paranoia. Additionally, and perhaps as a result of improved communicative psychosocial functioning, these individuals noted improvements in their physical health status. Hence, the utilization of amplification has the potential to improve significantly the quality of life of an individual with hearing impairment.

Monaural versus Binaural Amplification

A great deal of research has been devoted to the following question: if hearing loss is bilateral, are two hearing aids better than one? The intuitive answer is, of course, that two hearing aids would best offset the effects of a hearing loss in both ears. The question persists, however, because some patients choose monaural fittings, although this is becoming more uncommon. This decision is usually based on cosmetic or financial reasons, although some patients claim to hear just as well with one hearing aid as with two, and others appear to hear better with a single instrument.

The benefits of binaural amplification have been well documented in the aural literature. The most commonly cited benefits are as follows:

• improved word identification, particularly in adverse listening conditions,
• improved localization of the sound source,
• a sense of “balanced hearing,”
• the need for less gain,
• elimination of the head shadow effect, and
• increased perception of high-frequency consonants.

In addition to these advantages, recent studies document the effects of auditory deprivation in unaided ears. The research indicates that, with a monaural hearing aid fitting, word identification scores in the unaided ear decrease over time relative to the scores in the aided ear. In contrast, decrements are not observed in either ear in a binaural fitting. Further, limited recovery in word identification is observed following the provision of amplification to the deprived ear.

With regard to this evidence, binaural amplification should be recommended unless specifically contraindicated. Valid contraindications to binaural amplification are as follows:

• unilateral hearing loss,
• medical complication in one ear,
• one ear cannot be effectively aided due to insufficient residual hearing, and
• binaural amplification results in diminished word identification performance.

Rehabilitation of Unilateral Hearing Loss

Contralateral routing of signal (CROS) is a hearing aid technology for people with unilateral hearing, that is the other ear is unaidable. There are two implementations of this strategy: CROS and BiCROS (bilateral contralateral routing of signal).

Using this technology, a receiver resembling a hearing instrument worn on the unaidable side, and the microphone within the device picks up sound from that side and sends it to another instrument at the better ear. The sound is delivered to the better ear via a wire or wirelessly via FM radio transmission.

The CROS implementation is for an individual who has relatively normal hearing in the better side and has hearing that is too poor to be aided on the worse side. The receiving BTE device on the worse side transmits the sound to a device on the better side. The user hears the amplified sound from the unaidable side in their best ear. The user hears the sound delivered to the better ear naturally, without amplification, via an open hearing aid mold.

The BiCROS implementation is for a patient with unaidable hearing on one side and with some hearing loss in their better ear. It is similar to the CROS system, except that the device on the better side is a hearing aid fitted to rehabilitate the hearing loss in the better ear, and it is also capable of receiving the sound transmitted from the CROS aid on the other side. There are two advantages of CROS and BiCROS technologies: (1) elimination of the head shadow effect results in an improved ability to hear sounds arriving to the worse ear, and (2) the user can have improved cues for sound localization.

Another alternative to the CROS system is what used to be referred to as a bone-anchored hearing aid (BAHA). The Baha sound processor (Entification Medical Systems, Cochlear Americas, Englewood, CO; http://www.entification.com) is based...
on the principle of direct bone conduction (DBC). The Baha system uses a combination of sound processor attached to a percutaneous abutment and osseointegrated fixture. The vibrating Baha transducer is directly connected to the skull via the abutment and fixture and via DBC simulates the better hearing cochlea. Currently, the United States Food and Drug Administration (FDA) has approved the use of this system with single-sided deafness, as well as to rehabilitate individuals with unilateral conductive hearing loss due to congenital aural atresia and in the setting of chronic ear disease when chronic infection prevents the use of a traditional air-conduction hearing aid.

Hearing Aid Selection

The selection of an appropriate hearing aid requires a combination of factors. First, it is essential that the practitioner thoroughly assess the patient’s motivation, concerns, communicative goals, and listening needs before selecting a hearing instrument. Issues like cosmetics, dexterity, and financial constraints may significantly limit the style and technological options. Additionally, one’s communicative goals or typical listening environment may dictate the need for a directional microphone or other advanced features. To aid in this endeavor, the use of self-assessment inventories, which will be discussed in the following section, may be of benefit.

To aid in the selection of a hearing aid, multiple researchers have developed prescriptive formulae that are based on audiometric thresholds or suprathreshold information. The goal of these formulae is to provide the listener with the optimum-sounding intelligibility. However, formulae are not expected to be a panacea but, rather, are intended to provide the dispenser with a valid approximation, a logical starting point. From here, minimal modifications should be required. Currently, there are a number of prescriptive formulae available, but no standard has been adopted.

Assessment of Hearing Aid Outcomes

Whenever treatment is rendered, some measure of efficacy of the service should be performed. In the age of managed care, it is exceedingly important to document the success (or failure) of rehabilitation services, that is, treatment outcome. Currently, there are a number of means to assess the efficacy of amplification, which include electroacoustic analysis, functional gain measures, real-ear measures, and self-assessment inventories. Each of these procedures will be discussed briefly in the following sections.

Electroacoustic Analysis. When hearing instruments are received from the manufacturer, and before they are dispensed to the patient, it is essential that the devices be evaluated to determine if they are functioning appropriately. According to the American Speech Language Hearing Association (ASHA), hearing devices should be assessed via an electroacoustic analysis according to the ANSI S3.22 standard as well as a listening check. With first test, the hearing aid is attached to a 2 cm² coupler and placed in a test box that analyzes the sound pressure present within this cavity that is produced by the hearing aid receiver. The electroacoustic analysis provides information regarding the gain characteristics of the hearing aid at each frequency, the frequency response, the maximum output, battery drain, and distortion of the hearing aid. The results can then be compared to the specifications of the hearing instrument provided by the manufacturer. If discrepancies occur, the hearing instrument should be returned to the manufacturer for repair or replacement.

Additionally, a listening check of the instruments should be performed. This check will provide information regarding the sound quality, circuit noise, and any intermittent function of the device. Once again, if problems are noted, the device should be returned to the manufacturer.

Functional Gain Measures. Functional gain measures are designed to assess the realistic benefit the patient derives from his hearing instruments, by determining behaviorally the amount the hearing aid improves the patient’s thresholds of audibility. Utilizing a speech signal and/or warble tones, the procedure is conducted in the sound field (i.e., in a sound booth with the signals presented via loudspeakers) to determine the difference in the patient’s aided and unaided hearing thresholds. Although functional gain measures are designed to assess the patient’s “real-world” benefit, the procedure is plagued by serious limitations, including poor test-retest reliability, limited frequency response information, lack of maximum output information, and a dependence on the patient’s behavioral responses.

Real-Ear Measures. Real-ear measures are currently the most accepted means of verifying hearing aid performance. Real-ear measurement systems use a specially designed probe microphone to measure the sound pressure in the ear canal at the eardrum. The probe microphone is inserted along the side of the patient’s ear canal into a position located within 6 to 8 mm of the tympanic membrane. A broadband noise, speech composite noise, or tonal series is presented via a loudspeaker that is located approximately 1 m away from the patient. Measurements are made and graphically displayed with and without the hearing aid in place. Aided test results are usually compared to unaided results, and the hearing aid is then adjusted to match the prescribed target. At a minimum, real-ear measurement should be conducted at an input level of 60 to 70 dB SPL, which is typical of average conversational speech. Additionally, the saturation level of the hearing aid should be determined to ensure that the maximum output of the hearing aid is set below the patient’s threshold of uncomfortable loudness. For nonlinear hearing aids, testing at a high input level (80 to 85 dB SPL) and a low input level (50 dB SPL) should also be included. At each of these input levels, patient’s feedback regarding the volume of the input signal should be solicited.

Self-Assessment Inventories. Perhaps the most compelling evidence of the success of a hearing aid fitting comes directly from the patient. After a brief period of hearing aid use, most adult patients are quite capable of determining whether the prescribed amplification has improved their ability to hear. This is understandable considering that the vast majority of individuals who purchase hearing aids cope with the hearing impairment for many years before deciding to pursue amplification. After little experience wearing the new hearing aids, most patients are able to describe precisely the listening situations in which their hearing aids are effective or ineffective. To quantify the valuable patient report, a number of self-assessment inventories have been developed for use by audiologists and hearing aid dispensers. These inventories are widely used to evaluate the initial fitting and the effectiveness of subsequent modifications.

Patient Accommodation to Amplification. An individual with hearing impairment requires a period of adjustment to become accustomed to wearing hearing aids. The average patient has developed a hearing loss over a period of years before deciding to pursue amplification. During this time period, considerable adaptation has occurred in the central auditory system. The sudden introduction to amplified sound initiates compensatory neurophysiologic changes that may take 5 to 6 weeks to develop fully. Within this time period, adjustments to the hearing instruments are often needed to assist the patient in the process of accommodation. Many hearing aid programs encourage patients to utilize a wearing schedule that gradually extends the length of time that the hearing aids are worn each day. Some programs also restrict hearing aid use to quiet listening environments during the initial period of accommodation with systematic exposure to more demanding conditions as accommodation progresses.

A common problem arises when a patient is initially unhappy with the performance of the hearing aid. According to federal law, an individual may return a hearing aid to the dispenser within 30 days for a refund. Unfortunately, 30 days is often an insufficient period of time to allow for complete accommodation and/or modification of the instruments. Therefore, prospective hearing aid patients should receive proper counseling before, during, and after the initial fitting to avoid making a premature decision. To address this potential hearing aid fitting challenge, some clinicians allow an adjustment period longer than the federal law requires in recognition of the variability of the adaptation period.

Pediatric Issues in Amplification. Children present a unique set of challenges in the selection and fitting of amplification. Potential problems to be addressed include the small size of children’s ears in comparison to adult ears, noncompliance of some children, the increased demands in their communication needs, the important impact of the accuracy of the hearing aid fitting on the
successful acquisition of speech and language, and often a lack of complete audiometric data required to make these decisions. To address these challenges, audiologists have developed a special set of standards for selecting and fitting hearing aids for young children. As noted earlier in the chapter, BTE instruments are the most popular hearing aid style for children as they permit maximum flexibility. First, the BTE design allows for an inexpensive means for accommodating changes in the size of the auricle and ear canal as the child grows. As these adjustments are made over time, the child can continue to use the hearing instrument. Second, BTE devices are more resistant to feedback problems due to the increased distance between the microphone and the receiver. Furthermore, utilizing an ear mold with thick tubing may also decrease the likelihood of feedback. Third, the BTE style offers options that contribute to the retention of the hearing aid within the ear canal, like wire retention attachments, kiddle tone hooks, and Huggie-Aids. Finally, a BTE hearing instrument offers many additional technological features that may not be available on smaller styles.

In addition to the style of hearing aid, a number of other hearing aid options and features should be considered. Every hearing aid dispensed to a child should have several options, including direct audio input, the telecoil feature, and microphone/telecoil options. These features offer the advantage of maximum adaptability with assistive listening devices, such as FM systems. Additionally, tamper-resistant volume controls and battery doors should be considered. For maximum flexibility, digital hearing aids with feedback suppression, programmable features, and multiple memories that offer both omnidirectional and directional microphone technology are added assets. Finally, due to the likelihood of the hearing instruments becoming lost or damaged in young hands, a loss and damage insurance policy is highly encouraged.

Noting the difficulties in fitting and the communication needs of young children, Richard Seewald developed a prescriptive formula called the desired sensation level (DSL). This hearing aid fitting approach calculates a prescriptive target for average conversational speech and maximum output of the hearing instrument from a variety of sources, using either pure-tone thresholds obtained via behavioral audiometry under headphones or frequency-specific electrophysiological, for example, ABR or ASSR, estimations of auditory thresholds. Additionally, if hearing aid verification and adjustments cannot be made utilizing real-ear measures in the child's ear canals, the adjustments may be made using a 2 cm³ coupler in the hearing aid test box by using real-ear-to-coupler differences (RECDs). RECD is the decibel difference between the level of sound in the ear canal versus the level that is measured in the 2 cm³ coupler. RECD is determined by taking an unaided measurement in the child's ear canal. If this measurement cannot be obtained, the formula provides average RECDs for children of various ages. Hence, with this prescriptive formula, appropriate amplification can be provided with little dependence on the cooperation of the child.

**ADVISING THE PARENTS OF YOUNG CHILDREN WITH HEARING IMPAIRMENT**

**General Guidelines**

It is important to maintain an understanding and an appreciation for the various educational options and communication modalities available to the families of children with hearing impairments.22 Since otolaryngologists are one of the professionals responsible for the identification and the professionals responsible for the diagnosis of hearing impairments, they are often the first, if not only, resource that the parent has for information regarding these difficult choices. The debate over the best communication mode and training approach has raged since the fourteenth century. Unfortunately, no single communication modality is right for all children.23 Rather, decisions must be made on an individual basis taking into account issues like the characteristics of the child, that is, age of diagnosis and accompanying learning disabilities, available community resources, and the commitment of the family to the child and the chosen communication modality. A basic review of the various communication options is presented, and the major methods are summarized in Table 3. There are, of course, a number of variations in these methodologies.

**Oral Approaches.** Two major forms of oral English instruction in practice today are the auditory-verbal approach and the auditory-oral approach. These two approaches are based on the idea that all children with hearing impairment can realistically attain receptive and expressive language competence regardless of the degree of hearing loss. The auditory-verbal philosophy places an emphasis on the child's residual hearing through the use of amplification with the goal of developing listening skills through natural communication. With this approach, the child is placed in mainstream education beginning in preschool years. The auditory-oral approach, on the other hand, emphasizes the development of amplified residual hearing and spoken language, utilizing speech-reading cues as a supplement to the auditory signal. With this approach, the child is usually enrolled in an oral education program until he/she can be appropriately mainstreamed.

Both these approaches have their pros and cons. The biggest benefit of each program is the possibility that the child will develop effective access to the hearing world. Geers and Moog revealed that children who attended oral education programs attained better speech production, speech perception, and overall spoken language skills than those students who attended total communication programs.24 Additionally, evidence suggests that students educated with oral approaches attain literacy scores twice the national average for children with hearing impairments. Unfortunately, the success of these programs is heavily dependent on early identification of the hearing loss and early intervention with amplification, as well as consistent, quality aural habilitation training. A major drawback to these approaches is isolation from the deaf community due to a lack of training in sign language. For a readable review of oral education for hearing impaired children,

**CHAPTER 9 / Diagnostic Audiology, Hearing Instruments, and Aural Habilitation**

---

1 3
the reader is referred to a book entitled Practical Guide to Quality Interaction With Children Who Have Hearing Loss authored by Morag Clark, a woman who has successfully implemented such programs in developed and developing countries around the world.24 Because of the rapid implementation of universal infant screening programs and the resulting early identification of profound hearing loss, most deaf children undergo cochlear implantation before 18 months of age, with many children undergoing cochlear implantation before 12 months of age. Consequently, most children with cochlear implants are entering mainstream educational environments by the first grade. Cochlear implantation is addressed in Chapter 32, "Cochlear and Brainstem Implantation" and Chapter 33, "Cochlear Implant Coding Strategies and Device Programming."

**Manual Approaches.** In stark contrast to the aforementioned oral educational strategies are the manual approaches. American Sign Language (ASL) is the common language of the deaf community. It is a vast lexicon of hand shapes and motions, or signs, with its own syntax and grammar. Additionally, ASL places a heavy emphasis on the facial expressions and body language of the signer. It is a unique language, having no simple translation to the oral English language. Proponents of ASL believe that it is an easier, more natural mode of communication for the child with hearing loss. Additionally, ASL facilitates membership into and acceptance by the deaf community, with the resultant capability for improving the child’s self-esteem and confidence. A major limitation of ASL, however, is syntax that is not conducive to development of the English language, a feature that may hinder spoken language and literacy skill acquisition.

In an attempt to alleviate the difficulties in learning English language through manual communication, educators developed English-based sign systems. The most popular form of the English-based sign systems is Signing Exact English (SEE or SEE2). SEE2 utilizes much of the same vocabulary as ASL but adds grammatical features and follows English syntax. This system is primarily geared toward preschool and lower elementary school children to provide them access to English instruction during the language learning years. Opponents of this system believe that it is a denial of deaf culture, by inflicting the standards of the hearing world on the deaf child.

**Bilingual-Bicultural Approach.** Momentum has been growing for the development of bilingual-bicultural education for children who are deaf. This approach is designed to educate the child in the mores, customs, and practices, as well as the language, of the hearing world and the deaf culture. In these programs, the child is taught ASL as his or her first language, providing a base for which English is later taught. Early access to language is designed to promote increased literacy and academic skills. However, since these programs are relatively new, little information is available regarding their long-term success in developing effective communication in children with hearing impairment.

**Combination Approaches.** A combination of the oral and manual approaches is referred to as a combination approach. The most popular combination approach is total communication. Total communication involves the use of one or more modes of communication at any given time in the child’s educational program, whether it be manual, oral, auditory only, or written. The design of this approach is to utilize whatever communication modality is most appropriate for the child at that stage of development or for that given situation, allowing the child access to all means of communication. Despite its promise, the total communication approach has serious limitations. Few programs actually put this philosophy into practice due to biases of the instructor and the difficulty of combining all of these methods at the same time. Additionally, the utilization of all of these modalities may overstimulate the child and, therefore, actually interfere with the development of communication. A less popular combination approach is cued speech. Cued speech is a visual communication system that employs eight hand shapes placed at four different locations near the mouth. These hand shapes are designed to supplement spoken language and speech reading cues, since many sounds may not be visible or distinguishable by watching the lips. The purpose of the cued speech approach is to allow the child to see and hear the English language as it is spoken. Limitations of the cued speech approach are that few programs provide this type of education and few “translators” (individuals that cue what an instructor says) are available. Additionally, persons who learn cued speech are unable to communicate with the deaf community, unless they also learn ASL.

A variety of educational methods are, therefore, available to the individual with hearing impairment. For the vast majority of families, the important decision about the educational approach to be used for their child is made during a period of emotional turmoil. Parents naturally view the identification of a hearing impairment as a loss of their dream of a normal child and may grieve accordingly. Unfortunately, a lack of understanding of the hearing loss, its implications, and remedial interventions can only exacerbate this emotional reaction. Although most parents want to receive this information, few professionals offer the supportive counseling and information needed for parents to make appropriate and timely decisions regarding educational strategies.25

The concept of critical period of development during which the CNS exhibits maximal plasticity is central to any discussion about the education of the individual with hearing impairment. It is reasonable to ask the question: should one attempt to maximize language development or focus on the use of residual hearing within a given time period? With the recent implementation of universal newborn hearing screening, it is logical to ask if early identification and management results in a significant improvement in the acquisition of communication skills. Yoshinaga-Itano and colleagues provided compelling evidence that children with hearing loss who are identified prior to 6 months of age and who receive immediate intervention have greater language development, better receptive and expressive vocabulary, and higher social-emotional aspects of communication development than infants who are identified later, regardless of the degree of hearing loss or mode of communication.10,26 Additionally, no significant differences in language development were noted in terms of time of identification for those children identified after 6 months. This finding suggests that auditory and language stimulation within the first 6 months of life is critical for CNS development.

In summary, each of the currently available educational methods has proponents and opponents. Whenever appropriate, and with the support of the parents and other caregivers, otolaryngologists should encourage and facilitate maximal use of residual hearing and language development in an attempt to help hearing-impaired children reach their full communicative potential. It is essential that the otolaryngologist provide the parent with supportive, unbiased information regarding the benefits and limitations of the aforementioned modalities. No matter what the family’s educational decision, early intervention services should be highly encouraged. Indeed, with early identification and intervention for hearing loss, that is, before the child is 6 months old, the development of effective communication is greatly enhanced independent of the educational approach.

**GLOSSARY**

**ABLB** Alternate binaural loudness balance. A traditional diagnostic auditory procedure for detecting “loudness recruitment” used in differentiating cochlear versus retrocochlear auditory dysfunction in unilateral hearing loss. The task is to balance the sensation of loudness for the better versus poorer hearing ear. Loudness recruitment is a cochlear auditory sign.

**ABR (BAER)** Auditory brainstem response. Electrical activity, evoked (stimulated) by brief-duration sounds that arises from the eighth cranial nerve and auditory portions of the brainstem. The ABR is usually recorded from the surface of the scalp and external ear with disc-type electrodes and processes with a fast signal averaging computer. ABR wave components are labeled with Roman numerals (eg, I, III, V) and described by the latency after the stimulus (in msec) and the amplitude from one peak to the following trough (in microvolts).

**AC** Air conduction. Audiometric signals presented via earphones to the ear canal.

**Air–bone gap** The difference in pure-tone thresholds for air- versus bone-conducted signals. With calibrated audiometers, the normal ear and
the sensorineurally impaired ear show no airbone gap, whereas conductive hearing losses are characterized by an air-bone gap.

ASL American Sign Language. A manual mode of communication that is commonly used by the deaf community.

Audiologist A hearing care professional who is educated and trained clinically to measure auditory system function and to provide nonmedical management to persons with auditory and communicative impairments. Minimal educational requirements for audiologists are a master’s degree and certification and/or state licensure.

BC Bone conduction. Audiometric signals presented via an oscillator to the skull (eg, mastoid bone or forehead).

BCL Bekesy Comfortable Level. A Bekesy audiometry procedure conducted at a comfortable loudness level versus threshold level.

Bekesy audiometry An audiometric procedure performed with a Bekesy audiometer for differentiating cochlear versus retrocochlear auditory dysfunction. Bekesy audiometry is based on the comparison of responses to pulsed versus continuous tones varied across a wide frequency range. Four patterns of Bekesy responses were classified by Jerger.

BOA Behavioral observation audiometry. A pediatric behavioral audiometry procedure in which motor responses to sounds, for example, eye opening, head turning, are detected by a trained observer.

BTE Behind-the-ear hearing aid design.

CIC Completely-in-the-channel hearing aid design.

Configuration Term used to describe the shape or pattern of an audiogram, that is, how hearing loss varies as a function of the audiometric test frequency. There are three main configurations: rising (low-frequency loss), sloping (high-frequency loss), and flat.

CROS Contralateral routing of signals. A hearing aid configuration in which a microphone is located on the poorer ear and the sounds are transduced and delivered electrically to the normal or mildly impaired ear.

Crossover Sound stimulus presented to one ear (the test ear) travels around the head (by air conduction) or across the head (by bone conduction) to stimulate the other (nontest) ear. See interaural attenuation.

dB HL A decibel scale referred to accepted standards for normal hearing (0 dB is average normal hearing for each audiometric test frequency).

dB nHL A decibel scale used in auditory brainstem response measurement referenced to average behavioral threshold for the click stimulus of a small group of normal hearing subjects.

dB SL Sound intensity is described in reference to an individual patient’s behavioral threshold for an audiometric frequency or some other measure of hearing threshold, for example, the speech reception threshold.

dB SPL A decibel scale referenced to a physical standard for intensity (eg, 0.0002 dynes/cm²).
identify a speech signal (e.g., two syllable spondees words). See PTA.

**SSPL** Saturation sound pressure level. A measure of the maximum power output (MPO) of the hearing aid.

**Telecoil** An option on a hearing aid that enables it to receive the electromagnetic signals directly from the telephone. This option may be utilized to reduce the presence of feedback while the wearer is using the telephone.

**TEOAEs** Transient evoked otoacoustic emissions. OAE elicited by brief (click or tone burst) stimuli.

**Tone decay test** A clinical measure of auditory adaption in which a tone is presented continuously to a hearing-impaired ear until it becomes inaudible. There are numerous versions of tone decay tests. Excessive tone decay is a sign of retrocochlear auditory dysfunction.

**TROCA** Tangible reinforcement operant conditioning audiometry. A pediatric behavioral audiometry technique that reinforces a response to auditory signals with food. TROCA is used mainly with mentally retarded or developmentally delayed children.

**UCL/LDL** Uncomfortable level or loudness discomfort level. The intensity level of a sound that is perceived as too loud.

**VRA** Visual reinforcement audiometry. A pediatric behavioral audiometry procedure that reinforces localization responses to acoustic signals with a visual event (e.g., an animal playing).

Evaluation of the Vestibular System

Joel A. Goebel, MD
Judith A. White, MD, PhD
Katherine D. Heidenreich, MD

The human vestibular system is responsible for sensing angular head acceleration and maintaining objects in visual focus during rapid impulsive head motion and detecting gravity and impulsive linear acceleration for accurate control of balance. It can be subdivided into peripheral and central components. The peripheral component consists of the vestibular end organs (semicircular canals, utricle, and saccule) and the superior and inferior divisions of the vestibular nerve. The central component refers to the vestibular nuclei, their ascending and descending pathways, and higher centers in the brainstem and cerebellum which integrate signals that ultimately impart our sense of spatial orientation.

Disarrangements in the vestibular system can manifest unusual sensations that can be difficult to describe clearly, and, therefore, diagnose accurately. As a result, the catchall phrase “dizziness” has been used to describe symptomatology in patients who have true disorders of the vestibular system but may also include those whose underlying pathology is of an entirely different organ system. Understanding how to evaluate the integrity of the vestibular system and its relationship to visual and proprioceptive inputs is important because dizziness is the ninth most common complaint patients report to their primary care physicians, representing an enormous investment in healthcare dollars and medical personnel time. A systematic approach to the patient with dizziness will be presented which includes the history, physical examination, and laboratory testing that point to an underlying disorder of the peripheral component of the vestibular system will be reviewed in this chapter.

OBTAINING THE HISTORY

A comprehensive history is the single most valuable part of the evaluation of the patient with dizziness. This is best achieved by a written questionnaire filled out well in advance of the patient visit and a careful oral follow-up to their responses during the examination. Initially, patients are asked to describe their symptom without using the word “dizzy” and then the questioning rapidly focuses in on key symptoms of vestibular dysfunction. Vague complaints like “dizziness” warrant further clarification to determine if the patient really means vertigo, lightheadedness, specific visual disturbances, imbalance, feelings of dissociation, or poor concentration. Investing the time to distinguish between these symptoms often helps to narrow the differential diagnosis considerably.

Vertigo is a term often used to describe dizziness, but there is a lack of consensus—even among otologists—regarding its precise meaning. In general, vertigo should be reserved to describe the false illusion of rotational motion of the environment. Therefore, ask the patient specifically, “Do things spin in front of your eyes when you are dizzy?” Although vertigo strongly points to vestibular dysfunction, it is by no means pathognomonic and has been reported to occur in the setting of migraine, postural orthostatic hypotension, and stroke.

Some patients with chronic or uncompensated vestibular disease do not experience the spinning characteristic of vertigo but instead describe a sensation of visual blurring of their environment with rapid head movements or during ambulation. This symptom is consistent with oscillopsia and should raise concern for bilateral peripheral vestibular hypofunction or poorly compensated unilateral injury.

Eliciting a history of fainting, “blacking out,” or syncope suggests an underlying cardiac cause and practically excludes vestibular disorders which never manifest loss of consciousness. Reports of imbalance, difficulty ambulating, stumbling, or frank ataxia should raise concern for neurological disorders, particularly degenerative conditions of the cerebellum. Feelings of dissociation, inattention, lightheadedness, or a generalized sense of ill-being are nonspecific and neither implicate nor exclude an underlying vestibular component.

Once the clinician has elicited as specific a description of the dizziness as possible, attention should be directed toward determining the true duration and frequency of the symptom. Is the symptom constant or episodic? If the latter is the case, how long is each episode? In general, patients tend to overestimate the duration of vertigo and may initially report vertigo that lasted for hours but, when pressed, really mean seconds followed by hours of nausea or mild disequilibrium. Being able to discern the true length of the symptom has significant diagnostic implications. For example, the vertigo of benign paroxysmal positional vertigo (BPPV) lasts seconds, compared to minutes to 2 hours in Menière disease, and >12 hours in vestibular neuritis. For additional information regarding these disorders see Chapter 28, “Menière Disease, Vestibular Neuritis, Benign Paroxysmal Positional Vertigo, Superior Semicircular Canal Dehiscence, and Vestibular Migraine.”

An understanding of the events surrounding the onset of symptoms can be valuable by helping to identify activities that are known risk factors or triggers for the development of certain vestibular disorders. First, determine what the patient was doing immediately prior to the onset of symptoms by asking, “What exactly were you doing when the first episode occurred?” for example, rolling over in bed versus sitting quietly in a chair. Next, inquire about unusual antecedent events that may have occurred in hours to days leading up to onset of symptoms. Head trauma would predispose a patient to develop BPPV or postconcussive vestibulopathy. Travel by airplane with complaints of “ear popping” raise concern for perilymphatic fistula from inner ear barotrauma. An uneventful boat cruise followed by persistent rocking sensation on land suggests mal de debarquement syndrome. Recent recreational diving activity can lead to alternobaric vertigo, perilymphatic fistula, or inner ear decompression sickness.

Associated symptoms should be noted next. It is important to document any auditory symptoms such as hearing change or loss, tinnitus, or aural fullness. Focal neurologic symptoms such as visual loss, headache, numbness, and weakness should be inquired about specifically. Provoking factors such as position change, pressure changes, for example, sneezing or lifting, or loud noises should be addressed as well. It is safe to say that documented prolonged loss of consciousness is never attributable to vestibular dysfunction although a brief vasovagal episode is possible. A summary of symptoms associated with peripheral vestibular disease is included in Table 1.

A thorough review of the patient’s past medical and surgical history is important because it establishes risk factors and impacts on the likelihood of some diagnoses. The acute onset of prolonged, debilitating vertigo in a patient with

A careful otologic examination should be performed next. Tuning fork testing at 512 Hz is a rapid and simple assessment of the conductive and sensorineural components of hearing utilizing the Weber and Rinne tests. Careful visualization of the tympanic membrane with pneumatic otoscopy is undertaken to exclude active infections, chronic effusion, cholesteatoma, or structural disease. A positive fistula test occurs when nystagmus and/or vertigo are induced by applying positive and negative pressure to the external auditory canal and can be seen in otosyphilis, perilymphatic fistula, or superior semicircular canal dehiscence.

Cranial nerves II–XII are evaluated with attention to gross visual acuity, ocular motion in the 9 cardinal directions of gaze (neutral, up, down, left, right, up and left, down and left, up and right, down and right), ocular alignment, facial sensation to light touch, facial movement, palate elevation, shoulder shrug and head turn, and tongue motion. At this point, the physician performs a specialized oculomotor and vestibulo-ocular examination and evaluation of posture and gait. It is important that this examination be systematic and progress in a logical fashion from the seated to lying to standing position as each aspect of eye movement, coordination, and gait is assessed (Table 4).

Spontaneous Nystagmus

To begin the examination, spontaneous nystagmus is examined in the seated patient in neutral position. A history of cardiac arrhythmias, diabetes, poorly controlled hypertension, or known coagulopathy should heighten concern for acute cerebrovascular pathology, like cerebellar infarction, a true vestibular emergency. An otologic source of the dizziness is more likely in a patient with a history of chronic otitis media, prior ear surgery, or exposure to vestibulotoxic medications like aminoglycosides. A history of oncologic disease treated with chemotherapy may lead to imbalance from peripheral neuropathy or to bilateral peripheral hypofunction from exposure to ototoxic vestibulotoxic agents like cisplatinum.

Inquiry for history of migraine should be made in any patient presenting for evaluation of recurrent dizziness as it is increasingly recognized as a cause of episodic vestibular symptoms. One study found unexplained episodic dizziness in approximately 25% of patients meeting defined criteria for migraine. Because the term “migraine” is often used indiscriminately to refer to any severe headache, familiarity with migraine classification criteria is helpful in making the diagnosis of migraine-associated dizziness (MAD); and these criteria are outlined in Table 2. Vestibular symptoms in MAD may precede headache, occur variably (most commonly), or be totally unrelated to headache. The duration of vestibular symptoms ranges broadly from minutes to days, and any nystagmus observed can have peripheral, central, or mixed features. Photophobia during the attack is highly suggestive of MAD with or without cephalgia. A differential criteria for MAD have been proposed by Neuhauser and colleagues and are listed in Table 3.

Table 2: International Classification of Headache Disorders II (ICHD-II): Criteria for Migraine without Aura (1.1) 2004

A. At least 5 attacks fulfilling criteria B - D
   A. Headache attacks lasting 4 to 72 h (untreated or unsuccessfully treated)
   B. Headache has at least 2 of the following characteristics:
      1. Unilateral location
      2. Pulsating quality
      3. Moderate or intense intensity
      4. Aggravation by or causing avoidance of routine physical activity (eg, walking or climbing stairs)
   C. During headache at least 1 of the following:
      1. Nausea and/or vomiting
      2. Photophobia and phonophobia
   D. Not attributed to another disorder
   ICHD-II (2004) criteria for basilar-type migraine (1.2.6)
   A. At least 2 attacks fulfilling criteria B - D
   B. A aura consisting of at least 2 of the following fully reversible symptoms, but no motor weakness:
      1. Dysarthria (slurred speech)
      2. Vertigo (dizziness)
      3. Tinnitus (illusory noise)
      4. Hypacusia (reduced hearing)
      5. Diplopia (double vision)
   C. At least 1 of the following:
      1. At least 1 aura symptom develops gradually over 5 or more min and/or different aura symptoms occur in succession for 5 or more min
      2. Each aura symptom lasts for at least 5 min but not greater than 60 min
   D. Headache fulfilling criteria for ICHD-II migraine without aura begins during the aura or follows aura within 60 min
   E. Not attributed to another disorder

Table 3: Neuhauser Criteria for Migrainous Vertigo

1. Recurrent episodic vestibular symptoms (attacks)
2. Migraine headache meeting International Headache Society (IHS) 1988 criteria
3. At least 1 of the following migrainous symptoms during at least 2 of these attacks:
   a. Migraine-type headache
   b. Visual aura
   c. Photophobia
   d. Phonophobia
4. Other causes ruled out by appropriate investigations

Gaze Testing

After evaluation for spontaneous nystagmus is performed, the patient is asked to fixate on the examiner’s finger held in an eccentric gaze position. In normal subjects, there is no gaze-evoked eye movement. Nystagmus that is provoked on eccentric gaze at 20° from center should be noted for its intensity, direction, and persistence. Unidirectional nystagmus that increases while gazing in the direction of the fast phase (Alexander’s law) implies a peripheral cause. In contrast, gaze-evoked nystagmus which beats in the direction of gaze is indicative of floccular lesions or central effects of sedative and anticonvulsive medications.

Smooth Pursuit Testing

Ocular motility can be influenced by preexisting strabismus, which should be noted prior to onset of this portion of the examination. The value of the oculomotor examination lies in its ability to detect central oculomotor abnormalities, which will then affect the sensitivity and specificity of the vestibular examination that will follow. The ability to follow accurately a slowly moving target requires foveal vision and intact occipital cortices and oculomotor brainstem nuclei.

To assess smooth pursuit, the examiner slowly moves a finger or pen 20 to 40°/s in both the lateral and vertical planes at a comfortable distance in front of the patient using best corrected vision, for example, glasses or contact lenses. Finger movement that is too rapid will elicit rapid catch-up saccades and is the most frequent error in performing this examination. Restrict testing to the central 30° of vision (15° to the left and 15° to the right or up and down) to avoid provoking end-gaze physiologic nystagmus. Normal pursuit eye movements are smooth and accurately track the target. Saccadic breakup of pursuit is significant and can suggest visual problems, especially in the elderly, attentional problems or central pathology of the pursuit pathways in the brainstem, occipital cortex, or cerebellum.

Saccade Testing

The capability to fixate conjugately on a new visual target is generated by the saccadic system in the frontal motor cortex and brainstem. Saccades are tested in both vertical and horizontal planes and are characterized by their accuracy, velocity, and latency. The patient is instructed to look rapidly back and forth between two fingers presented 15 to 20° lateral or vertical to neutral eye position. Several repetitions are optimal in...
each direction (right, left, up, and down). Accurate saccades will demonstrate conjugate movements of the eyes without target overshoot or undershoot. Cerebellar disease may cause saccadic overshoots or undershoots. If the abducting eye moves slowly while the abducting eye overshoots or exhibits nystagmus, an internuclear ophthalmoplegia (INO) is present, and further evaluation for multiple sclerosis or other central brainstem pathology should be undertaken.

Vestibulo-Ocular Reflex Testing
Office testing of the vestibulo-ocular reflex (VOR) is performed using the head thrust, headshake, and dynamic visual acuity tests. The VOR is a 3-neuron arc that stabilizes vision during high velocity impulsive head movements. Office assessment of VOR by rotating the examination chair while having the patient wear Frenzel lenses to eliminate fixation can provide a rough estimate of vestibular function but lacks a standardized stimulus. The most widely used bedside test of the VOR is the head thrust test, which was developed by Halmagyi and Curthoys to enable evaluation of the high-frequency VOR for each ear individually. The patient is placed facing the examiner with the head tilted down about 30° to place the lateral semicircular canals in earth horizontal position. The examiner grasps the patient’s head in both hands and asks the patient to keep their gaze on the examiner’s nose. The head is slowly rotated back and forth laterally until an unexpected high velocity, low amplitude thrust is made to bring the head from lateral to midline. The normal patient keeps the eyes on the examiner’s nose without difficulty. The patient with a significantly weak peripheral vestibular system cannot stabilize vision in this situation, and the eyes slide past the target and are redirected to the examiner’s nose with a compensatory saccade immediately after the thrust. This abnormality is seen when the thrust is in the direction of the weak ear in unilaterial lesions and in both directions with bilateral deficits (Figure 1).

Headshake testing is performed by rotating the patient’s head at 2 Hz in the horizontal or vertical plane for 20 to 30 seconds using Frenzel lenses and examining the eyes for postheadshake nystagmus. If present, postheadshake nystagmus beats in the plane of head rotation toward the stronger ear. However, in Ménière’s disease and other acute vestibular losses, the nystagmus may beat toward the affected or unaffected ear depending on the state of compensation. Vertical nystagmus after horizontal headshaking is indicative of central brainstem pathology.

Dynamic visual acuity (DVA) is assessed by comparing the change in visual acuity induced with a high velocity, low amplitude headshake. Under normal circumstances, the VOR stabilizes the image on the fovea well enough to preserve acuity to within 3 lines of static acuity as measured on a standard Snellen eye chart with best-corrected vision. In cases of bilateral vestibular loss, retinal slip occurs and dynamic acuity is severely impaired. However, poor DVA scores may also be seen in cases of unilateral loss with poor central compensation.

Positional and Positioning (Dix-Hallpike) Testing
A survey of reflexes and motor strength may be completed with assessment of postural stability, gait, and cerebellar function. Finger-to-nose and heel-to-shin testing and rapid alternating movements are examined as indicated. In appropriate patients (older patients, diabetics, and those complaining of leg numbness or clumsiness), vibration sense is tested at the ankle and compared to the wrist. A Rydel-Seiffer graduated or other 128 Hz tuning fork may be used. Decreased lower extremity vibration sense suggests neurologic processes, such as peripheral neuropathy. Proprioception is assessed with toes up or toes down positioning. A survey of reflexes and motor strength may be included as needed if deficits are suspected.

Postural control is assessed by observing static stance and dynamic gait. The Romberg test...
test is performed with the patient standing feet together and eyes open and closed and primarily assesses proprioceptive input. However, a tandem Romberg stance or Romberg stance on a 4” compliant foam pad distorts somatosensation and with eyes closed places emphasis on vestibulospinal inputs for balance (Figure 5). Patients with poorly compensated vestibular loss show increased sway on foam eyes closed whereas bilateral loss patients freely fall into the examiner’s outstretched arms. Finally, observation of gait is done to observe any signs of ataxia, extrapyramidal signs, musculoskeletal dysfunction, or exaggeration. Since there is no true “vestibular” gait, the purpose of this part of the examination is to look for confounding factors other than vestibular loss. In some instances, however, patients may deviate toward the side of a vestibular lesion during a marching stance test known as the Fukuta or Unterberger test.

DIAGNOSTIC TESTING

Comprehensive Audiometry

An audiogram remains one of the most helpful tests in the clinical evaluation of the patient with dizziness. It is important that a comprehensive test is performed which includes air and bone conduction thresholds with adequate masking, word recognition testing at appropriate presentation levels, tympanometry, and acoustic reflex testing including reflex decay. A symmetric sensorineural hearing loss (>10 dB at two or more frequencies or >15 dB at any one frequency), word recognition scores (>10% difference between ears), absent reflexes with normal tympanometry and adequate air and bone thresholds and reflex decay are indications to consider a retrocochlear evaluation. Low-frequency sensorineural hearing loss is suspicious for endolymphatic hydrops whereas a low-frequency conductive loss with normal tympanogram and reflexes is seen in cases of superior semicircular canal dehiscence syndrome. Although a normal audiogram does not eliminate a labyrinthine or cochleovestibular nerve source of vertigo, an abnormal test frequently supports it.

Other tests of audiometric function involve evoked response protocols which include auditory brainstem response (ABR), otoacoustic emissions (OAE), and electrocochleography (ECochG). Auditory brainstem testing in patients with dizziness is primarily used to measure the integrity of eighth nerve function in suspected cases of neoplasm, vascular compression, or degenerative diseases. Otoacoustic emissions are used to document cochlear outer hair cell function. Finally, ECochG using either external auditory canal or transtympanic electrodes measures the summing potential (SP) to action potential (AP) ratio or absolute SP amplitude to either click or tone stimuli and is supportive but not solely diagnostic of endolymphatic hydrops. Details of these audiometric tests can be found in Chapter 9, “Diagnostic Audiology, Hearing Instruments, and Aural Habilitation.”
Vestibular Function Testing

Formal vestibular testing in the laboratory may not be needed in every patient seen for a vestibular evaluation. Diagnoses that can be readily established based on history and examination findings alone in the office obviate the need for further testing. The classic example of this is benign paroxysmal positional vertigo, which can be diagnosed during positioning testing and treated without further studies.

Quantitative vestibular function testing should be chosen by the informed physician based on the quantitative information each test can provide, as well as by the inherent limitations and sensitivity of each test. As a general rule, the history and physical examination provide the physician with a qualitative diagnosis; and, therefore, the primary role of laboratory tests is to document and quantify the suspected deficits. Vestibular function tests can also serve to assess the degree of compensation following vestibular injury, to follow compensation over time, and to quantify function prior to vestibular ablative procedures.

The traditional vestibular test battery assesses the oculomotor system, positional and positioning testing, low-frequency VOR caloric responsiveness, multi-frequency VOR gain, phase and symmetry, vestibular–visual interaction and postural control. Note that none of the standard vestibular laboratory studies assesses vertical canal function (aside from Dix-Hallpike testing for posterior canal BPPV) or otolith function. There are also other inherent limitations to vestibular testing. These tests are not a substitute for a thorough history and examination. They do not measure the degree of disability in a patient complaining of dizziness. They are human operator-dependent, and, therefore, computerized interpretation systems cannot replace the role of the experienced operator in obtaining optimal, cooperative performance from the patient which yields valid and reliable data. Finally, the results of vestibular testing can be influenced by factors such as medications, making adequate patient preparation essential. Patients should be instructed to refrain from antihistamines, alcohol, sedatives, and PRN benzodiazepines 24 to 48 hours prior to testing. Other routine medications which may affect test sensitivity should not be discontinued, and interpretation should note all medications taken and include their possible effects on the test results.

Test Conventions. To interpret accurately vestibular test data, it is important to understand certain test conventions. Nystagmus refers to rhythmic repetitive eye movements. Vestibular nystagmus is characterized by a distinct slow and fast phase. The direction of the nystagmus is named for the fast phase as seen from the patient’s perspective. Nystagmus data are often presented on a horizontal strip recording, in which the horizontal axis designates time and the vertical axis represents eye deviation. Rightward nystagmus (fast component to the right, slow component to the left) appears on a strip recording as a sharp upward deflection followed by a gradual deflection downward. Strength of nystagmus is calculated by measuring the degrees that the eye moves in 1 second during the slow phase.

There are several methods employed to record nystagmus with advantages and disadvantages to each method. Visual inspection in room light is the simplest, least expensive method but affords the least sensitivity as patients can fixate on objects in the room, which can diminish or abolish vestibular nystagmus. Electrooculography (EOG) uses surface skin electrodes around the eye to record changes in the strength of the field generated by the corneoretinal potential, and nystagmus is recorded in the dark or with eyes closed. EOG resolution is 1°/s and...
and anticonvulsants may cause atypical spontaneous nystagmus. A search for gaze-evoked nystagmus is undertaken next. Rightward, leftward, upward, and downward gaze are assessed by having the patient look 15 to 30° of eccentric gaze. Having the patient look any further than 15 to 30° may provoke normal end-gaze physiologic nystagmus. In general, gaze-evoked nystagmus is indicative of central pathology but may occur in the setting of patients who have recently consumed alcohol or are on anticonvulsants. Figure 8 demonstrates a central gaze-evoked nystagmus. In extreme cases, gaze-evoked nystagmus can interfere with the patient's ability to follow visually a moving object, as seen in Figure 9.

Next, saccades which are extremely high acceleration eye movements which voluntarily redirect sight, or reflexively gaze toward a starting stimulus are tested. When assessing saccades, 4 parameters are of particular interest: latency, accuracy, peak velocity, and conjugacy. Latency refers to the delay between the presentation of the stimulus and beginning of the saccade and is usually 200 ms in normal subjects. Prolonged latency can be secondary to inattention, advanced age, or central pathology. Saccadic accuracy can be described as overshoot (hypermetria) or undershoot (hypometria). Hypometria must be severe and reproducible to be considered abnormal. Hypermetric responses are more significant even if slightly abnormal and suggest midline cerebellar injury. Any disconjugate saccade abnormality is considered significant. For example, internuclear opthalmoplegia (INO) is a central disorder which causes slowing in the adducting eye and over-shooting or gaze-evoked nystagmus in the abducting eye during attempted saccades. Bilateral INO is most commonly associated with lesions of the median longitudinal fasciculus in conditions like multiple sclerosis whereas unilateral INO can be seen in brainstem lesions or infarction.

In summary, oculomotor tests can be particularly valuable for detecting central pathology but are affected by age, vision, medication, alertness, and cooperation. Thus, interpret oculomotor abnormalities cautiously and recognize that central pathologic patterns are usually evident on several of the tests. Bilateral findings are less often central in origin than are unilateral asymmetric findings. The demonstration of an intact oculomotor system during oculomotor testing was discussed briefly in the previous section on physical examination. Laboratory oculomotor testing is similar; but, in addition to assessment of pursuit, saccade, spontaneous, and gaze-evoked nystagmus, optokinetic nystagmus may also be evaluated. The oculomotor tests should be performed first in the vestibular test battery in order to identify abnormalities and to ensure that nystagmus can be recorded accurately during later vestibular stimulation.

Calibration is performed first and is important for computerized interpretation systems to ensure accurate measurement of the amplitude and direction of nystagmus throughout testing. It is done by having the patient look at fixed points 1 m away, including center, left (27 cm), and right (27 cm). These lateral points correspond to approximately 15° of eccentric gaze. Calibration errors are the most common reason corneal responses appear "reversed."

Spontaneous nystagmus is recorded with the patient sitting comfortably and is recorded with and without visual fixation. A small light located inside the infrared goggle or projected on the wall is illuminated for fixation testing. Vestibular nystagmus is characterized by a persistent horizontal unidirectional nystagmus that diminishes at least 50% with fixation. As already noted, vestibular nystagmus may appear stronger when the patient directs their gaze in the direction of the fast phase (Alexander's law). It is usually seen in the acute period following a unilateral vestibular loss, and the fast phase beats away from the affected ear.

Spontaneous nystagmus that does not have these important characteristics (unidirectional, horizontal, diminishes with fixation and worsens with gaze in the direction of the fast phase) should be considered potentially central. This includes vertical nystagmus (upbeat or downbeat), direction changing nystagmus (Figure 6), irregular or disconjugate nystagmus, or nystagmus that worsens with fixation (Figure 7). Alcohol and certain medications such as sedatives and anticonvulsants may cause atypical spontaneous nystagmus.

**Figure 8** Gaze-evoked nystagmus of central origin. No nystagmus is observed on central gaze, whereas a right beating nystagmus is seen on rightward gaze and a left beating nystagmus is observed with left gaze.

Positional and Positioning Testing. Positional and positioning testing was addressed earlier in the bedside/office physical examination section. Formal testing in a laboratory is essentially identical, and therefore is not discussed in detail. A laboratory testing is typically performed in the absence of the interpreting clinician, it is useful to record the nystagmus seen during positional and positioning testing and to replay it during interpretation by the physician. This permits greater sensitivity in identifying torsional eye movements, which are not accurately analyzed by commonly used computerized systems which record only horizontal and vertical eye movements.

Caloric Testing. Caloric testing of the VOR compares responses of the left with the right lateral semicircular canal; and, therefore, it is notable for being the only vestibular test that provides lateralizing information. It should also be noted that caloric testing evaluates only the lowest frequency response of the VOR (about 0.003 Hz); and, therefore, any interpretation of abnormal function should not be extrapolated to higher frequencies or vertical canal or otolith function.

Testing is conducted with the patient placed supine in the darkness with the head of bed elevated 30°. This effectively brings the lateral semicircular canal into a vertical orientation. Standardized warm (44°C) and cool (30°C) stimuli are applied to the external auditory canal, in an alternating bithermic manner, that is, left warm (LW), right warm (RW), left cold (LC), right cold (RC). Water is the most dependable stimulus and can be directly irrigated into the external auditory canal (open loop), or used in a “closed loop” balloon system when prior surgery, infection, or tympanic membrane perforation precludes direct instillation of water. A warm caloric stimulation is easier to use but may provide a less reliable and even paradoxical stimulus using warm air with a moist canal or tympanic membrane perforation due to evaporation.

A warm caloric test transmits heat to the lateral semicircular canal, causing endolymph to rise and flow toward the cupula (ampullopetal flow). This is stimulatory to the lateral canal, and nystagmus is generated with the fast phase beating toward the tested ear. The cool caloric stimulus effectively cools endolymph, making it more dense and causing it to fall away from the cupula (ampullofugal flow), which is inhibitory. This generates nystagmus away from the tested ear. The mnemonic devices, COWS (cold-opposite, warm-same), is a simple way to remember the association. Johnksee’s formula is used to calculate differences in caloric responses between the ears, where % caloric paresis = 100 × [(LC + LW) – (RC + RW)]/[LC + LW + RC + RW]]. A 18 to 30% difference is considered significant and varies between laboratories and type of stimulation (open water, closed-loop water, or air). The strength of leftward nystagmus to rightward nystagmus can also be calculated:

% directional preponderance (DP) = 100 × [(LC + RW) – (RC + LW)]/(LC + LW + RC + RW)]

Greater than 30% directional preponderance of nystagmus is considered abnormal, although this is a rather nonspecific finding in isolation. An example of graphic caloric results is shown in (Figure 12).

Fixation is tested following peak caloric nystagmus measurement. The patient is instructed to stare at a strong fixed light, which should cause nystagmus to decrease by at least 50% after 2 seconds. After 10 seconds of fixation, the patient is returned to darkness and nystagmus should rebound. Failure of fixation suppression is a strong central sign and would be expected to be seen consistently throughout caloric (and VOR) testing when there is true central pathology. Isolated failure of fixation is generally disregarded.

If caloric responses are low or absent, ice water irrigation should be tested. Ice water is
Object to anatomic variability and conductivity of movement. Moreover, caloric responses are sub-

The vestibular system works in tandem; and, therefore, its results can be used to assess for both compensation following unilateral loss and extent of bilateral loss. During rotary chair testing, the body is passively rotated with the patient’s head immobilized in a headholder. Frequencies between 0.01 and 1.0 Hz are generated by a computer and presented as sinusoidal chair movement. On a time strip, the movement of the chair appears as a sinusoid moving left and right. The slow phase of the eye movements can be recorded on the same strip, but the eyes will appear as a mirror image of the chair, moving rightward with left rotation of the chair and leftward with right chair rotation (Figure 13). Standard computerized VOR summary analysis is shown in Figure 14.

Three VOR parameters of interest are measured during sinusoidal rotary chair testing: gain, phase, and symmetry. Gain is a measure of how closely the eye movements match the head (chair) movement, with a perfect match resulting in a gain of 1. Phase measures the timing of eye versus chair movement and is best calculated as a first-order difference in degrees at the 0 crossing during low-frequency testing. Symmetry compares the gain of eye movements during rightward versus leftward head rotation. In normal individuals, gain increases toward 1, phase decreases toward 0, and symmetry is preserved with increasing frequency. In patients with acute unilateral loss, gain is moderately decreased, phase is abnormally increased, and asymmetry may be seen, especially in cases with spontaneous nystagmus. With compensation, gain variably recovers, phase usually remains increased, and symmetry abates. With bilateral loss, gain is so low that phase and asymmetry are incalculable.

An alternate approach for rotational testing is to spin the patient in one direction as a constant speed (100 to 300°/s) and observe the resultant nystagmus slow phase velocity both during rotation (per-rotary) and after an abrupt stop (post-rotary). During the initial acceleration of the step velocity test, the VOR generates nystagmus in the direction of rotation which decays at a certain rate dependent on cupular deflection and central velocity storage of the cupular signal. After an abrupt stop, nystagmus is generated in similar fashion in the opposite direction. A measure called “time constant” refers to the time in seconds it takes for the initial nystagmus to decline to 37% of its initial value. In normal individuals, this time constant is of the order of 12 to 15 seconds and reflects intact central velocity storage of the peripheral cupular signal. In cases of vestibular disease, central velocity...

storage is disabled, and the time constant reverts to the cupular value of <6 seconds. Both time constant and phase are sensitive markers of vestibular dysfunction.

Rotary chair testing of the VOR is performed in the dark to eliminate visual fixation. Visual stimuli are included in two additional portions of the test, fixation and visual–vestibular interaction testing. During vestibulo-ocular fixation (VFIX), a steady light rotating with the subject is used to test for the expected (>50%) decrease in vestibulo-ocular gain during visual fixation. During visual–vestibular (VVOR) interaction, earth-fixed visual stimuli are used to increase the perceived motion of the subject by stimulating both the VOR and the optokinetic systems. Since the VOR works best at higher frequencies and the optokinetic system at lower frequencies, the union of these 2 systems during VVOR testing in normal subjects yields unity gain, 0 phase, and no asymmetry across all frequencies. Pathology or poor vision can affect the integration of visual and vestibular inputs, resulting in abnormal fixation suppression during VFIX testing and/or VOR enhancement during VVOR testing.

Limitations of rotary chair testing include cost of the systems, limitation to earth-vertical stimulation of only the lateral semicircular canals and limitations of peak velocity and frequency due to problems with head and body restraint in the chair. Enhancements to standard protocols are being investigated, including eccentric dynamic testing and off-vertical-axis-rotation to assess otolith function and canal–otolith interaction.

**Computerized Dynamic Posturography.** Postural control involves a complex interplay of visual, proprioceptive, and vestibular input. Computerized dynamic posturography (CDP) tests static postural control in a series of conditions designed to emphasize or minimize each of these inputs. The somatosensory system detects contact force and motion between the feet and contact surface and utilizes tactile, deep pressure, joint receptor, and muscle proprioceptive input to influence static posture in a “bottom-up fashion” via the ankle joint. Under normal conditions, the somatosensory system dominates balance control. Firm, fixed surfaces favor the somatosensory system, and classic Romberg testing utilizes these features by testing postural control on a stable surface with eyes closed. The visual system relies on visual cues from the environment to assist in maintaining upright posture. It may be affected by decreased vision, or inappropriate dependence on visual stimuli, for example, standing next to a moving bus and perceiving sway. The vestibular system usually functions to allow head and eye movements that are independent in most situations and functions as a “top down” system for gaze stabilization and head-on-body coordination. In situations of decreased proprioceptive and visual input, the vestibular system is crucial for maintaining upright postural control. Patients with bilateral vestibular hypofunction have great difficulty maintaining postural control on compliant surfaces in the dark, such as deep carpeting or uneven landscape.

CDP presents 6 differing conditions to maximize or minimize input from the somatosensory, visual, and vestibular systems (Figure 15). Postural sway is assessed using force plate technology in 6 different sensory organization test (SOT) conditions 1 to 6. Initially using a fixed platform, the patient is tested with eyes open, closed, or with a swaying visual surround (SOT conditions 1 to 3). Next, the platform is allowed to sway, and the tests are repeated with eyes open, closed and swaying surround (SOT conditions 4 to 6). Normal subjects control their center of gravity over their base of support. When movement of the feet is not allowed, subjects generally will fall if swaying is greater than about 12.5° in the anterior–posterior direction (termed the limits of stability). Patients are compared to age-matched norms, and the degree of peak sway is reported with 100% indicating no sway and 0% indicating sway approaching the limits of stability or a fall into the safety harness.

Interpretation of posturography begins with noting overall postural control. Subscale scores on somatosensory, visual and visual preference, and vestibular subscales are noted. Position of the center of gravity, use of hip and ankle strategies to maintain postural control, and examination of the pattern of falls on the raw data tracings are made. Posturography demonstrates which sensory systems the patient uses to maintain balance, but it does not directly assess deficits in those systems. Thus, a low score on the vestibular subscale (SOT conditions 5 and 6) suggests either that the patient is not using vestibular input when appropriate to maintain posture (late falls on the raw data) or that vestibular input may be deficient (early falls on the raw data) (Figure 16). Hence, CDP uniquely assesses the functional use of the vestibular system to achieve postural control and is best included in a comprehensive vestibular test battery for patients with complaints of postural instability. An additional use of posturography is to identify patients with “aphysiologic” performance on various test conditions. Patients who fail easier conditions and pass harder conditions are demonstrating performance that is not consistent with known physiologic patterns and may be identified by this pattern of test performance.

**Vestibular-Evoked Myogenic Potential.** Vestibular-evoked myogenic potential (VEMP) testing is based upon residual acoustic sensitivity of the saccule and serves as a screening test of saccular otolith function. VEMPs can be elicited by air conduction stimuli (click or tone burst), bone conduction stimuli, or galvanic stimulation. Most commonly, click stimuli are used, and changes in the static contraction of the ipsilateral sternocleidomastoid muscle are measured via electromyography. A normal VEMP response consists of a biphasic wave, with a positive peak (P1) and a negative peak (N1). It is of short latency, with P1 normally occurring within 13 to 15 milliseconds of the stimulus, while N1 occurs within 21 to 24 milliseconds. Normal click-evoked VEMP thresholds fall within 85 to 90 dB SPL and are present in normal individuals younger than 60 years of age.

A binaural VEMP response may be indicative of certain disease processes and may be useful in differentiating pathologic conditions. Click-evoked VEMPs may be present at lower than normal thresholds in ipsilateral superior semicircular canal dehiscence (Figure 17). They may be absent in patients with true conductive hearing loss (such as in otosclerosis) with air-bone gaps as low as 8.75 dB, and in certain diseases like late Menière disease, vestibular neuritis affecting the inferior division of the vestibular nerve, acoustic neuroma, or peripheral vestibular hypofunction (including iatrogenic hypofunction due to intratympanic gentamicin). It should
be noted that normal subjects older than 60 years may have absent click VEMPs; and, thus, their absence in these patients, being evaluated for dizziness, must be interpreted carefully and should not be used solely to guide diagnosis and treatment.19

**Eccentric Dynamic Subjective Visual Vertical.** The otolith organs (utricle and saccule) detect linear acceleration, in contrast to the semicircular canals which detect angular acceleration. Linear vectors of force can be applied to each utricle by rotating a subject around a vertical axis while the subject is eccentrically displaced 4 cm. This centers 1 utricle on the axis of rotation and subjects the other side to a linear force vector. While rotating, the patient feels as if they are being pushed outward toward the side of displacement (similar to standing on the edge of a merry-go-round). The response of each utricle can be contrasted when the subject is rotated with the right ear displaced laterally versus the left ear displaced laterally.

One response mediated by the utricles is the assessment of visual vertical. In the dark, a subject is asked to move a light bar until it appears vertical. The accuracy of the subject’s placement is recorded. This technique can be affixed to the rotary chair to provide subjective visual vertical assessment during eccentric rotation. This protocol allows for comparison of right and left utricular function.24

**Off Vertical Axis Rotation.** Research applications use off vertical axis rotation (OVAR) to tilt the entire rotary chair unit and allow for analysis of gravitational forces on utricular function in rotating subjects.25 This method can be visualized as a spinning holiday tree tilting from side to side in its base. OVAR testing requires complex chair construction and interpretation and is mainly utilized by research laboratories.

**Vestibular Test Battery Interpretation.** Interpretation begins with a review of oculomotor testing performance. Central oculomotor abnormalities are usually obvious and recurrent (see the discussion included in the section “Oculomotor Testing” of this chapter). Demonstration of normal oculomotor function allows assessment to progress to the next level.

Next, check for spontaneous nystagmus. Spontaneous nystagmus may affect results on oculomotor, caloric, VOR symmetry, and directional preponderance. Note any spontaneous nystagmus, and consider its effect on the aforementioned tests. Caloric asymmetry is assessed next. Caloric asymmetry in our laboratory is defined by a greater than 28% difference between ears as calculated with Jonkees’ formula. The next task of the interpreter, once a caloric asymmetry is noted, is to determine if this is an acute uncompensated unilateral loss, a partially compensated loss, or a compensated loss. The following pattern suggests acute uncompensated peripheral vestibular loss:

1. Spontaneous horizontal nystagmus away from the affected ear that decreases at least 50% with fixation.
2. Positional or positioning nystagmus away from the affected ear, especially if seen in several positions.
3. Gaze-evoked unidirectional horizontal nystagmus worse in the direction of gaze away from the affected ear.
4. Asymmetric vestibulo-ocular reflex (VOR) gain decreased with rotation toward the affected side.
5. Low-frequency VOR phase elevation may be present (variable).
6. VOR gain may be normal or reduced.
7. Posturography may show a vestibular pattern of deficit.

In contrast, a unilateral caloric loss which is fully compensated is associated with

1. no spontaneous nystagmus;
2. no gaze-evoked nystagmus;
3. minimal positional and positioning nystagmus (less than 6°/s and not present in several positions);
4. symmetric VOR gain;
5. low-frequency VOR phase elevation may be present (variable);
6. normal VOR gain;
7. normal posturography;
8. asymmetric caloric responses.

5. Fall conditions: 1, 2, 3, 4, 5, 6
6. Composite: 52
Patterns that are a mixture or acute uncompensated and compensated features are described as partially compensated.

Bilateral vestibular hypofunction is suggested by caloric responses less than 22°/s total eye speed and confirmed by rotary chair VOR that is 2 or more standard deviations below normal. The time constant on impulse testing is less than 5 seconds, and sinusoidal VOR testing results indicate reduced VOR gain (at 0.05 Hz <0.20; at 0.2 Hz <0.21; at 1.0 Hz <0.62). Medication effects must be excluded.

REFERENCES

The temporal bone is unique in the human body because it contains, in the small volume of a cubic inch (petrous bone), a concentration of vital osseous and membranous structures surrounded by a more or less extensive system of petromastoid pneumatic cells. Because of the different densities of its bony components and of the air and fluid-filled spaces around and within it, the temporal bone lends itself to accurate visualization and assessment by various imaging modalities.1–10

Conventional radiography, computed tomography (CT), magnetic resonance imaging (MRI), and arteriography are the techniques currently used to study the temporal bone and auditory-vestibular pathways.2–30 Familiarity with clinical applications of these varied modalities is essential for requesting the proper imaging study.

CONVENTIONAL RADIOGRAPHY

Today, the use of conventional radiography is limited to evaluation of the mastoid pneumatization and assessment of the position and integrity of cochlear implant electrodes and gross evaluation of the temporomandibular joint (TMJ). Only 3 projections are of practical interest: the lateral or Schüller projection, the frontal or transorbital, and the oblique or Stenvers projection. The other special projections have historic significance but no useful clinical application.

Schuller or Rungstrom Projection

The Schüller projection is a lateral view of the mastoid obtained with a cephalocaudad angulation of the X-ray beam of 25° to 30°. The patient’s head is turned so that the sagittal plane of the skull becomes parallel to the tabletop and the side under examination is closer to the film. Proper centering is obtained by placing the external auditory meatus of the side to be examined 1 cm above the center of the film or of the tabletop.

The extent of the pneumatization of the mastoid, distribution of the air cells, and degree of aeration and status of the trabecular pattern are the main features of this projection (Figure 1). The anterior plate of the vertical portion of the sigmoid sinus groove (corresponding to the most lateral part of the posterior aspect of the petrous pyramid) casts an almost vertical line, slightly concave posteriorly in its upper portion, superimposed on the air cells. At its upper extremity, this line joins another line that slopes gently forward and downward to form the sigmoid angle of Citelli. The latter line is produced by the superior aspect of the lateral portion of the petrous pyramid. The more medial portion of the superior petrous ridge, from the arcuate eminence to the apex, has been displaced downward by the angulation of the X-ray beam and casts a line that extends forward and downward, crossing the epitympanic area, and more anteriorly, the neck of the mandibular condyle. A bove this line, the upper portion of the attic with the head of the malleus is usually visible. Finally, the TMJ joint is outlined.

Transorbital Projection

The transorbital projection can be obtained with the patient’s face either toward or away from the film. The patient’s head is flexed on the chin until the orbitomeatal line is perpendicular to the tabletop. For better details, each side should be obtained separately, and the central X-ray beam should be directed at the center of the orbit of the side under examination and perpendicular to the film.

The petrous apex is outlined clearly but foreshortened because of its obliquity to the plane of the film. The internal auditory canal (IAC) is
visualized in its full length as a horizontal band of radiolucency extending through the petrous pyramid (Figure 2). At the medial end of the canal, the free margin of the posterior wall casts a well-defined and smooth margin, concave medially. Often, the radiolucent band of the IAC seems to extend medially to the lip of the posterior wall into the petrous apex. This band is not caused by the IAC but is produced by the medial extension of the upper and lower lips of the porus (opening) of the canal and by the interposed groove. Lateral to the IAC, the outline (radiolucency) of the vestibule and of the superior and horizontal semicircular canals are usually detectable. The apical and middle coils of the cochlea are superimposed on the lateral portion of the IAC, whereas the basilar turn is visible underneath it and the vestibule.

**Stenvers Projection**

The patient is positioned facing the film, with the head slightly flexed and rotated 45° toward the side opposite the 1 under examination. The lateral rim of the orbit of the side under investigation should lie in close contact with the tabletop. The X-ray beam is angulated 14° caudad. The entire petrous apex is visualized in its full-length lateral to the orbital rim (Figure 3). The porus of the IAC seen on face appears as an oval-shaped radiolucency open medially and limited laterally by the free margin of the posterior canal wall. Lateral to the porus, the IAC appears foreshortened. The vestibule and semicircular canals, especially the superior, which lies in this projection in a plane parallel to the film, are usually recognizable. On the outside, the entire mastoid is outlined, with the mastoid process free from superimpositions.

**COMPUTED TOMOGRAPHY (CT)**

CT is the imaging study of choice for the assessment of intratemporal pathology. CT is also very good for the evaluation of retro-labyrinthine pathology; however, MRI in this respect is superior to CT scanning. CT is a radiographic technique that allows measurement of small differentials of absorption coefficients of X-ray not recognizable to such extent by previously available recording or displaying systems. The scan is initiated at a chosen level, and the X-ray tube, collimated to a thin or pencil beam, rotates around the patient. The transmitted X-rays are picked up by detectors arrayed along the circumference of the tube trajectory and converted into electronic current that is amplified and transmitted to the computer for storing and processing. The computer analyzes these data and develops an image on a matrix of picture element (pixel) where the brightness of each point is proportional to its attenuation coefficient.

Spatial resolution of CT is measured by the volume of tissue represented by the displayed pixel. In the later generation of multidetector CT scanners, spatial resolution has been reduced to 0.1 cu mm by a special software reconstruction technique of the area of interest. Narrowing the collimator of the X-ray beam and the aperture of each detector has reduced the slice thickness to 0.625 mm or less.
Enhancement of the lesion after intravenous administration of iodine-based contrast material allows the recognition of vascularity of lesions, such as a glomus tumor, and vascular structures, such as the jugular bulb and the internal carotid artery. Further differentiation of the type of lesions can be obtained by CT angiography (CTA) or by CT dynamic scanning, in which 6 or more consecutive scans of a single preselected section demonstrating the mass are obtained in a few seconds. The exposure starts simultaneously with the bolus injection of 30 to 45 mL of iodine-based contrast material. A curve, characteristic of the type of lesion, is obtained by plotting the amount of enhancement expressed in CT numbers versus time. A glomus tumor shows a high peak and rapid wash-in and wash-out phases. A schwannoma or meningioma often shows a delayed wash-out phase. Following the development of CTA, CT dynamic study is infrequently used.

CT Projections of the Temporal Bone

**Horizontal or Axial Projection.** This is the basic projection of the CT study. It is comfortable for the patient who lies supine on the table, and is easy to obtain and reproduce. It allows a good
Figure 7 (A) Axial T2-weighted MR scan, obtained with a 3T MR unit, showing high definition of otic labyrinth. Note scala tympani, scala vestibuli, cochlear and vestibular nerves, facial nerve, vestibule, posterior and lateral semicircular canals, common crus, and endolymphatic duct (arrow). (B) Coronal T2-weighted MR scans, obtained with 3T MR unit, showing otic labyrinth, cochlear, vestibular and facial nerves, and cochlear aqueduct (arrow). (C) Coronal T2-weighted MR scan (top) and coronal macrosection of temporal bone (bottom). Note cochlear and facial nerve on MR scan (top). (D) Coronal T2-weighted scans showing cochlear and facial nerves (top) and inferior and superior vestibular nerves (bottom).
(E) Sagittal T2-weighted MR scan of IAC (top) showing inferior vestibular nerve (arrow), superior vestibular nerve above it, cochlear nerve in anterior inferior compartment of IAC, and facial nerve above the cochlear nerve. Coronal T2-weighted MR scan showing vestibule, ampulla of superior semicircular canal, and vestibular nerves within the IAC. (F) Axial T1-weighted MR scan (top) showing facial nerve (short arrows), greater superficial petrosal nerve (long arrow), and superior vestibular nerve behind the facial nerve within the IAC. Horizontal macrosection of temporal bone, showing structures of the inner and middle ears. (G) Axial (top) and coronal (bottom) enhanced T1-weighted MR scans showing facial nerves. Note abnormal enhancement on the left (arrows) in this patient with viral neuritis of facial nerve. (H) Maximum intensity projection (MIP) 3D MRI of normal inner ear (top) and volume rendered 3D MRI of the normal inner ear. Note cochlear aqueduct (arrow).
Coronal or Frontal Projection. The patient lies on the table, either prone or supine, with the head extended. The gantry of the scanner is often tilted to compensate for an incomplete extension of the head. This projection is indispensable to complement the axial sections (Figure 5) but often difficult to obtain, particularly in young children and older patients.

Sagittal or Lateral Projection. It is impossible or extremely difficult to obtain direct sagittal sections. However, computer-reconstructed sagittal images can be obtained from the raw data collected for the horizontal sections. This is particularly true if fast or spiral CT is used, and thin sections at 1 to 0.625 mm increments are obtained. Although these images are not as satisfactory as the direct sections, they are always sufficient for the demonstration of the mastoid segment of the facial canal, the vestibular aqueduct, cortical outline of the superior semicircular canal (Figure 6), other parts of the otic labyrinth, carotid canal, jugular fossa, external auditory canal (EAC), and TMJ.

**MAGNETIC RESONANCE IMAGING (MRI)**

MRI is an imaging modality capable of producing cross sections of the human body in any plane without exposing the patient to ionizing radiation. MR images are obtained by the interaction of hydrogen nuclei (protons) of the human body with a high static magnetic field and radio frequency pulses. The strength of the MR signal to be converted into imaging data depends on the concentration of the free hydrogen nuclei or protons and on 2 magnetic relaxation times, T1 and T2, which are tissue specific. One of the characteristics of MR is the possibility of changing appearance and therefore information of the images by changing the contribution of the T1 and T2 relaxation times. This is accomplished by varying the time between successive pulses (TR or repetition time) and the time that the emitted signal or echo is measured after the pulse (TE or echo time).

Examination is performed with the patient supine and the plane extending from the tragus to the inferior orbital rim perpendicular to the tabletop. Different projections (views) are obtained by changing the orientation of the magnetic field gradients without moving the patient’s head. Axial, coronal, and sagittal projections are usually obtained.

T1-weighted (T1W) images obtained by a short TR (400 to 1,000 ms) and TE (20 to 30 ms) offer the best anatomical delineation. T2-weighted (T2W) images obtained with long TR (1,500 to 4,000 ms) and TE (80 to 120 ms) better differentiate normal from pathologic tissues. Proton-weighted (PD) or spin-density-weighted MR images are obtained with long TR (1,500 to 4,000 ms) and short TE (20 to 30 ms). PD images are a kind of balanced...
images between T1W and T2W MR images, not frequently used in routine MR studies.

Air, cortical bone, and calcifications contain few free protons and therefore appear in the images as dark areas of no signal. Fat and body fluid are rich in free protons and produce signals to be detected. Tissues with short T1 relaxation time such as fat appear hyperintense (bright) on T1W and hypointense (dark) on T2W spin-echo (SE) MR images. Water and tissues with long T1 and T2 relaxation times, such as cerebrospinal fluid and vitreous, appear hypointense on T1W and hyperintense on T2W SE pulse sequences.

Fast-moving blood in arterial vessels usually appear as areas of signal void (dark) because the stimulated protons of the circulating blood have moved out of the selected section before their emitted signals can be detected. Because cortical or nondiploic bone and air emit no signal, the normal mastoid, EAC, and middle ear appear in the MR images as dark areas without pattern or structures within them. At times malieus and incus can be recognized because of their bone marrow. The petrous pyramid is equally dark except for a gray or white cast of the inner ear structures and IAC, produced by the fluid within their lumens (Figure 7). The marrow of petrous apex appears hyperintense on T1W MR images.

Pathologic processes are demonstrated by MRA whenever the hydrogen density and relaxation times of the pathological tissues are different from the normal. The T1 and in particular T2 relaxation times of pathologic tissue will be longer than those of normal tissue. The intravenous injection of paramagnetic contrast agents (gadolinium DPTA (diethylenetriaminepentaacetic acid) and gadolinium chelate) has improved the recognition and differentiation of pathologic processes. Because the contrast material does not penetrate the intact blood-brain barrier, normal brain does not enhance except for structures such as the stalk of pituitary gland and choroid plexus that lack a complete blood-brain barrier. Enhancement of brain lesions occurs whenever the blood-brain barrier is disrupted, when there is sufficient blood flow to the lesions. Extra-axial lesions such as meningiomas, neurofibromas, and schwannomas as well as most intra-axial lesions cause disturbance of the blood-brain barrier and therefore undergo a moderate to marked enhancement.

**Diffusion-Weighted Imaging (DWI)**

Diffusion is a process in which molecules are mixing together via the action of random collisions (the so-called Brownian motion) among themselves and with other molecules or structures such as cell membrane. When the diffusion process is the same in all directions, it is called isotropic diffusion. When the diffusion process is not appearing the same in all directions (x, y, and z), it is referred to as anisotropic diffusion. The apparent diffusion coefficient (ADC) is a diffusion coefficient that is determined by displacement of diffusion along a particular direction.

**Magnetic Resonance Angiography (MRA)**

Gradient-echo (GE) techniques and flow-encoding gradients have enabled the development of MRA. Time-of-flight (TOF) angiography is a GE technique in which the stationary tissues within the imaging plane are saturated with the radiofrequency pulses so that they will not produce a signal. Blood flowing within the same plane is unsaturated and will be the only tissue to produce a signal. Three-dimensional (3D) TOF MRA is used for intracranial angiography, and 2-dimensional (2D) TOF MRA is used for cervical angiography. 2D-TOF is used for intracranial MR venography.

Phase-contrast (PC) angiography is acquired differently. Instead of saturating the stationary tissues with radiofrequency pulses, a bipolar gradient of magnetization is applied to the entire slice, first with a positive value and then with a negative value. In the stationary tissues, the 2 opposite gradients cancel each other out. In the flowing blood, however, the 2 opposite gradients cannot cancel out each other because the blood will have moved to a different plane in the region before the inverse gradient is applied.

The obtained slices are reconstructed into projection images, which can be rotated in different planes to separate vessels and eliminate superimposition. MRA of the intracranial
Figure 13 Anatomical variations of the temporal bone. (A) Axial and coronal CT scans showing high jugular fossa with dehiscence. Note extension of jugular bulb into the round window niche seen in coronal image. (B) Forward and lateral lying sigmoid sinus plate. Axial CT scans showing marked forward and lateral position of the sigmoid plate (arrows). Note that at one point, the bone is so thin (lower image) that the cortical bone is missing and only the periosteal layer is outlined. (C) High jugular fossa. Direct sagittal CT scans, showing high jugular fossa (top image). The fossa (arrows) extends to the level of IAC, with focal bone dehiscence adjacent to the posterior aspect of IAC. The bottom image shows normal carotid canal (black arrow), jugular fossa (white arrow) and IAC (arrowhead) for comparison with top image. (D) Dehiscent facial canal. Coronal CT scan (left) showing a cochlear implant electrode, touching the facial nerve (arrow). This patient developed hemifacial spasm following activation of the implant. A axial CT scan (right) showing a cochlear implant (arrow) adjacent to the labyrinthine segment of the facial canal. This patient also developed facial dysfunction following activation of the electrode. (E) Large emissary mastoid canal. A axial CT scans showing congenital deformity of the malleus and incus and a prominent mastoid emissary canal (arrow). (F) Large petromastoid (subarcuate) canal. Coronal (top) and axial (bottom) CT scans of an infant, showing a large petromastoid canal (arrows). The enlarged canal gives the appearance of pseudodouble IAC.
vasculature has been particularly useful in the demonstration of intracranial vascular anatomy and pathology such as vascular stenosis, aneurysms in the region of the circle of Willis (Figure 11), and arteriovenous malformation (AVM), for example, dural AVM that may not be visible on routine SE images. Magnetic resonance venography (MRV) is essential to show dural sinus thrombosis (Figure 12). MRA of the extracranial circulation provides excellent information about the patency of the carotid and vertebral arteries. These vessels may be compressed or displaced by neck masses and their lumens stenosed or obstructed by thrombosis, dissection, or atheromatous plaques.

Conventional angiography is seldom required for the diagnosis of vascular tumors or anomalies within or adjacent to the temporal bone. Arteriography is, however, mandatory for identifying the feeding vessels of lesions, usually glomus tumors, whenever embolization or surgical ligation is contemplated. Subtraction is necessary to delineate the vascular mass and feeding vessels, which are otherwise obscured by the density of the surrounding temporal bone. The injection should be performed in the common carotid artery to visualize both internal and external carotid circulation. Selective external carotid and vertebral injections are often performed to evaluate the tumor's feeding vessels and the anatomy of collateral circulation if embolization is planned.

Retrograde jugular venography is no longer used for the diagnosis of a high jugular bulb or its occlusion by a mass. 2-D TOF MRV and contrast-enhanced SPGR (spoiled gradient-recalled) imaging and pulse sequence venography are excellent to evaluate dural sinus and jugular bulb (Figure 12).

Figure 14  (A) Acute mastoiditis. This axial computed tomographic (CT) section of the left mastoid shows clouding and air-fluid levels within the air cells. The trabecular pattern is intact. (B) Coalescent mastoiditis, axial CT section of the left mastoid. A large coalescent cavity is noticed in the mastoid (arrows) with erosion of the outer cortex and formation of a subperiosteal abscess.

Figure 15  (A) Otogenic perisinus (sigmoid) abscess. Enhanced coronal T₁-weighted MR scans showing a large mastoid abscess (single arrow) and a large perisinus abscess (double arrows) in another patient. Note also a mastoid subperiosteal abscess in the patient with perisinus abscess. (B) Otogenic cerebellar and temporal lobe abscesses are enhanced. Enhanced T₁W MR (left) CT scan (right) showing cerebellar and temporal lobe abscesses in two different patients.

Figure 16  Chronic adhesive otomastoiditis. Macroscopic tissue section and coronal CT scan of a different patient with chronic otomastoiditis. Note contracted middle ear due to scarring, sclerotic malleus, and a large calcification (arrow) in the mesotympanum due to tympanosclerosis.
ANATOMICAL VARIATIONS

Recognition of anatomical variation of the temporal bone is important. These include the forward-lying sigmoid sinus plate, dehiscent jugular dome with the jugular bulb protruding into the hypotympanum, ectopic internal carotid artery coursing into the middle ear, aberrant course of the internal carotid artery, dehiscent facial canal, enlarged subarcuate (petromastoid) canal, prominent Hyrtl fissure, prominent groove for superior petrosal vein, dehiscence of the tegmen tympani and ant, and widened geniculate fossa (Figure 13A–F). In aberrant course of the internal carotid artery, the absence of vertical segment of the internal carotid artery results in the lateral coursing of the artery. The vertical petrous portion is represented by the enlarged inferior tympanic artery. A persistent stapedial artery may be found in patients with an aberrant internal carotid artery. The persistent stapedial artery on its way to become the middle meningeal artery results in enlargement of the proximal portion of the tympanic segment of the facial canal. In these patients, the foramen spinosum through which the middle meningeal artery passes may be absent.

PATHOLOGIC CONDITIONS

The pathologic conditions of the ear and temporal bone will be reviewed by anatomic location. Seven sites of involvement are considered: mastoid, EAC, middle ear, inner ear, petrous pyramid, facial nerve canal, and cerebellopontine angle region.

M astoid

Conventional views, and CT, and MRI are used for the study of this region.

Acute Mastoiditis. The early findings of acute mastoiditis are diffuse and homogeneous clouding of the middle ear cavity and mastoid air cells, and often air-fluid levels within the air cells (Figure 14A). With the progression of the process, the mastoid trabeculae become first demineralized and then destroyed, with formation of coalescent areas of suppuration and subperiosteal abscess over the outer cortex of mastoid (Figure 14B). Involvement of the posterior sinus plate often leads to thrombophlebitis of the sigmoid or lateral sinus and to perisinus as well as posterior fossa abscesses (Figure 15), whereas erosion of the tegmen may lead to extension of the infection into the middle cranial fossa.

Chronic Mastoiditis. The mastoid is often poorly pneumatized, and the mastoid antrum and mastoid air cells appear nonhomogeneously cloudy. Reactive mucosal thickening and new bony formation produces thickening of the trabeculae (Figure 16), which may lead to complete obliteration of the air cells (sclerotic mastoiditis).

Eosinophilic Granuloma (Langerhans Cell Histiocytosis). Lytic lesions of variable size are observed in the mastoid, petrous, external ear, and temporal squama in eosinophilic granuloma. In the involved areas, the trabecular pattern is partially or completely erased and the mastoid cortex may be thinned out, destroyed, or expanded (Figure 17).2

External Auditory Canal (EAC)

CT is the study of choice for the evaluation of EAC, but MRI may add useful information whenever the lesion extends outside the confines of the canal into the adjacent structures (Figures 18–22).

Congenital Malformations. Microtia and atresia of varying degrees are often associated with
dysplasia of the EAC. The degree of malformation of the EAC varies from complete agenesis of the tympanic bone (Figure 18) and EAC to stenosis of its lumen and atresia (atretic bony plate) of an otherwise well-developed EAC. The malleus may be fused to the atretic plate. The small tissue tag and pit frequently observed in patients with atresia of the EAC often have no topographic relationship to the underlying mastoid and middle ear.

Trauma. Fractures of the EAC are the result of a longitudinal fracture of the temporal bone, direct trauma to the anterior wall after a blow to the mandible, or projectile missiles such as bullets or metallic fragments from industrial accidents. Longitudinal fractures usually pass from the temporal squama into the superior canal wall. The fracture often extends to the anterior canal wall and TMJ.

Figure 19 (A) Necrotizing external otitis. Axial computed tomographic section of the left ear. There is erosion of the anterior wall of the external auditory canal with stenosis of the lumen of the canal caused by soft tissue swelling. The infection has spread into the middle ear. (B) Necrotizing external otitis. Axial enhanced T1-weighted (left) and T2-weighted (right) scans showing marked enhancement of tissue around left external auditory canal (arrow). Note fluid in the TM joint, depicted on T2-weighted image (arrow). (C) Necrotizing external otitis and carcinoma of left EAC. Coronal enhanced CT scan showing increased thickening and enhancement (double arrows) in this patient with necrotizing external otitis. Note extension of disease along the adjacent fascial planes and base of skull. (D) Coronal enhanced T1-weighted MR scan in another patient with carcinoma of right EAC. Note increased soft tissue thickening and enhancement similar to necrotizing external otitis. Note extension of carcinoma along dura (arrow).

Necrotizing External Otitis. This condition, also known as malignant external otitis, is an acute osteomyelitis of the temporal bone that occurs in debilitated, diabetic, and immunosuppressed patients, and is usually caused by Pseudomonas bacterium. The infection starts in the EAC and spreads rapidly to the other portions of the temporal bone and adjacent areas. CT reveals initially increased soft-tissue thickening and later on erosion of the bony external canal, particularly of its floor, and stenosis of the lumen of the canal caused by soft-tissue swelling. The infection may then spread inferiorly along the undersurface of the temporal bone to involve the facial nerve at the stylomastoid foramen, anteriorly to the temporomandibular fossa, and parotid space, posteriorly to the mastoid, and medially into the middle ear, and petrous pyramid and base of the skull (Figure 19).
EAC Cholesteatoma. Cholesteatoma of the EAC is caused either by blockage of the EAC, with consequent accumulation of epithelial debris (keratosis obliterans), or by dyskeratosis with localized accumulation of debris on the floor of the canal (invasive keratitis). In the first type, a soft tissue mass fills and expands the canal medial to the site of stenosis or obstruction (Figure 20). In the second type, the lumen of the canal is patent, but areas of bony erosion and scalloping are demonstrated in the involved portion of the canal. When the cholesteatoma is large and erodes the annulus, it may extend into the middle ear cavity and mastoid.2

Carcinoma. Carcinoma of the temporal bone usually arises in the EAC epithelium. The CT findings vary with the extent of the lesion. In an early lesion, portions of the bony wall of the EAC are eroded (Figure 21). When further destruction occurs, the neoplasm may spread anteriorly into the temporomandibular fossa; posteriorly into the mastoid, where it often reaches the facial canal; and mediially into the middle ear, jugular fossa, petrous pyramid, and labyrinth. Extension into the mastoid and petrous pyramid causes a typical moth-eaten appearance because of infiltration of the bone.

Middle Ear and Ossicular Chain
CT is the study of choice for pathologic processes that arise in the middle ear and involve the ossicular chain. Because granulation tissue enhances after the injection of paramagnetic agents, MRI with contrast is useful in some cases to differentiate granulation tissue from fluid and cholesteatoma, which have a similar density in CT images.

Congenital Malformations. Malformations of the middle ear space vary from minor hypoplasia to complete agenesis. In the majority of cases with an atretic EAC, the middle ear cavity is near normal in size and aerated. The head of the malleus and the body of the incus are often fused (Figure 13A) and fixed to the atretic plate at the level of the malleus neck. If the middle ear cavity is grossly hypoplastic, the malleus and incus form a rudimentary amalgam that is often in an ectopic position (Figure 22). A congenital anomaly may be confined to the ossicular chain, which may be malformed or fixed. Malformations of the stapes superstructures and fixation of the stapes footplate are not uncommon isolated defects. The jugular bulb sometimes projects into the hypotympanum or mesotympanum. The bulb

(B) Notice the lack of development of the mastoid pneumatization and the outward rotation of the vertical segment of the facial canal (arrow).

Figure 23 Ectopic left internal carotid artery. Coronal (A) and axial (B) computed tomographic sections. The ectopic carotid artery courses throughout the entire length of the middle ear cavity. Notice the absence of the vertical portion of the carotid canal normally seen underneath the cochlea and of the bony wall dividing the anterior part of the mesotympanum from the horizontal segment of the carotid canal.

Figure 24 Longitudinal fracture of the right temporal bone, axial computed tomographic section. The longitudinal fracture extends from the cortex of the posterior portion of the mastoid to the posterosuperior canal wall (arrow). The fracture reaches the attic and disrupts the ossicular chain. The body of the incus is displaced laterally and posteriorly.

Figure 25 Longitudinal fracture of the right temporal bone. (A) Axial and; (B) coronal computed tomographic sections. A fracture extends from the mastoid cortex to the region of the aditus (black arrows). The head of the malleus and the body of the incus are in normal relationship, but the incudostapedial joint is disrupted (white arrows).
may be covered by a thin bony shell or may be exposed in the middle ear, often in contact with the medial surface of the tympanic membrane, and thus mimicking a glomus tumor. Whenever the diagnosis is in doubt, we perform MRV and enhanced SPGR pulse sequence. The intratemporal segment of the carotid artery may take an ectopic or an aberrant course through the middle ear. In these cases, the CT examination shows a soft tissue mass extending throughout the entire length of the middle ear cavity to regain its normal position in the petrous apex (Figure 23). The vertical portion of the carotid artery, rather than being located underneath the cochlea, enters the temporal bone through an enlarged inferior tympanic artery canal in the floor of the posterior part of the hypotympanum. MRA may be used to confirm the anomalous course of the artery.

**Meningoencephalocele.** Meningoencephalocele, after modified radical mastoidectomy. (A) Coronal computed tomographic section showing a large defect in the tegmen of the cavity with a soft tissue mass underneath it. (B) T1W coronal magnetic resonance image clearly identifying the soft tissue mass (arrow) as a brain herniation.

**Trauma.** The middle ear cavity is usually involved in longitudinal fractures of the temporal bone. CT permits precise evaluation of the course of the fracture and status of the ossicular chain (Figure 24, 25). A fracture line may disappear at the diagnosis is in doubt, we perform MRV and enhanced SPGR pulse sequence. The intratemporal segment of the carotid artery may take an ectopic or an aberrant course through the middle ear. In these cases, the CT examination shows a soft tissue mass extending throughout the entire length of the middle ear cavity to regain its normal position in the petrous apex (Figure 23). The vertical portion of the carotid artery, rather than being located underneath the cochlea, enters the temporal bone through an enlarged inferior tympanic artery canal in the floor of the posterior part of the hypotympanum. MRA may be used to confirm the anomalous course of the artery.

**Figure 26** Meningoencephalocele, after modified radical mastoidectomy. (A) Coronal computed tomographic section showing a large defect in the tegmen of the cavity with a soft tissue mass underneath it. (B) T1W coronal magnetic resonance image clearly identifying the soft tissue mass (arrow) as a brain herniation.

**Figure 27** (A) Right chronic otitis media, coronal computed tomographic section. The tympanic membrane is thickened and retracted. The mesotympanum is markedly contracted, and the mastoid air cells appear cloudy. The lateral wall of the attic and incudostapedial junction is intact. (B) Tymanosclerosis. Coronal CT scan (left) showing sclerotic mastoid, contracted middle ear, sclerotic ossicles, and calcification (arrow) due to tymanosclerosis. Axial CT scans (right) showing an attic-antral cholesteatoma (arrows) of the right ear. Note left ear for comparison. Note that only a piece of the matter is present on the right ear.
a certain level only to reappear a few millimeters distant. This apparent gap is not caused by interruption of the fracture line but rather by a change in its course so that the fracture becomes invisible in some of the sections. The tegmen is usually involved, and cerebrospinal fluid (CSF) otorrhea or rhinorrhea occurs whenever the dura is torn. Anterior extension of the fracture may reach the eustachian tube, which becomes obstructed. Conductive hearing loss is usually secondary to disruption of the ossicular chain (Figure 24, 25). The body of the incus is usually rotated and displaced superiorly, posteriorly, and laterally. Interruption at the incudostapedial area results from a fracture of the lenticular process of the incus or the stapes superstructure and from a dislocation of the incudostapedial joint.

**Meningocele and Meningoencephalocele.** A soft tissue mass contiguous to a defect in the tegmen of the mastoid suggests the possibility of a meningocele or meningoencephalocele. If the brain and meninges herniate into the small space of the antrum or epitympanum, the constant pulsation of the CSF is transmitted through the walls of the meningocele to cause a gradual resorption of the surrounding bony walls. CT demonstrates the bony defect in the tegmen and a soft tissue mass filling the mastoid cavity (Figure 26). This soft tissue lesion cannot be reliably differentiated from a recurrent cholesteatoma since the absorption coefficients of both lesions are similar. A more definite diagnosis of meningoencephalocele is reached by injecting, by means of lumbar puncture, a small amount of myelographic contrast that will diffuse in the subarachnoid space and produce an enhancement of the herniated CSF mass. The differentiation between a meningocele and a cholesteatoma may also be made with MR. On MR, cholesteatoma appears as a lesion of low to intermediate signal in the T1W and high signal intensity in T2W images. A meningocele will have the same characteristics as CSF: low signal intensity in T1W and high intensity in the T2W images. On DWI, cholesteatoma appears hyperintense while meningocele remains hypointense. On MR, meningoencephaloceles have the same characteristics of the adjacent brain, which are quite different from a cholesteatoma (Figure 26).

**Acute Otitis Media.** In acute otitis media, the CT images demonstrate a nonspecific and diffuse clouding of the middle ear cavity. Occasionally, on CT scans, air bubbles may be seen within the middle ear. The tympanic membrane is often swollen and bulges externally.

**Chronic Otitis Media.** There are 2 types of chronic otitis media which can be differentiated with imaging studies. In chronic supplicative otitis media, a partial, nonhomogeneous clouding of the middle ear cavity is caused by granulation tissue, polyps, and fluid or pus. Because the tympanic membrane is perforated, some aeration of the middle ear space may be present. Erosion of the long process of the incus is a common finding, whereas erosion of the body of the incus and the head of the malleus is rare unless a cholesteatoma is present. In chronic adhesive otitis media, the middle ear space is contracted because the tympanic membrane is perforated and some aeration of the middle ear space may be present. Erosion of the long process of the incus is a common finding, whereas erosion of the body of the incus and the head of the malleus is rare unless a cholesteatoma is present. In chronic adhesive otitis media, the middle ear space is contracted because of retraction of the tympanic membrane on the promontory (Figure 27). The handle of the malleus is foreshortened, and the long process of the incus is often thinned out or eroded. In these cases, the retracted tympanic membrane may be attached to the head of the stapes with formation of a natural myringostapediopexy.

Tympanosclerotic deposits are recognizable by CT whenever they are sufficiently large and calcified. The deposits appear as punctate or linear densities within the tympanic membrane or the mucosa covering the promontory. Large deposits of tympanosclerosis in the attic may surround and fix the ossicles.

**Figure 31** (A) Right cholesteatoma with labyrinthine fistula. Coronal computed tomographic section: a soft tissue mass fills the attic, eroding the ossicles and the lateral aspect of the horizontal semicircular canal (arrow). (B) Cholesteatoma eroding facial canal and posterior semicircular canal. Coronal CT scans (left) showing a large acquired cholesteatoma. Note erosion of posterior semicircular canal (black arrow) and erosion of mastoid segment of facial canal (white arrow). (C) Enhanced axial T1-weighted MR scan showing an infected cholesteatoma extending into the IAC (arrow). The abnormal enhancement of IAC and labyrinth is due to infection.

**Figure 32** Right glomus tympanicum. (A) Coronal computed tomographic (CT) section showing a small soft tissue mass in the lower portion of the middle ear cavity (arrow). (B) Dynamic CT study of the preselected section at the level of the mass. Graphic display of the circulation in the tumor (1) and internal carotid artery (2). Notice the high peak of the tumor at arterial time.
Cholesteatoma. Congenital cholesteatomas appear as well-defined soft tissue masses often adjacent to the tensor tympani tendon, handle of the malleus, or long process of the incus, and produce an outward bulge of the intact tympanic membrane (Figure 28).\(^{10}\) The middle ear and mastoid air cells appear otherwise well-aerated. If there is an accompanying serous otitis media related to obstruction of the eustachian tube, the fluid may obscure the mass as the entire tympanic cavity becomes cloudy. If the lesion extends into the attic, the medial or the lateral wall of the attic may be eroded. Other sites of congenital cholesteatomas (epidermoid) are in the petrous apex, around the facial nerve canal and in the mastoid (least common).

Acquired cholesteatomas produce a soft tissue mass mainly in the attic or in the middle ear, resulting in typical erosion of the lateral attic wall, posterosuperior canal wall, and ossicles.\(^{3,7,9}\) If the middle ear cavity is aerated, the soft tissue mass is well-outlined (Figures 29-30). When fluid or inflammatory tissue surrounds the cholesteatoma, the margin of the mass is obscured because the X-ray densities of cholesteatoma, inflammatory tissue, and fluid are similar. MRI with contrast may be useful in these cases to differentiate the enhancing granulation tissue from fluid and cholesteatoma. On DWI, cholesteatoma appears hyperintense while fluid and granulation tissues appear hypointense. Different patterns of X-ray findings are observed. Cholesteatomas that arise from retraction of the pars flaccida of the tympanic membrane produce erosion of the anterior portion of the lateral wall of the attic and of the anterior tympanic spine (Figure 29). The lesion extends into the attic lateral to the ossicles, which may become medially displaced.

Cholesteatomas arising from retraction of the pars tensa, usually from the posterosuperior

**Figure 35** Stapedial otosclerosis, 20° coronal oblique section of the left ear. The footplate of this stapes appears thickened (arrow).

**Figure 36** Michel malformation of the right inner ear structures. Axial (A) and coronal (B) computed tomographic sections. The middle ear cavity is normal, but the petrous pyramid is hypoplastic. The cochlea is absent or markedly hypoplastic. Notice the cavity in the region of the vestibule with rudimentary semicircular canals.
margin of the membrane, appear as a soft tissue mass in the middle ear eroding the long process of the incus and extending into the attic medial to the ossicles which may be displaced laterally (Figure 24). The lateral wall of the attic is usually intact, but the posterosuperior canal wall is often eroded. Sometimes a cholesteatoma may involve both the pars flaccida and pars-tensa, producing a mixed X-ray pattern. In advanced cholesteatomas of all types, extensive bony destruction occurs, and no distinct patterns remain. The ossicles in the attic, particularly the body of the incus, are eroded; the aditus is widened; and the mastoid antrum becomes enlarged, cloudy, and smooth in outline because of erosion of the air cells lining the walls of the antrum. Further extension into the mastoid causes destruction of the trabeculae with formation of large cavities. Erosion of the tegmen may lead to meningeal and intracranial complications. Labyrinthine fistulas occur most commonly in the lateral portion of the horizontal semicircular canal. The CT sections show flattening of the normal convex contour of the horizontal semicircular canal and erosion of the bony capsule covering the lumen of the canal (Figure 31). Further complications of cholesteatoma are extension into the petrous pyramid, which usually occurs in well-pneumatized bones, and erosion of the facial canal, which may lead to facial paralysis (Figure 31B, C).

Neoplasms. Osteomas are frequent in the EAC, but also rarely occur in the middle ear, where they may cause conductive hearing loss by impinging
on the ossicular chain. Glomus tumors, also called chemodectomas or nonchromaffin paragangliomas, arise in the middle ear or jugular fossa from minute glomus bodies. Glomus tympanicum tumors arise from glomus bodies along Jacobson nerve on the promontory. The CT sections reveal a soft tissue mass of variable size, usually in the lower portion of the middle ear cavity (Figure 32A). As the lesion enlarges, it may cause a lateral bulge of the tympanic membrane, smooth erosion of the promontory, and involvement of the mastoid and hypotympanic air cells. If the lesion erodes into the jugular fossa, it becomes indistinguishable from a glomus jugulare. A dynamic CT study of a preselected section showing the tumor mass generates a curve with a high arterial peak (Figure 32B).
rather than the high but delayed venous peak of a high jugular bulb.\textsuperscript{18,23} On T2W and unenhanced T1W MRI, glomus tympanicum may not be differentiated from fluid or cholesteatoma. However, on contrast-enhanced T1W MRI, glomus tumors show marked enhancement hence they can be readily recognized (Figure 33). On sensitive MR sequences such as GE and MRA, glomus tumors appear hyperintense, reflecting their nature of increased vascularity. Selective arteriography with subtraction is indicated to identify feeding vessels before embolization. Squamous cell carcinomas extend into the middle ear from the EAC. Adenocarcinoma and adenomas are rare and produce nonspecific soft tissue masses. Erosion of the walls of the middle ear is a feature in keeping with adenocarcinoma.

Rhabdomyosarcoma is the most common malignant mesenchymal tumor of childhood. Common primary sites include the head and the neck (45%), trunk (40%), and extremities (15%).\textsuperscript{14} In the temporal bone, the neoplasm may arise within the middle ear, EAC, mastoid, petrous region, or adjacent to eustachian tube. On CT and MRI, the tumor appears as a soft tissue mass, often associated with bone erosion. There will be marked contrast enhancement on enhanced CT and MRI scans. At times, aggressive fibromatosis as well as modular fasciitis may mimic rhabdomyosarcoma of the mastoid and EAC. Langerhans cell histiocytosis of the mastoid, middle ear, and petrous apex may simulate rhabdomyosarcoma (Figure 34).

**Otospongiosis and Otosclerosis.** The middle layer of the otic capsule is composed of combined intrachondral and endochondral bone. The intrachondral bone is composed of irregular areas of calcified hyaline cartilage that contain true bone within the original cartilage lacunae.\textsuperscript{13} The histogenesis of the middle layer of otic capsule is noteworthy because it has no counterpart in the human skeleton. It is in the avascular, ivory-hard, endochondral bone that the pathologic process of otospongiosis arises. Otosclerosis that involves the oval window causes fixation of the stapes and consequent conductive hearing loss.\textsuperscript{2,13} In active otosclerosis or otospongiosis, the margin of the oval window becomes decalcified so that the window seems larger than normal. In mature otosclerosis, the oval window becomes narrowed (Figure 35) or closed, and in severe cases the entire oval window niche is obliterated by calcified otosclerotic foci. The CT assessment may be useful before surgery in some cases to confirm the clinical diagnosis, and in some bilateral cases for selection of the ear on which to operate. More important is the study of the expected anatomical variations, and post-stapedectomy ear for determining the cause of recurrent or persistent hearing loss and immediate or delayed vertigo. CT can demonstrate protrusion of the prosthesis into the vestibule, reobliteration of the oval window with fixation of the prosthesis, dislocation of the ossicles, on the right side.
Figure 48  (A) Jugular fossa schwannoma. Enhanced axial (top) and coronal (bottom) T₁-weighted MR scans showing a large jugular schwannoma, extending into the posterior fossa. (B) Jugular fossa paraganglioma. Coronal CT scans (top) showing a large right glomus jugulare (arrows), resulting in destruction of the mastoid segment of facial canal. Note normal left facial canal (black arrows). Enhanced T₁-weighted coronal MR scan in another patient, showing a large glomus jugulare (white arrow). Note extension into middle ear (black arrow) and into EAC.

Figure 49  (A) Petrous apex cholesteatoma and cholesterol granuloma. Axial CT scan (top) showing a large expansile mass involving right petrous bone. Note erosion of clivus (black arrows) and right hypoglossal canal. Note normal left hypoglossal canal (white arrow). This was due to a cholesterol granuloma. Axial CT scan (bottom) showing a similar destructive and expansile lesion, involving left petrous bone in another patient. This was due to a primary petrous apex cholesteatoma. Note erosion of cochlea (arrow). (B) Coronal (top) and axial (bottom) CT scans in another patient showing bilateral cholesterol granulomas (arrows) of the petrous apices.
medial end of the prosthesis from the oval window, air within the vestibule, and separation of the lateral end of the prosthesis from the incus or necrosis of the long process of the incus.

**Inner Ear**

Both CT and MRI are used for the study of the inner ear structures. CT is better for the study of the labyrinthine capsule; MRI is better for the assessment of the membranous labyrinth and neurovascular structures of the IAC.

**Congenital Anomalies.** Most cases of congenital sensorineural hearing loss have abnormalities limited to the membranous labyrinth and therefore not demonstrable with present imaging studies. Defects in the otic capsule are visible by CT. Anomalies may involve a single structure or the entire capsule. The most severe anomaly is the Michel type, which is characterized by hypoplasia of the petrous pyramid and almost complete lack of development of the inner ear structures (Figure 36). A less severe but more common malformation is the Mondini defect, which is characterized by hypoplasia or absence of the bony partitions within the cochlear turns, a short but wide vestibular aqueduct and dilation of the vestibule, and ampullated ends of the semicircular canals (Figure 37, 38, 39). Enlargement of the vestibular aqueduct, hypoplasia of the cochlea and IAC, and deformity of the vestibule and semicircular canals may occur as isolated anomalies. Dilation of the cochlear aqueduct is extremely rare. If the cochlear aqueduct is enlarged, the lateral portion of it can be readily seen on CT scans. The medial end of it is quite wide and can be several millimeters in size. Its lateral portion is considered enlarged if it is more than 1 mm in diameter. An enlarged cochlear aqueduct may be responsible for CSF gush, which rarely occurs during a stapedectomy for congenital footplate fixation or otosclerosis. CSF gushing or repeated episodes of meningitis in patients with the Mondini deformity or Mondini variants of inner ear dysplasia is often related to abnormal communication of the IAC with the dysplastic inner ear rather than an enlarged cochlear aqueduct (Figure 38C).

**Trauma.** Bleeding within the lumen of the inner ear structures may occur after trauma. If bleeding occurs due to concussion without actual fracture, MR may be indicated to confirm the diagnosis. Methemoglobin appears as a bright signal in both T1 and T2 MR images (Figure 40). The inner ear structures are seldom crossed by longitudinal fractures of the temporal bone but are usually involved in transverse fractures. These fractures typically cross the petrous pyramid at a right angle to the longitudinal axis of the pyramid and extend from the dome of the jugular fossa to the superior petrous ridge (Figure 41). Laterally located transverse fractures involve the promontory, vestibule, horizontal and posterior semicircular canals, and occasionally the tympanic segment of the facial nerve canal. Medially situated fractures involve the vestibule, cochlea, fundus of the IAC, and common crus.

**Labyrinthitis.** Enhancement within the lumen of the bony labyrinth (perilymphatic and membranous labyrinth) is often observed in MRI obtained after injection of contrast material in patients with acute bacterial and viral labyrinthitis and sometimes in patient with sudden deafness (Figure 42). Chronic labyrinthitis varies from a localized reaction caused by a fistula of the bony
Figure 51. (A) CPA meningioma. Axial CT scans showing a markedly calcified CPA meningioma (arrows). (B) CPA meningioma. Axial T\textsubscript{2}-weighted (top) and enhanced axial T\textsubscript{1}-weighted (bottom) MR scans showing a CPA meningioma (arrows). Note dural tail (small arrows). (C) Axial enhanced T\textsubscript{1}-weighted and coronal enhanced T\textsubscript{1}-weighted MR scans showing a CPA meningioma extending into IAC and a small meningioma arising within IAC (arrows).

Figure 52. Paget disease, axial section of the left temporal bone. Notice the severe demineralization of the petrous pyramid and mastoid with thinning of the otic capsule, particularly of the cochlea.

Figure 53. Longitudinal fracture of the right temporal bone, axial computed tomographic section. The fracture passes from the mastoid through the attic into the petrous pyramid anterior to the labyrinth. The fracture reaches and involves the facial canal at its anterior genu (arrow).

Figure 54. Comminuted fracture of the left mastoid, coronal computed tomographic section. Multiple fractures are noticed in the mastoid. One of the fractures passes underneath the posterior semicircular canal and transects the vertical segment of the facial canal (arrow).
labyrinth to a diffuse process. The lumen of inner ear is partially or totally filled with granulation and fibrous tissues. Later, calcific obliteration of the bony labyrinth may occur, which may lead to a partial or complete bony obliteration (labyrinthitis ossificans) of its lumen (Figure 43). Whereas the bony obliteration of the inner ear is readily identified by CT, fibrous obliteration is recognizable only by MRI. In the T2W images, the high signal seen within the normal inner ear structures is absent, therefore making the involved structures no longer recognizable. Fibrous obliteration will appear as area of enhancement on postgadolinium T1W M R images.

Labyrinthine Schwannomas. In the past, small schwannomas have been found within the vestibule and cochlea during postmortem dissections of the temporal bones or during labyrinthectomies. These lesions are usually not recognizable by CT but are well demonstrated as small enhanced masses in MR examinations particularly if performed after injection of contrast material22,27 (Figure 44). The CT and MRI characteristics of labyrinthine pathology were first reported in 1990 by Mafee and colleagues.27

Otospongiosis and Otosclerosis. Osteosclerosis involving the cochlear capsule is often responsible for sensorineural hearing loss by an unknown mechanism. Cochlear otosclerosis is caused by progressive enlargement of the perifenestral foci or by single or multiple foci in other locations in the cochlear capsule. The CT findings vary with the stage of maturation of the process. In the active or spongiotic phase, small areas of demineralization are first observed in the normally sharp contour of the capsule.13 These foci may enlarge and become confluent, producing large areas of demineralization and finally complete dissolution of the capsule. In the mature or sclerotic stage, localized or diffuse areas of demineralization are present.2,13 A typical sign of active cochlear otosclerosis is the “double ring” caused by confluent spongiiotic foci within the thickness of the capsule (Figures 45A and B).

Petrosal Pyramid

Primary tumors of the petrous bone involve a number of solid and cystic lesions, the more common of which are (1) primary cholesteatoma (epidermoid), (2) cholesterol granuloma, (3) meningocele, (4) mucocele (least common), (5) menigioma, (6) glomus tumor, (7) schwannoma/neurofibroma, (8) lymphoma (multiple myeloma), (9) Langerhans cell histiocytosis, (10) rhabdomyosarcoma (children), (11) chondrosarcoma, chondroblastoma (12) chondromyxoid tumor, (13) chordoma, (14) carotid aneurysm, and (15) metastases.2,20

Glomus jugulare Tumors. Glomus jugulare tumors (paragangliomas) arise from minute glomus bodies (chemoreceptors) found in the jugular fossa.2,4,16,23,24 The typical CT findings include erosion of the cortical outline and enlargement of the jugular fossa, erosion of the septum dividing the jugular fossa from the outer opening of the carotid canal, and erosion of the hypotympanic floor with extension of the tumor in the middle ear cavity (Figure 46). As the lesion enlarges, the posterior/inferior aspect of the entire petrous pyramid becomes eroded, as well as the adjacent aspect of the occipital bone including the hypoglossal canal. Large tumors protrude extraocularly in the posterior cranial fossa and inferiorly below the base of the skull along the jugular vein. These extensions are better demonstrated by MRI in which the tumor appears in both T1W and T2W images as a mass of medium signal intensity containing several small areas of signal void produced by blood vessels25,23,24 (Figure 47). After the injection of contrast material, the tumor undergoes a moderate to marked enhancement. The signal intensity of the glomus tumor is differentiated easily from the surrounding intra- and extracranial structures. In addition, MRI allows determination of displacement, encroachment, narrowing, or obstruction of the jugular vein and internal carotid artery because these large vessels are well-visualized with no need for invasive vascular procedures. Jugular venography and carotid arteriography are replaced by MRA and MRV and seldom needed, and carotid arteriography is limited to pre-embolization studies.

Jugular Fossa Schwannoma. Jugular fossa schwannoma and neurofibroma are the second most common jugular fossa masses. These lesions can be readily detected by CT including OTA and MRI scanning (Figure 48). MRI is preferred as the outline of the mass and its extent is better evaluated on MR than CT scans. At times extension of a posterior cranial fossa meningioma or metastasis to the jugular fossa may simulate a jugular fossa neuroma or glomus jugulare tumor.

Congenital Cholesteatomas and Cholesterol Granulomas. Congenital cholesteatomas (epidermoids) may arise in the petrous pyramid. In the CT images, the involved area of the pyramid appears expanded by a cyst-like low-density lesion2,9,10,21,26 (Figure 49), which often reaches and erodes the IAC and labyrinth. A CT study with infusion shows no enhancement of the mass except for its thin capsule. With CT, a congenital cholesteatoma of the petrous apex is difficult to differentiate from a cholesterol granuloma cyst that occurs in extensively pneumatized petrous...
pyramids. The 2 lesions can be differentiated with MR because congenital cholesteatomas produce a signal of medium intensity in the T1W images and high intensity in T2W, whereas cholesterol granulomas have a similar high signal in both T1W and T2W sequences (Figure 50). In addition, areas of hypointensity are observed in cholesterol granulomas produced by deposits of hemosiderin or blood of varied ages. Epidermoid cysts may be intradural and adjacent to the cerebellopontine angle. Petrous epidermoids as well as intradural epidermoid cysts demonstrate diffusion restriction on DWI, being hyperintense on DWI and hypointense on ADC mapping sequence. Epidermoid cysts also appear hyperintense on fluid attenuated inversion recovery (FLAIR) MR pulse sequence. Both DWI and FLAIR pulse sequences differentiate epidermoid cysts from arachnoid cysts and meningoceles.

**Meningiomas.** Meningiomas arise from the arachnoid cap cells of the meningeal covering around the temporal bone and from the meningeal extension into the IAC (Figure 51). The latter mimics, both clinically and in imaging, the appearance of a vestibular schwannoma. Meningiomas that arise from the petrous ridge are usually recognizable in the CT images as highly enhancing masses producing hyperostotic or lytic changes in the adjacent petrous pyramid. Unlike neurogenic tumors, calcifications are frequently seen in meningiomas (Figure 51A). With en plaque meningiomas, only the bony changes may be recognizable. MRI obtained after injection of paramagnetic contrast demonstrates a strong and usually homogeneous enhancement of the tumor. En plaque meningiomas are recognizable as areas of enhancing meningeal thickening.

**Paget Disease.** Paget disease often affects the calvarium and the base of the skull including the petrous pyramids. The disease usually spreads from the petrous apex laterally and produces a typical washed-out appearance of the involved pyramid caused by extensive demineralization (Figure 52). The IAC is usually involved first, followed by the otic capsule, which becomes first thinned out and then completely erased. In the late stage of the disease, deposition of irregularly mineralized bone occurs and results in thickening of the petrosa, narrowing of the IAC, and fixation of the footplate of the stapes.

**Facial Nerve**

CT is the study of choice for imaging the facial canal. The examination should be performed in
2 or 3 planes to visualize the various segments of the canal. MRI makes the facial nerve itself geniculate ganglion visible, particularly when the nerve is pathologic. Additional imaging examples of facial nerve disorders are found in Chapter 34, “Facial Paralysis.”

**Congenital Anomalies.** Congenital anomalies involve the size and course of the facial canal. The canal may be partially or completely absent, hypoplastic, or unusually narrow. Minor variations of the course of the facial nerve are common and of no clinical significance. More severe anomalies should be identified to avoid serious damage of the nerve during surgery. The horizontal segment may be displaced inferiorly to cover the oval window or lie exposed adjacent to the promontory. In congenital atresia of the EAC, the mastoid segment of the facial canal is rotated laterally and anteriorly. The rotation varies from minimal obliquity to a true horizontal course (Figures 13B and 18B).

**Trauma.** Traumatic lesions of the intratemporal portion of the facial nerve occur in approximately 20% of longitudinal fractures of the temporal bone and 50% of transverse fractures. The most common site of involvement in longitudinal fractures is the anterior genu (Figures 53 and 54), and in transverse fractures the labyrinthine or intracanalicular segments. The facial nerve may be transected by the fracture, compressed, sheared by a depressed fragment of the canal wall, or simply confused by the violent shock.

**Facial Neuritis.** Moderate bilateral enhancement of the normal facial nerve, particularly in the region of its anterior genu, is often observed in MRI obtained after injection of contrast material. A symmetric enhancement of the facial nerve more prominent on the paralyzed side is common in patients with Bell palsy and Ramsay Hunt syndrome. In Bell palsy, the involvement is segmental and usually confined to the anterior genu and adjacent labyrinthine and tympanic segments. In Ramsay Hunt syndrome, the involvement by the herpes zoster virus is more uniform and often extends to the part of the nerve within the IAC (Figure 55), associated with abnormal enhancement of Scarpa ganglion and vestibular nerves.

In viral neuritis, the nerve is usually not thickened. In sarcoidosis, the involvement is similar to Bell palsy, but the nerve is moderately thickened. In sarcoidosis and Lyme disease, facial nerve involvement may be bilateral.

**Neoplasms.** Although primary neoplasms of the facial nerve are rare, facial neuromas are the most common (Figure 56). Even rarer, facial neuromas may be congenital. Facial neuromas can cause thickening of the nerve and expansion of the canal (Figure 46A). Further enlargement of the lesion can result in erosion of the bony canal, extension into the middle ear space, and involvement of the mastoid and petrous pyramid (Figure 57A). MRI is the study of choice to depict a facial neuroma...
and to differentiate facial nerve neuromas from other lesions. The mass has a nonspecific low signal in T1W and high signal in T2W images and shows marked enhancement in T1W MR images obtained after injection of gadolinium DPTA (Figure 57B). Facial neuromas arising from the geniculate region of facial nerve and those arising from greater superficial petrosal nerve and facial nerve hemangioma (Figure 58) may present as a small or large extra-axial mass in the middle cranial fossa. The facial nerve, particularly its vertical segment, may be involved by carcinoma arising in the parotid gland and extending into the temporal bone. This is found particularly with adenoid cystic carcinomas which have a tendency for perineural and perivascular spread.

Cerebellopontine Angle

Vestibular Schwannomas. Vestibular schwannomas account for 80 to 90% of the tumors of the cerebellopontine angle.3 These neoplasms usually arise within the IAC, which becomes enlarged. Expansion of the IAC, shortening of its posterior wall, and erosion of the crista falciformis are well visualized in high-definition CT images targeted for bone. Both sides should always be examined to compare differences. Vestibular schwannomas are often missed on plain CT scans because the neoplasm is isodense to the surrounding brain and usually is not surrounded by edema. After infusion of iodinated contrast material, the mass enhances and may become visible (Figure 59). Intracanalicular lesions and cisternal masses smaller than 0.5 cm usually are not visualized with CT scanning. Before the development of the M. R. I technique, small vestibular schwannomas were diagnosed with CT pneumo-cisternography.2,26-30

M. R. I is the study of choice for diagnosis of vestibular schwannomas without exposing the patient to ionizing radiation and without the necessity for spinal puncture. The neoplasm appears in the T1W images brighter than CSF and isointense to gray matter. In the T2W MR images, the neoplasms are brighter than brain. Large masses are easily identified in both sequences, but small lesions can be detected only in the T1W images because in the T2W they may be obscured by the hyperintense CSF. A final diagnosis of small neoplasms is achieved by injecting intravenously paramagnetic contrast agents. Gadolinium DPTA concentrates in the tumor produces a shortening of the T1 relaxation time with consequent marked increase of the M. R signal in the T1W images (Figures 60 to 61). Vestibular schwannomas as small as 2 mm can be diagnosed by this technique.2,29

Meningioma. Meningiomas account for approximately 3 to 7% of the cerebellopontine angle tumors. The lesion has signal intensity less than the brain in the T1W MR images. In the T2W MR images, the lesion has variable signal characteristics, ranging from slight to moderate hyperintensity. After intravenous injection of paramagnetic contrast material, meningiomas show in the T1W MR images a marked increase in signal intensity similar to that seen in vestibular schwannomas. Unlike the latter neoplasm, which is centered at the IAC, meningiomas usually are centered in the cerebellopontine angle anterior to the IAC and spare the ICA. Meningiomas show increased thickening and enhancement of the adjacent dura (so-called dural tail), which is an important imaging finding favoring the diagnosis of meningiomas (Figure 62). Unlike schwannomas, which are often round and globular in shape, meningiomas have a broad base with the dura. At times cerebellopontine angle meningiomas may enter the IAC, or they may arise within the IAC, mimicking an intracanalicular schwannoma (Figure 51C). M. etastasis may mimic primary tumors of T. A. C (Figure 63).

Endolymphatic Sac Neoplasms and Fibro-Osseous Lesions of the Temporal Bone and TMJ

Endolymphatic Sac Neoplasms. Primary adenomatous lesions of the temporal bone are rare neoplasms.31-35 In 1989, Heffner described 20 cases of a type of papillary cystic adenocarcinoma in which the neoplasm destroyed a large portion of the posterior petromastoid part of the
temporal bone and included a prominent extension into the posterior cranial fossa. Patient histories indicated a slow growth rate of the lesions. There were resemblances of the normal distal endolymphatic sac tissue to some portions of many of the neoplasms. Tissue submitted to the US Armed Forces Institute of Pathology from a rare case of papillary adenomatous neoplasm of endolymphatic sac origin, reported by Hassard and colleagues had a strong similarity to the larger, destructive neoplasms reviewed by Heffner. In his final analysis, Heffner concluded that the neoplasms in his series grew slowly, but the neoplasms manifested a destructive, infiltrating growth into the temporal bone. Heffner preferred to diagnose them as low-grade papillary adenocarcinoma. Because the neoplasms were epithelial and manifested a distinctive destructive growth along the posterior-medial petromastoid portion of the temporal bone, Heffner inferred that the endolymphatic sac seems an ideal location to give rise to these neoplasms with their combined intrabony and posterior fossa components. These neoplasms characteristically cause destruction of the vestibular aqueduct and at times marked erosion of the petromastoid plate.

There may be extension of the neoplasm into the jugular fossa and middle ear cavity. There may be fine or coarse calcifications present within these neoplasms. The neoplasm may be solid or a combination of solid and cystic components. There will be moderate to marked contrast enhancement on CT and MRI scans (Figures 64 to 66). Some of the neoplasms may arise from sublabyrinthine mastoid air cells mucosal glands with intact endolymphatic sac and vestibular aqueduct. Bilateral neoplasms have been reported in patients with Von Hippel-Lindau disease. Other rare neoplasms found in the temporal bone include mucoepidermoid and adenoid cystic carcinoma, may have similar CT and MRI findings to low-grade papillary adenocarcinoma of endolymphatic sac origin. These neoplasms should be included in the differential diagnosis of destructive or nondestructive tumors about the posterior petromastoid plate as well as extraxial cerebellopontine tumors.

**Fibro-Osseous Lesions of the Temporal Bone and TMJ.** The temporal bone and TMJ can be affected by a variety of benign and malignant conditions, including fibrous dysplasia, osteoma, osteochondroma, osteoblastoma, chondroblastoma, chondrosarcoma (Figure 67), osteogenic sarcoma, chondromyxoid tumor, osteoelasta (true giant cell tumor), aggressive fibromatosis, and synovial chondromatosis. 

Fibrous dysplasia, osteoma, osteochondroma, and osteoblastoma have characteristic CT and MRI findings limited to the involved bone without involvement of the surrounding soft tissue. Chondroblastsoma and chondrosarcoma are rare neoplasms of the temporal bone and TMJ, resulting in bone destruction and an enhancing heterogeneous mass in the TMJ and squamous portion of the temporal bone with invasion into the adjacent soft tissues. Fine or coarse calcification may be present. Osteogenic sarcoma typically involves the mastoid process and is associated with periosteal reaction and bone formation in the involved surrounding soft tissue. Osteoclastomas typically result in marked expansion of involved bone and most often occur in the squamous portion of the temporal bone and its articular fossa. On MRI and CT, osteoclastomas contain multiple hemorrhagic
cystic components, simulating the appearance of an "aneurysmal bone cyst."

Pathologic Correlates in Otology and Neurotology

Joseph B. Nadol, Jr, MD

INTRODUCTION

Otopathology is important not only for the understanding of the pathogenesis and pathophysiology of otologic disease but also as a critical method for evaluating the results of medical and surgical interventions for such disorders.

SURGERY FOR OTOSCLEROSIS

Residual and Recurrent Conductive Hearing Loss

Primary stapedectomy can be expected to close the preoperative air-bone gap to within 10 dB in approximately 90% of cases. However, over time the mean air-bone gap tends to increase, causing at least some degree of recurrent conductive hearing loss. Furthermore, the success rate as measured by closure of the air-bone gap to within 10 dB in revision stapedectomy is considerably lower than in primary stapes surgery with a success rate of approximately 50%. The causes for both residual and recurrent conductive hearing loss can be validated by temporal bone histopathology in patients who had undergone stapes surgery during life.

Residual Conductive Hearing Loss. The most common causes for failure to close the air-bone gap to within 10 dB at the time of primary stapedectomy include unrecognized or untreated fixation of the malleus, unrecognized obliteration of the round window by otosclerosis, malposition of the stapes prosthesis resulting in inadequate transmission of sound from the tympanic membrane to the oval window, and adhesions in the middle ear as a consequence of surgical intervention.

Fixation of the Malleus. Fixation of the malleus occurs in the epitympanum (Figure 1) and can be the result of developmental disorders, chronic otitis media, and trauma, including previous surgery. Fisch and his colleagues suggested that at least partial fixation of the malleus at the anterior malleal ligament may occur in up to 38% of cases. In an otopathologic study, Oktay and colleagues identified a much lower incidence, that is, in 4 out of 52 specimens with otosclerotic fixation of the stapes footplate.

In a series of 279 consecutive stapes operations, both primary and revision, Lesinski identified an incidence of malleus fixation of 4%.

In a series of clinical and histopathologic cases, Harris and colleagues identified an air-bone gap ranging from less than 10 to 28 dB as caused by fixation of the malleus. In a histologic study of 1,108 temporal bones, which otherwise demonstrated a normal middle ear, bony fixation of the malleus was found in 14 cases and almost always unilaterally. Fixation was most common at the lateral epithympanic wall and did not include the ligaments of the malleus. Otosclerosis did not seem to be a predisposing factor. The use of preoperative laser doppler vibrometry may be an adjunct to pneumo-otoscopy for preoperative diagnosis of fixation of the malleus.

Obliteration of the Round Window. Although it is known that the round window is a site of predilection for otosclerosis, fixation of the round window is not commonly reported as a cause of residual conductive hearing loss following primary stapedotomy. Clinically, otosclerosis in the area of the round window may be obvious at the time of surgery. However, confirmation of complete closure of the round window, necessary for production of residual conductive hearing loss, is difficult to determine by otomicroscopy. Therefore, most authors would suggest completion of stapedectomy in suspected round window obliteration, but not if it had been identified as present at a previous operation.

Malpositioning of Stapes Prosthesis and Formation of Cicatrix in the Middle Ear. Residual conductive hearing loss may also be caused by inadequate size of the fenestration of the footplate, the angle of the incus attachment prosthesis with the footplate resulting in friction of the prosthesis against the margin of fenestration, or by a prosthesis that is too short.

Superior Semicircular Canal Dehiscence. Although the usual presenting symptom of dehiscence of the superior semicircular canal (Figure 3) is vestibular disturbance, conductive hearing loss has also been reported.

Recurrent Conductive Hearing Loss. Most authors agree that after stapedectomy, the postoperative mean air-bone gap increases over time, producing some degree of conductive hearing loss in many patients. In a series of 279 consecutive cases of revision stapes surgery, Lesinski identified displacement of the prosthesis out of the oval window and/or fixation of the prosthesis against the otic capsule or residual footplate as the most common causes of recurrent conductive hearing loss. The most common cause of displacement of the prosthesis was erosion of the incus.

![Figure 1](Image 296x153 to 493x302) Residual conductive hearing loss after stapedectomy. This 65-year-old woman suffered a bilateral progressive hearing loss caused by otosclerosis. She underwent a right stapedectomy 11 years prior to death. A conductive hearing loss persisted after surgery. The cause of the residual conductive hearing loss could be attributed to fixation of the head of the malleus (M) to the anterior lateral wall of the epitympanum (arrow) by lamellar bone. Otosclerosis was found at the oval window niche, and the stapes prosthesis was in good position. I = incus; M = malleus.

![Figure 2](Image 508x183 to 705x359) Residual conductive hearing loss after stapedectomy. This 81-year-old woman with bilateral otosclerosis had undergone stapes surgery during life. A progressive hearing loss caused by otosclerosis. She underwent a right stapedectomy 11 years prior to death. A conductive hearing loss persisted after surgery. The cause of the residual conductive hearing loss could be attributed to fixation of the head of the malleus (M) to the anterior lateral wall of the epitympanum (arrow) by lamellar bone. Otosclerosis was found at the oval window niche, and the stapes prosthesis was in good position. I = incus; M = malleus.
bone formation following primary stapedectomy

Resorption of Incus. The pathogenesis of resorption of the incus is unknown. The histopathology (Figures 4 and 5) suggests the presence of a resorptive osteitis with small amounts of granulation tissue and inflammatory cells. Although resorption of the incus occurs frequently following stapedectomy, it may occur from other causes. In fact, Lannigan and colleagues suggested that there is an age-related resorption of the normal incus. Similarly, Imauchi and colleagues described in a patient with conductive hearing loss due to ossicular discontinuity bilateral spontaneous resorption of the long process of the incus. Experimental studies suggest that osteoclastic bone resorption in the temporal bone, including the incus, is enhanced in osteoprotegerin deficient mice.

New Bone Growth at Oval Window. In two histopathologic studies, a total of five cases were described with new bone formation at the oval window following stapedectomy and resulting in refixation of the stapes prosthesis. In all five cases the primary stapedectomy had required drill out of obliterator otosclerosis in the oval window niche. Furthermore, the histopathology of the new bone formation following primary stapedectomy appeared to be lamellar new bone rather than progression of otosclerosis (Figure 6). This would suggest that extensive drilling in the oval window may induce reparative new bone formation following stapedectomy. Therefore, a somewhat larger than normal fenestra should be made to accommodate for postoperative new bone formation when confronted by obliterator otosclerosis.

Displacement of the Prosthesis. A stapes prosthesis may migrate with the passage of time following primary stapedectomy resulting in inefficient sound transmission and the development of recurrent conductive hearing loss. This may be the result of resorption of the incus, but it has also been seen in cases of total stapedectomy in which an otherwise well positioned prosthesis migrated to the margin of the oval window (Figure 7).

Figure 3 Bony dehiscence of the superior semicircular canal. This vertically sectioned temporal bone demonstrates a very thin bony layer between the arch of the superior semicircular canal (SC) and the middle fossa (MF). As seen in the inset, the dura (D) seemed to be intact. Although there is some artifactual fracture of the thin bone, in one area (arrowhead) only periosteum of the superior semicircular canal separates the canal from the middle fossa. (Adapted from reference 13.)

Figure 4 Incus resorption following stapedectomy. This 65-year-old woman had a progressive bilateral mixed hearing loss starting early in life. She underwent a right stapedectomy at age 42 using a Teflon wire piston. Although there was initial improvement in hearing, over the years a conductive hearing loss recurred. Although the prosthesis remained in appropriate position, there was evidence of resorption (R) of the incus (I) at the site of the wire crimp. M = malleus.

Figure 5 Incus resorption following stapedectomy. This 80-year-old man with bilateral otosclerosis underwent a left stapedectomy at age 66 using a Teflon wire incus to oval window prosthesis. (A) The outline of the stapes prosthesis (SP), malleus (M), and incus (I) are seen. Oto- sclerosis (O) is visible within the footplate and anterior to the stapediovestibular joint. (B) Resorptive osteitis (R) of the incus (I) is seen near the wire crimp.

Figure 6 New bone formation after “drill out” of foot-plate and oval window niche. This 70-year-old man suffered bilateral otosclerosis. At age 56, he underwent a right stapedectomy. Obliterator otosclerosis of the oval window was identified, and the footplate and oval window were saucerized using a microdrill. A gel wire prosthesis was then inserted. Initial closure of the air-bone gap occurred. However, at age 66 there was a recurrent 20 dB conductive hearing loss on the right. The outline of the gel wire stapes prosthesis (SP) is seen. At the oval window, in proximity to the stapes prosthesis, there is not only otosclerosis (O) but also reparative new bone formation (RNB).

Figure 7 Displacement of stapes prosthesis following stapedectomy. This 57-year-old woman with known bilateral otosclerosis underwent a right stapedectomy at age 45 using a fat-stainless steel wire prosthesis. A total removal of the stapes footplate was performed. Postoperative audiometry demonstrated closure of the air-bone gap. The outline of the stapes prosthesis (SP) and the fatty tissue graft (F) in the oval window are seen. The stapes prosthesis has become marginalized to the posterior aspect of the oval window niche. C = cochlea; M = malleus.
Complications of Stapes Surgery

Although the success rate for primary stapedectomy in closing the air-bone gap to within 10% has been reported as 90% or better, complications other than residual or recurrent conductive hearing loss may occur following stapedectomy. Such complications include perilymphatic gusher, trauma to the inner ear including delayed endolymphatic hydrops, and supplicative labyrinthitis.

**Perilymphatic Gusher.** Although the most common association of perilymphatic gusher is with x-linked mixed deafness with congenital fixation of the stapes footplate and perilymphatic gusher\(^{29,30}\) which has been recently associated with the POU3F4 gene (DFN-3),\(^ {31}\) it is certainly not exclusive to this diagnosis. A congenital defect in the modiolus has been demonstrated as the etiology of a perilymphatic gusher (Figure 8).\(^ {32}\) Thus, perilymphatic gushers have been identified at cochlear implantation in a variety of congenital malformations of the inner ear, including common cavity deformities (widely patent communication between the cochlea and vestibule), and Mondini malformations.\(^ {33}\) Although CT scanning of the temporal bone may identify a defect in the modiolus, which predisposes to a perilymphatic gusher,\(^ {34}\) this abnormality is not always identified.\(^ {35}\)

**Surgical Trauma to the Inner Ear.** Surgical trauma to the inner ear may occur during stapedectomy in the process of fenestration of the footplate or the insertion of a prosthesis. A common mechanism appears to be subluxation of part of, or the entire, footplate into the vestibule and direct damage to the saccular wall. An excessively long stapes prosthesis or plugging of the prosthesis during insertion may cause similar injury to the saccular wall (Figure 9). Trauma to the inner ear may result in severe vertigo and either immediate or delayed sensorineural hearing loss. Delayed endolymphatic hydrops is a well-known complication of surgical trauma to the inner ear.\(^ {36-38}\)

**Suppurative Labyrinthitis.** Suppurative labyrinthitis and/or meningitis has been reported in the interval 20 days to 5 years after stapes surgery.\(^ {39-42}\) Histologic evidence would suggest that an open communication between the middle ear and the perilymphatic space is responsible for most cases (Figure 10).

---

**Figure 8** Anatomic potential for perilymphatic gusher. This 2.5-year-old boy with otopalatodigital syndrome had multiple temporal bone anomalies including an incompletely formed cribrose area (CA) between the cochlea (C) and the internal auditory canal (IAC) providing a large communication between the perilymphatic and cerebrospinal fluid spaces.

**Figure 9** Surgical trauma to the inner ear secondary to stapedectomy. This 55-year-old woman with otosclerosis underwent a right stapedectomy at age 41. Obliterative otosclerosis was identified, and a “drill out” of the oval window was done using a microdrill. A stapes prosthesis was inserted. Postoperatively there was no significant change in her hearing. However, 8 months following surgery a sudden sensorineural loss occurred without vertigo. At age 49, the speech discrimination in the right ear began to decrease and she had occasional episodes of vertigo. (A) The silhouette of the stapes prosthesis (SP) is seen deep within the vestibule (V). (B) In the hook region of the basal turn, between the round and oval windows a spicule of otosclerotic bone (SO) was found impaling the spiral ligament (SL). There was marked endolymphatic hydrops and severe neurosensory degeneration presumably secondary to surgical trauma.

**Suppurative Labyrinthitis** following stapedectomy. This 39-year-old man had a slowly progressive bilateral hearing loss. A left stapedectomy was performed at age 37, and a polyethylene tube was used between the lenticular process of the incus and residual fragments of the footplate. At 20 months after stapedectomy while on a trip at high elevations, he experienced several brief attacks of vertigo; and 2 years following the stapes procedure during an upper respiratory infection, he developed an acute suppurative otitis media complicated by fever, headache, ataxia, and meningitis and died 2 days later. The outlines of the polyethylene tube stapes prosthesis (SP) can be seen between the incus (I) and the vestibule (V). There is an open communication between the vestibule and the middle ear within the lumen of the polyethylene tube which contained purulent material (PM) secondary to the acute otitis media. Inflammatory cells were also seen within the vestibule.

**Figure 10** Suppurative labyrinthitis following stapedectomy. This 39-year-old man had a slowly progressive bilateral hearing loss. A left stapedectomy was performed at age 37, and a polyethylene tube was used between the lenticular process of the incus and residual fragments of the footplate. At 20 months after stapedectomy while on a trip at high elevations, he experienced several brief attacks of vertigo; and 2 years following the stapes procedure during an upper respiratory infection, he developed an acute suppurative otitis media complicated by fever, headache, ataxia, and meningitis and died 2 days later. The outlines of the polyethylene tube stapes prosthesis (SP) can be seen between the incus (I) and the vestibule (V). There is an open communication between the vestibule and the middle ear within the lumen of the polyethylene tube which contained purulent material (PM) secondary to the acute otitis media. Inflammatory cells were also seen within the vestibule.

---

**SURGERY FOR CHRONIC OTITIS MEDIA**

**Causes of Failure**

The goals of mastoid surgery for chronic otitis media are the: (1) elimination of disease to produce a safe, dry ear; (2) alteration of the anatomy of the mastoid and middle ear to prevent recurrent disease; and (3) reconstruction in the form of ossiculoplasty and tympanoplasty to restore serviceable hearing if possible.\(^ {43,44}\) Failure of the first two goals will result in either recurrent cholesteatoma and/or recurrent suppuration. Failure rates of primary mastoidectomy range from 3 to 26%.\(^ {45}\) The reasons for failure of primary surgery as judged by surgical findings at revision mastoidectomy are multiple, including residual recurrent cholesteatoma,\(^ {46}\) or recurrent granulation and suppuration.\(^ {47}\) The following are examples of various factors resulting in failure of primary mastoidectomy.

**Aditus Block.** As in other organ systems, sequestration of disease behind an obstruction may lead to residual or recurrent chronic otitis media. In canal wall up mastoidectomy in which the aditus ad antrum is preserved and expanded through the use of a posterior tympanotomy, obstruction of this communication may result in a recurrent inflammatory reaction (Figure 11).

**The Symptomatic (Draining) Mastoid Bowl.** The creation of a canal wall down mastoid bowl may result in recurrent drainage, even in the absence of cholesteatoma. There is no better clinical evidence for the fact that surgical technique alone may result in recurrent...
surgical obliteration pedicles, either superiorly or inferiorly based. However, these flaps have a distinct tendency to atrophy over time (Figure 15), decreasing their efficacy. As a result, others have recommended fibroperiosteal flaps50 and the use of bone dust.51 The use of fibromuscular flaps based on named vessels such as the wing flap52 or the temporoparietal fascial flap53 may result in better preservation of the oblitative bulk and a more stable mastoid bowl.

Ossicular Replacement Prostheses. In an effort to reconstruct the ossicular chain, a variety of materials have been used as replacement materials over the years, including autologous bone or cartilage grafts and synthetic materials, including Plastipore, ceramic, and hydroxyapatite prostheses. Histologic study of ossicular implants in human subjects demonstrate that bone grafts derived from ossicles of cortical bone maintain their morphologic structure for many years and are slowly replaced by new bone growth (Figure 16). Although cartilage grafts persist without significant inflammatory response, they tend to lose tensile strength and to be resorbed.

Figure 11 A defect blocking a canal wall up tympanomastoidectomy. This 62-year-old man underwent a canal wall-up tympanomastoidectomy at age 50. Despite the presence of a posterior tympanotomy and placement of a silastic implant between the middle ear and antrum at the time of surgery, dense fibrous tissue (FT) was found in the aditus ad antrum causing obstruction and inflammatory cells within the mastoid.

Figure 12 Incompletely exenterated mastoidectomy and high facial ridge. This 79-year-old man had a history of mastoidectomy for acute mastoiditis in childhood on the left side. At age 77, recurrent pain and swelling occurred over the left mastoid, and revision mastoidectomy was done. Many air cells remained within the mastoid (MA), and dense fibrous tissue (FT) containing cystic space was found within the exenterated portion of the mastoid. The bone lateral to the descending segment of the facial nerve (FN) was not lowered to the level of the facial nerve. PSC = posterior semicircular canal; RW = round window; TM = tympanic membrane.

Figure 13 The symptomatic mastoid bowl. This 67-year-old woman underwent a modified radical mastoidectomy on the right side at age 59. Operative findings included granulation and thickened mucosa but no cholesteatoma. Following surgery, the right ear continued to discharge despite medical management. In much of the mastoid bowl, the lining skin (LS) has become ulcerated and replaced by granulation tissue (GT).

Figure 14 Sequestration and infection of hypotympanic cells. This 67-year-old woman underwent a left modified radical mastoidectomy at age 59 for an attic perforation and cholesteatoma. Underlying an intact epithelialized mastoid bowl (MA) unexenterated cells of the hypotympanum (HC) had become sequestrated and in part filled with fibrous tissue.

Figure 15 Obliterative musculofascial pedicle. This 76-year-old woman underwent a canal wall down tympanomastoidectomy at age 61 for chronic otitis media with granulation but without cholesteatoma. An inferiorly based musculofascial flap was used to obliterate the mastoid. There is a large canal wall down mastoidectomy bowl (MA). The posterior aspect of the obliteration pedicle (POP) is thicker than the more anterior portion (AOP) presumably due to postoperative atrophy over time.

Figure 16 Incus autograft. This 46-year-old man underwent an autologous incus interposition between the capitulum of the stapes and the manubrium of the malleus. Because a large air-bone gap persisted postoperatively, the procedure was revised 2 years later. The incus graft had become ankylosed to the promontory and also embedded in fibrous tissue. The incus strut has retained its shape including the recess to receive the manubrium (RM) and the recess to articulate with the capitulum (RA). The bone graft had become revascularized with new bone vessels, and over 75% of the bone had been remodeled as evidence by the presence of living osteocytes.
There was cellular and fibrous tissue ingrowth into the prosthetic membrane at the time of death, with little evidence of bony ingrowth.\textsuperscript{54,55} 

Over time (Figure 17). Cartilage therefore can be effectively used to prevent retraction of the tympanic membrane or as an interposition between a synthetic ossicular reconstruction prosthesis and tympanic membrane; however, it is not ideal as a primary ossicular replacement graft.

Plastipore prostheses elicit a very vigorous foreign-body giant-cell reaction (Figure 18) which results in resorption with time and perhaps predisposes to extrusion. Prostheses made of hydroxyapatite seem to invoke less foreign-body giant-cell reaction and tend to be encapsulated over time, with little evidence of bony ingrowth.\textsuperscript{54,55}

\textbf{Lessons Learned From Histopathology on Limitations on Hearing Reconstruction in Chronic Otitis Media}

Although the major limitation to successful ossicular reconstruction and hearing restoration in surgery for chronic otitis media appears to be persistent dysfunction of the eustachian tube resulting in a poorly aerated or nonaerated middle ear, the biologic response to chronic otitis media and related surgery may also result in interference with hearing restoration. The principal processes appear to be fibrocystic sclerosis and fibro-osseous sclerosis. Thus, as a result of chronic inflammatory change associated with chronic otitis media, fibrous tissue may be deposited in a submucosal plane causing sequestration and obstruction of previously pneumatized spaces. This is particularly critical in the area of the oval window (Figure 19) and round window (Figure 20).

\textbf{Osteitic Complications of Chronic Otitis Media}

The resorptive osteitis that may occur in chronic otitis media with or without cholesteatoma may result in fistulization of the vestibular labyrinth (Figure 21) or the cochlea (Figure 22) either at the otic capsule or due to osteolysis of the footplate (Figure 23).

\textbf{Complications of Surgical Intervention in Chronic Otitis Media}

In addition to failure to control chronic otitis media, surgical intervention may result in iatrogenic damage or trauma to the facial nerve (Figure 24), accidental fenestration of the round window (RW). PSC = posterior semicircular canal.

\textbf{Pathologic dehiscence of cochlea. This 76-year-old woman underwent a right canal wall up tympanomastoidectomy at age 50. According to the operative notes, a cartilage graft was placed between the footplate and the grafted tympanic membrane. At the time of death, there was a 40 dB conductive hearing loss on the right side. The tympanic membrane (TM) consisted of a thick facial graft. Embedded within it was a cartilage graft (CG). No living chondrocytes were found within the graft, and the extension from the tympanic membrane to the footplate was no longer present presumably because of postoperative resorption.}

\textbf{Histologic thinning of the stapes footplate (FP) underlying an attic retraction lined by squamous epithelium, fibrocystic obliteration (FCD) of the epi tympanum, and mastoid and erosion of the posterior part of the bony labyrinth (arrow) extending to the endosteum of the lateral semicircular canal (LSC). FN = facial nerve; V = vestibule.}

\textbf{Erosion of stapes footplate. In the left ear of a patient described in Figure 22, there was marked pathologic thinning of the footplate (FP) underlying fibrous tissue separating it from the mastoid bowl (MA).}
lateral semicircular canal (Figures 25 and 26), fenestration of the cochlea or fracture or luxation of the stapes (Figures 27 and 28).

SURGERY FOR MENIERE SYNDROME

Surgery may be offered to patients with Meniere syndrome which has been refractory to medical management and which can be attributed to one ear. Surgical techniques can be categorized by their ability to preserve cochlear function in the operated ear and those which are destructive of both cochlear and vestibular function. Examples include decompression of the endolymphatic sac as a function-sparing procedure and labyrinthectomy as a destructive procedure.

Decompression of the Endolymphatic Sac

The goal of decompression or shunting of the endolymphatic sac has been to decrease the volume of endolymph within the inner ear due to the hydropic state in Meniere syndrome. Surgery of the endolymphatic sac was introduced to otologic surgery by Georges Portmann and a number of variations have been proposed in subsequent years, including establishment of shunts between the lumen of the sac and the subarachnoid space or the mastoid air cell system. Although many authors continue to report a high incidence of relief of vestibular symptoms using endolymphatic sac procedures, others could find no difference between excision of the endolymphatic sac and a shunting procedure between the sac and mastoid. Furthermore, a series of papers by Thompson and colleagues has suggested on the basis of a double-blind study that patients undergoing endolymphatic sac shunt surgery benefited significantly from a placebo effect. These authors could show no significant difference between shunt and sham surgery.

Only a few cases of endolymphatic sac surgery have been studied histopathologically. In one, the histologic findings in three patients who had undergone endolymphatic/subarachnoid shunt for Meniere syndrome were reported. A fibrous tissue response, presumably the result of the surgery in the area of the shunt, was observed. The feasibility of achieving permanent shunting between the subarachnoid space or the mastoid air cell system and the endolymphatic sac was questioned by Schuknecht resulting in the speculation that the effectiveness of the surgical procedure was more related to labyrinthine insult than true shunting of endolymph (Figure 29).
has been completely ablated. Linthicum and the neuroepithelium of the vestibular system a wider field and therefore more assurance that mastoid approach for labyrinthectomy provides semicircular canal. Mononuclear cell reaction are seen. PSC/H11005 capsule (FCA) around the foreign body and an intense tic near the vestibular aqueduct (VA). (B) The fibrous capsule (FCA) around a foreign body, presumably silastic. Semicircular canal revision labyrinthectomy and singular neurectomy. The cristae were totally degenerated and the utricle missing. (A) The superior aspect of the vestibule was occupied by fibrous tissue and bone. The superior division of the vestibular nerve (SVN) was partially atrophied. However, there was a traumatic neuroma (TN) on the vestibular side of the cribrose area. (B) At the saccular level, the saccular macula and part of the vestibule were replaced by fibrous tissue (FT). The inferior vestibular nerve (IVN) was partially atrophied. However, there was a traumatic neuroma (TN) embedded in the fibrous tissue on the vestibular side of the cribrose area.

**Cochlear Implantation**

Cochlear implantation has become the standard of care for rehabilitation of individuals with severe to profound sensorineural hearing loss in both ears. Histopathology of temporal bones from patients who in life had undergone cochlear implantation has shed light both on immediate and delayed changes in the inner ear as a consequence of the implant device and provided some insight into the histopathologic correlates of success of cochlear implantation as measured by speech recognition scores.

**Immediate and Delayed Changes**

Histopathologic study of the temporal bones from patients who in life had undergone implantation has demonstrated a variety of immediate and delayed changes in the inner ear. Immediate changes may include fracture-dislocation of the osseous spiral lamina (Figure 32) and dissection of the lateral cochlear wall (Figure 33). Delayed changes include new bone and fibrous tissue (Figures 34 and 35) in the cochlea and around the implanted electrode.

Bacterial meningitis has been reported as an infrequent complication of cochlear implantation.
To date, the pathogenesis of meningitis is unclear. Histologic study of the tissue seal and biologic response around the cochlear implant has demonstrated a very robust fibrous and osseous reaction to several types of implants and no obvious communication between the middle and inner ear (Figures 34 and 35). In addition, a significant inflammatory cellular response, including mononuclear leukocytes, histiocytes, and foreign body giant cells were present in over 50% of the implanted specimens (Figure 36). This may result in a local immuno ne compromise. Correlates of Success with the Implant Khan and colleagues demonstrated that despite significant trauma to the cochlea, the mean spiral ganglion cell count for implanted and impaired nonimplanted ears were not significantly different, particularly in the basal turn of the cochlea. In addition, the segmental and total spiral ganglion cell counts of the implanted ears were not significantly correlated with word recognition scores although some correlation of numbers of surviving spiral ganglion cells and psychophysical measures has been identified.

In summary, continued histologic study of human temporal bones will provide insight into the pathogenesis of otologic disease and, in addition, as illustrated in this chapter, will provide important data concerning the consequences of medical and surgical intervention.

REFERENCES
Sir Francis Bacon, Renaissance author, courtier, and father of inductive reasoning, observed that the true essence of progress is in the application of scientific knowledge for enhancing the human condition. Today we express that same expectation by calling for studies that bridge the bench-to bedside gap. In the past half-century new challenges to the healthcare system have been presented by deadly new viruses, antibiotic-resistant strains of bacteria, and broad societal and environmental changes that have altered disease epidemiology, raising medical, social, legal, and economic issues. These challenges have been paralleled by rapid advances in biomedical and information technology, vaccines to protect against many infectious diseases, the Human Genome Project, an explosion in the volume of medical literature, and increasing demands for evidence of the effectiveness, quality and outcome of the care provided to patients.

Rather than solving patient care decisions or creating consensus on disease management, however, these achievements in biomedical science and technology have paradoxically increased uncertainty and practice variation among healthcare providers by offering a constantly expanding menu of choices. Patient-oriented research, once limited largely to randomized clinical trials conducted in large academic medical centers by highly trained physician-scientists, is now being done in greater numbers by community-based practitioners who are motivated to find answers to the problems they encounter in daily clinical practice, make a contribution to their specialty, and take an active role in generating evidence about the effectiveness of otolaryngology interventions for providers, patients, and their colleagues in other specialties.

In this chapter we will use clinical vignettes to illustrate how questions that arise in an otolaryngology practice can be used to guide the selection of an appropriate study design, the strengths and weaknesses of each, and some representative studies using that design. Finally, we will briefly discuss the trend in evidence-based medicine and how it will affect the practice of otolaryngology-head and neck surgery.

THE RESEARCH QUESTION: THE CORE OF THE PROCESS

A well-constructed, focused research question is paramount in the clinical research process. The nature and structure of the research question will determine the research design and the types of statistics needed to analyze the data collected. Do you want to know about associations, correlations, risk factors related to a group of patients or to a treatment, the sensitivity or specificity of a diagnostic test, or how commonly a clinical event occurs? These questions can be formed into a focused research question using the PICO format. Using this paradigm, the well-constructed research question has four parts.

**Patient or Problem of Interest**

How would you describe a group of patients similar to yours? What are the most important characteristics in addition to the primary diagnosis? You may want to specify an age range, ethnicity, or gender if that is important to the condition.

**Intervention, Prognostic Factor, or Exposure**

What treatment, intervention, or diagnostic test is being considered? What risk factor is at issue that may influence the prognosis?

**Comparison**

Is there an alternative treatment or test you would like to compare? Comparisons are not always strictly necessary, depending on the nature of the question.

**Outcome**

What are you hoping to accomplish, measure, or improve? Be specific as to what your goal is; a quantifiable goal is preferable.

Closely related to the specification of the focused research question is the decision about whether to take a passive role in observing the events and their effects on the study subjects by designing an observational study or to take a more active role and design a prospective experimental study and examine the effects of an intervention in a clinical trial. We will examine the characteristics, advantages and disadvantages, with some examples of each of these options in the following sections.

**OBSERVATIONAL RESEARCH**

As its name implies, observational research is one in which the investigator takes an essentially passive role in the research process, simply observing events taking place in study subjects under various conditions and configurations, thus determining how exposure to certain risk factors influences the probability of developing a disease or disorder of interest. The risk factors may be endogenous, such as genetic or familial history, or exogenous, related to environmental, lifestyle, or other medical intervention factors. This is in contrast to experimental studies, such as clinical trials, where the investigator applies an intervention and studies its effects under controlled circumstances. Observational studies may be prospective or retrospective; the three most common types are cross-sectional studies, cohort studies, and case-control studies.

**Cross-Sectional Studies**

At the tenth reunion of their medical school class, two good friends and colleagues who trained in otolaryngology strike up a conversation about their practices. Dr Cold, who now lives in Wisconsin, has been extremely busy caring for children with ear infections and has inserted over 60 pairs of tympanostomy tubes in the last month of January. His friend, Dr Warm, who lives in Florida, comments that while he has seen an increase in children with ear infections (which he usually does in January), he does not think that it is nearly as great as Dr Cold’s. Their discussion prompts the following research question:

Is the prevalence of young children with otitis media in a multispecialty practice in Wisconsin who receive tympanostomy tubes different than the prevalence of children with otitis media in a multispecialty practice in Florida who receive tympanostomy tubes during the same time period?

Each physician decides to return to his multispecialty group and review the charts of all children between the ages of 6 months and 3 years seen by the group in January. They decide to record the primary diagnosis noted in the chart, allergies, age of first ear infection (if they had one), and whether they were breastfed. No patient identifiers are recorded. These are their results:

<table>

Our clinicians have a convenient sample that lends itself to a simple retrospective study.
cross-sectional study, sometimes called a prevalence study. Prevalence is the number of persons with a given disease at any specified point in time and is arrived at by a simple calculation:

\[
\text{Prevalence} = \frac{\text{number of people with the disease}}{\text{number of people at risk}}
\]

Our two classmates can readily compare the prevalence of wintertime otitis media in their respective practices. In the Florida practice, the prevalence is 150/1000 or 0.15 (15 cases per 100). In the Wisconsin practice, the prevalence is 500/2000 or 0.25 (25 cases per 100). Dr Cold’s impression that his caseload of otitis media is higher in Wisconsin is justified—at least for the month that was examined. A variation of this kind of study would be to examine period prevalence, by calculating the prevalence over a longer period of time, usually 1 year. Here, the period prevalence is calculated as follows:

\[
\text{Period prevalence} = \frac{\text{number of people with disease during the time period}}{\text{number of people at risk during the time period}}
\]

Gathering these data would also allow the investigators to calculate quarterly prevalences and to examine the question of whether there are seasonal fluctuations in the disease that correspond to certain predictors of interest.

A cross-sectional design can help provide information about the association of variables of interest [such as number of children who have otitis media with effusion (OME) at a particular time] with other factors (such as season of the year) that may be predictors, although it cannot establish causality. However, seasonal trends in disease recurrence or exacerbation in established cases could be readily examined by a cross-sectional chart review, with the understanding that this is not a random sample and that existing disease may not be representative of all cases of the same disease. A cross-sectional study would answer the question “What is happening?” with relative ease and low cost.

Cross-sectional studies have several advantages: they are relatively inexpensive; they are fast (no waiting for the outcome to occur); and there is no loss to follow-up. The results of a cross-sectional study can sometimes serve as the baseline study for a prospective cohort study (see next section) by revealing associations (not correlations or evidence of causality) of interest. For example, if there were peaks in OME prevalence in the spring or fall that corresponded with peaks of environmental ragweed or other pollens, it would be natural to study allergy as a risk factor for OME. However, they have limitations as well: they provide only a snapshot in time of the condition of interest and thus may be misleading if one is interested in the natural history of a disease or in the disease process in general. It is difficult to choose appropriate, nonbiased control groups for cross-sectional studies, and, as previously noted, the affected group may not be representative of the entire population.

### Cohort Studies

Dr Cold enlists his colleague in pediatrics, Dr Snow, to explore further the natural history of ear infections and to try to identify possible risk factors that may predispose patients to the development of ear infections which may begin to explain why they have a higher incidence of otitis media than children in Dr Warm’s practice. Since children in Milwaukee spend more time indoors and are closely grouped at daycare in the winter compared to Florida children who continue to play outside, they believe that daycare may be a risk factor for ear problems.

Drs Cold and Snow decide to examine this idea in their practice and follow two groups of patients for 1 year. At the first well-child visit, Dr Snow will ask the parent if their child will be going to daycare or not. This determination will divide the children into two groups. The two groups of children are checked every 3 months, or more often if an ear infection occurs. Dr Cold confirms the presence or absence of an ear infection in children every month.

Drs Cold and Snow determine that children in daycare have more ear problems than children cared for at home.

In a cohort study patients who have a particular disease are recruited into a study based on whether they have had exposure to a particular risk factor. A cohort study is also called an incidence study. Incidence is the number of new cases in a fixed time period and is calculated as:

\[
\text{Incidence} = \frac{\text{number of new cases in fixed time period}}{\text{number of people at risk}}
\]

The risk factor may be environmental, genetic, behavioral, traumatic, or even a treatment. These individuals are then followed over time for the occurrence of an outcome of interest. A different focused research question would be developed for this type of study:

What is the incidence of recurrent acute otitis media in young children who are in daycare compared with those cared for at home in a specified time interval after treatment?

For this question, the outcome of interest is the number of documented episodes of acute otitis media in a specified time interval after the treatment. Here, we would select a group of children with histories of recurrent acute otitis media and group them according to their daycare environment. The cohort of “exposed” children (E) are in group daycare; the cohort of “unexposed” children (N) are cared for at home. These numbers are then easily analyzed to determine the relative risk for the “E” and “N” groups.

If “e” designates the children in the group care cohort who develop future infections and “n” designates the children in the home care cohort who develop future infections, the relative risk is calculated as:

\[
\text{Relative Risk} = \frac{(e/E)/(n/N)}
\]

It is important to consider the possible contribution of confounding factors in collecting and analyzing the data from any clinical research study. A confounding factor is one that could be related both to the outcome and to the risk factor and thus could be considered responsible for some or all of the observed effect. In this example, the investigator would want to examine other factors, such as exposure to second-hand smoke and predisposing conditions such as craniofacial anomalies to determine whether these factors were disproportionately represented in one cohort. Statistical procedures are necessary to help analyze the impact of confounding factors in analysis of the data.

The cohort study is one of the best designs for studying the course of a disease or risk factors. When biases and confounding factors are minimized, it is a powerful design to provide strong evidence for the time sequence between outcomes and risk factors. However, it can be expensive and time-consuming when serial data collection is involved, and it is not especially useful for rare diseases because of the difficulty in gathering an adequate sample size. Finally, because this is an observational study, causation cannot be proved since other factors invariably will affect the outcome, and the best the investigator can do is to be meticulously aware of those factors and to control for them to the greatest extent possible.

### Case-Control Studies

Meanwhile, Dr Warm and his colleague Dr Sun embark upon their own study to examine whether children of large families have more ear problems than single-child families. They review the charts of the previous year’s patients who had tympanostomy tube insertion and children who only had a visit for vaccinations. They match each patient who had tympanostomy tubes inserted with one from the vaccination group on age, ethnicity, daycare setting, and a few other factors. They contact each patient’s family and determine how many siblings the child has in the house. They divide the whole group of patients by “only-child families” and “multisibling families.”

They find that 50% of the children with tympanostomy tubes insertion had larger families, while 45% of the vaccination children had larger families.

<table>
<thead>
<tr>
<th>100 patients with ear tubes</th>
<th>100 vaccination patients</th>
</tr>
</thead>
<tbody>
<tr>
<td>50 had large families</td>
<td>45 had large families</td>
</tr>
</tbody>
</table>

Odds ratio of having tympanostomy tubes if you have a large family is:

\[
\frac{50}{45} = 1.1
\]

Most case-control studies tend to be retrospective: they identify a group of individuals with the condition of interest and another without the same condition (ideally matched on critical variables such as age, gender, ethnicity, etc.), and look backward in time to determine differences in predictor variables that might explain why one group developed the disease and the other did not. This is a standard epidemiological approach for risk factors determination.

A another excellent example of a simple case-control study appears in the following abstract. The focused research question might be constructed in the following way:

Do children who swim regularly develop otitis media more frequently than children matched for age, sex, and race who do not swim?
To determine the influence of swimming on the incidence of otitis media in children, the authors designed a case-control survey involving 32 children, aged 1 to 4 years, who were participating in swimming classes. Thirty control subjects were matched for age, race, and sex. The participants were pooled from the general pediatrics clinic and toddler swimming classes in Nassau County, N.Y. Parents completed a questionnaire gathering data over a 12-week study period during the winter months. Information was gathered regarding demographics, number of ear infections, history and frequency of swimming during the study period, presence of head submersion, daycare center attendance, allergies, chronic medical conditions, oto-laryngology consultations, ear surgery, and air travel. Forty-three percent of nonswimmers compared with 19% of swimmers had one or more ear infections during the study period (p < .02). The remaining factors surveyed did not differ significantly between groups. A review of the literature yielded two studies suggesting that swimming may have a beneficial effect on eustachian tube function and may indirectly decrease the occurrence of otitis media. Based on these findings, the authors conclude that there appears to be no basis to the commonly held belief that swimming may induce or exacerbate otitis media. In fact, the converse may be true.5

In this example, the cases were the children who developed otitis media and the controls were those who did not. The investigators were testing the validity of a theory that swimming is a risk factor for the development of otitis media. The major feature of a case-control study is that the groups are identified on the basis of an outcome of interest (in this case, otitis media) and the search for exposure to a putative cause (in this case, swimming) is retrospective. Stated differently, the case-control study looks backward in time to detect possible causes or risk factors that occur in the history of the cases but not in the history of the controls to answer the question “What happened to cause this outcome?” The case-control study is the quickest and least expensive of the observational study designs and is also the most useful for investigating a preliminary hypothesis about risk factors that may be associated with an outcome or condition of interest, although it does not establish the sequence of events. For rare diseases or conditions that develop over a long time, the case-control study is by far the best choice. It is not without its limitations, however: because it is retrospective, it is difficult to exercise appropriate controls, and it is subject to the largest number of biases, including sampling bias, measurement bias, and observer bias. It also depends on recall or on existing records, both of which may be imperfect and lead to error. Case-control studies do not provide indications of prevalence, incidence, or excess risk, although they are useful in estimating the odds ratio, a good approximation of relative risk.

The relative merits of these three designs of observational research are summarized in Table 1.

**EXPERIMENTAL RESEARCH**

Following these three observational studies, Drs. Cold, Snow, Warm, and Sun won the funding for a large grant to explore further the relationship of ear infections and number of children in their daytime play environment. Stated in the PICO format, they want to know:

- In newborn babies who have two working parents, will home care compared to daycare decrease the number of ear infections during the first year of life?
- They conduct an experimental study in which first newborn children of young double-income families are randomized to home care or daycare. If they are home-cared, the grant pays for a qualified babysitter to care for the child in the child’s home. If they are randomized to daycare, the grant pays for the child to be in a qualified daycare with at least eight children. The study follows each child for 1 year, and each child visits their pediatrician and has an ear exam every 2 weeks. Ear infections are documented and treated according to standard of care.

The number of ear infections is counted and compared for each group.

Clinical trials are the most widely recognized form of experimental clinical research. They may be controlled or uncontrolled, randomized or nonrandomized, blinded or nonblinded, but all have in common the feature that an experimental drug or procedure is introduced to the patient and its effect on the patient’s condition is observed prospectively; thus, they provide the most compelling evidence of a causal relationship between a treatment and an effect. One of the earliest randomized controlled clinical trials was conducted by Scottish physician James Lind in the mid-eighteenth century, who daily gave citrus fruits to a pair of British sailors suffering from scurvy aboard the HMS Salisbury; five other similarly affected pairs of sailors received different treatments. Only the group treated with citrus fruits recovered from their disease, establishing the evidence for a causal link between vitamin C deficiency and scurvy and leading to a simple treatment and prevention of this debilitating disease. Lind’s study was published and recognized, but the translation of research into practice was even slower 250 years ago: it was not until some 40 years after publication of A Treatise on Scurvy that the British Navy issued an order for a daily ration of lime juice to sailors on long sea voyages, almost immediately wiping out scurvy from the British Fleet and Navy hospitals.4

Not every clinical question, of course, lends itself to investigation by means of a clinical trial, and questions involving surgical management are notoriously difficult to investigate using this methodology. Sackett has gone so far as to say that because they are so expensive and cumbersome, clinical trials should be undertaken only...
when six criteria are fulfilled: (1) the trial needs to be done; (2) the question posed is both appropriate and unambiguous; (3) the trial architecture is valid; (4) the subject inclusion/exclusion criteria strike a balance between efficiency and generalizability; (5) the trial protocol is feasible; and (6) the trial administration is effective.5

But how does one know when a clinical trial “needs to be done”? The US Food and Drug Administration (FDA) requires evidence of the safety and efficacy of new drugs, devices, and other medical products that will be approved for use in medical and dental settings for specific indications before they can be placed on the market. Efficacy refers to the impact of an intervention in a clinical trial, indicating that the intervention has the desired ability to produce an expected effect, for example, a new antibiotic kills bacteria. Efficacy differs from effectiveness, which relates to the impact of the intervention in “real world” situations when it is used with a broader range of patients than those who participated in the clinical trial, and who may have comorbid conditions that require the use of other medications. Stated differently, efficacy studies are focused on determining whether the compound/intervention works in the expected way; effectiveness studies focus on whether the patient is clinically and functionally better to a worthwhile degree as a result of the intervention, on some range of systematic objective, subjective, and outcomes measures.7

Drugs may be used for indications other than those for which they were approved (“off-label” use). Clinical trials are needed when the efficacy of the off-label treatment is unclear; the treatment is moderately different from the standard treatment; or when the frequency or severity of adverse effects associated with the new treatment is unclear. A clinical trial is not needed when the new treatment is unequivocally superior to the standard treatment. Nonetheless, because randomized clinical trials have achieved a reputation as the gold standard for the methodical assessment of treatment efficacy and adverse effects, they have become the lynchpin on which evidence-based medicine rests, as we shall see in a later section.

Basic Requirements of a Clinical Trial

Under most ordinary circumstances, a clinical trial has the following characteristics: (1) it is prospective; (2) it involves human subjects; (3) it has both intervention and control groups; (4) subjects are randomized into the intervention and control groups; and (5) the subjects, and sometimes the investigators (as well as other participants in the trial), are masked (or blinded) as to the group assignment of the subjects.5 The latter is not always possible in surgical, behavioral, and some device trials but is frequently possible with drug trials.

The central legal, moral, and ethical requirement of clinical trials—and all other clinical research involving human subjects—is informed consent. Patients must be fully aware that they are participating in a research study and must know what the potential risks and benefits are, what the procedure is, what is expected of them, what they can expect as a result of participating in the study; and they must freely consent to participate once they know all of the above. There are well-defined elements that must appear in every informed consent. These are presented in Table 2.

Informed consent documents should be written in such a way as to translate complex scientific and medical terms into easily understood language and be written in the patient’s native or preferred language. Care should be taken to avoid making any concrete or implied assurances of benefit or effectiveness of the interventions on the trial. It is important that the informed consent be signed, dated, and witnessed to demonstrate that consent was obtained before treatment began.

The Ethics of Clinical Trials

When the topic of ethics in clinical trials is raised, the most polarizing issue is that of randomization, particularly if the comparison treatment is a placebo or nonactive drug. Random assignment to intervention groups gives all subjects the same chance of receiving each possible treatment, and it serves several important purposes. It constitutes a means of assigning patients to treatments in a way that is free of personal bias, and it forms the basis for the statistical tests that will be used to test the underlying hypotheses. Most importantly, randomization distributes the variables, both measured and unobserved (and possibly unknown) among the groups in a chance, and therefore in an impartial manner. It is another way of ensuring lack of bias and permitting unambiguous statistical analysis and interpretation of group data.9

Unfortunately, many clinicians and even more patients are uncomfortable with the concept of random assignment to treatment arms; only 3% of all cancer patients in the United States participate in clinical trials.10 Both physician and patient want the best possible treatment to be administered, whether it is new or the standard of care, and the prospect of receiving an “inferior” treatment by chance assignment is troubling. This has given rise to the principle of clinical equipoise: patients should be entered into a randomized controlled clinical trial only if there is substantial uncertainty within the expert medical community about which intervention is superior and both interventions appear to offer the same probability of benefit for treatment of the disease under study.11

Not every clinical trial is placebo-controlled, nor should it be.12 Many authorities agree that placebos should be used as a control only under the following circumstances:

- There is no standard treatment available for the disease being studied;
- The standard treatment is ineffective or unproven to be effective;
- The standard treatment is inappropriate for this particular clinical trial;
- Placebo has been reported to be relatively effective in treating the disease/condition of interest;
- The disease process is characterized by frequent exacerbations and remissions;
- Allowing concomitant treatment shown to be effective on an as-needed basis;
- In a population of patients who are refractory to standard treatment and for whom no standard second-line treatment exists; or
- When testing an add-on treatment to standard therapy when all subjects receive all treatments that would be prescribed; and
- “Escape clauses” or points are designed into the protocol.13

The ethical principles governing the conduct of clinical trials are discussed in detail in The Belmont Report,14 a document based on the work of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. It identifies three fundamental ethical principles for all human subject research—respect for persons, beneficence, and justice. Those principles remain the basis for the US Department of Health and Human Services, human subject protection regulations and are an essential reference for institutional review boards. Among the topics covered in this report are the use of vulnerable populations who may not be able to give fully informed consent (eg, mentally retarded, demented, or psychotic patients) or who are subject to coercion and thus may not

be autonomous (eg, impoverished, addicted, or imprisoned patients); and the important principle that in all cases the benefits of the trial should be maximized and the potential risks minimized.

The Surgical Clinical Trial

There is little question that randomized controlled clinical trials are the most effective ways to evaluate new pharmacologic interventions, but controversy still attends their role in nonpharmacologic interventions, such as surgery. A surgical trial is unique in that the expertise of the surgeon becomes an integral part of the intervention, unlike drug and device trials, where the physician is the case manager, but the treatment efficacy depends on the pharmacologic compound or on device technology rather than on the physician’s skill. In a traditional surgical trial, the patient is randomized to Procedure A or Procedure B; randomizing patients to one of the procedure arms requires the assumption that the surgeon has equal expertise in the interventions under evaluation and that all participating surgeons have comparable expertise.

An alternative to the traditional randomized trial is the expertise-based trial, in which patients are randomized to clinicians with expertise in Procedure A or to clinicians with expertise in Procedure B, and the clinicians perform only the procedure in which they are expert. Devereaux and colleagues in 2005 presented a cogent argument and multiple clinical illustrations of the ways in which the expertise-based design will enhance the validity, applicability, feasibility, and ethical integrity of randomized controlled trials in surgery.15

The potential for bias in favor of one surgical approach over another is significant in surgical trials: surgical expertise takes training and experience to develop and surgeons tend to primarily use a single surgical approach to treat specific problems. If, as Devereaux and colleagues demonstrate, surgeons with expertise in, for example, an endoscopic approach treat 70% of the patients in both groups A and B and surgeons with expertise in, for example, an open approach treat 30% of those in both groups A and B, the trial results will be biased in favor of the endoscopic approach. Devereaux refers to this type of bias as differential expertise bias and suggests that its potential is high in surgical trials for three reasons. First, measures are rarely instituted to ensure that the number of participating surgeons with expertise in each procedure is equal. Second, there is usually no assurance that participating surgeons have reached the asymptote of their learning curves for the procedures under evaluation, and outcomes usually continue to improve with extensive experience. This is especially true if new devices or procedures are being compared to an existing standard of care. Third, even if these two problems are overcome, one of the procedures may be more technically challenging; thus, surgeons who have to acquire expertise in the more challenging procedure will remain less proficient than those who are learning the less technically challenging procedure or who are already proficient in one procedure. In this situation the trial will be biased toward the latter.

One important advantage of the expertise-based design for randomized surgical clinical trials is that the consent process can inform patients that, regardless of the procedure to which they are assigned, a surgeon with specific expertise will perform the surgery. This may not always be the case in traditional randomized surgical trials, and it is a significant ethical consideration.

Clinical Trial Phases

Clinical trials are generally described in terms of their phase, a descriptor that designates the overall purpose of the trial. Phase I trials are small trials of 20 to 80 patients designed to study the toxic and pharmacologic effects of a new treatment that has been studied in an animal model but which now needs to be tested in humans. Phase I trials are either done in healthy volunteers or in patients with severe or terminal illnesses who have failed accepted treatments. Phase II trials generally involve 100 to 200 patients to expand study of the treatment effect on a disease; dose-response parameters are obtained, as well as safety data. Phase III trials are large-scale, randomized, tightly controlled trials designed to study the efficacy of the experimental treatment in a rigidly defined sample of patients. Usually conducted as a multicentered trial, the treatment is compared to a standard of care treatment to determine which is more effective. Phase III trials may also be planned to test the efficacy of an established drug for a new (non-FDA-approved) indication. If a standard treatment is not available, a placebo may be used as a comparison. Considerable controversy has surrounded some surgical trials, where sham procedures have been conducted on patients randomized into the control group.16–18 The Phase IV trial involves postmarketing surveillance of the drug in the general population and may be structured more as an effectiveness study, including use of the drug in combination with other drugs or in patients with comorbidities. Phase IV trials (and other forms of clinical research) may also be conducted using patient outcomes and quality-of-life instruments to assess a more global impact of the intervention on the patient’s life.

Measurement of Outcomes

There are several different ways to categorize outcome measures. The broadest scheme describes outcome measures as being either generic (or general) or disease-specific. As their name implies, the generic measures are generalizable across health conditions, practice settings, and types of treatments. They may be applied to most patient populations and are widely used to measure health-related quality of life (HRQOL), activities of daily life (ADL), mental health, role disability, pain, and feelings of well-being. Some well-known generic instruments are the Quality of Well-Being Index (QWB) and the 36-item short-form health survey (SF-36).19 While these measures are sensitive to the impact produced by serious diseases such as cancer, however, they are relatively insensitive to the effects of less serious conditions such as rhinosinusitis, mild to moderate hearing impairment, or laryngeal disorders. Disease-specific outcomes capture more detailed information about function directly related to the condition of interest and make it more straightforward to attribute change to treatment response. There are a number of well-known disease-specific outcome measures in otolaryngology—head and neck surgery, including those examples shown in Table 3, which is not meant to be comprehensive.

Some measures are linked temporally to the disease or intervention process and thus enjoy a high degree of specificity with respect to health outcomes; recovery from a surgical procedure, for example, or changes that occur early in the natural history of the disease. Other measures occur later in the process and are more subject to the influence of external factors: life satisfaction, for example, will certainly be affected by health status but will also be influenced by unrelated social, economic, and psychological factors.20 HRQOL,
the patient’s perception of how a disease affects their physical, social, and emotional function, is inescapably individual and subjective and may vary widely among patients with the same disease stage, severity, and symptoms. This being the case, the difference or change in disease-related quality of life following intervention is the more meaningful parameter to track.

Selecting an Outcome Measure

When selecting an outcome measure for use in a study, investigators should be aware of three major characteristics of the instrument. First, an outcome measure should have evidence of its validity or the ability to measure what it is supposed to measure. Second, there should be evidence of its responsiveness or the ability to detect clinically and socially important differences when change has indeed occurred. Third, there should be evidence of its reliability or the ability to provide consistent values between and within subjects. Further, the outcome measure should have these characteristics defined within the population of interest. For example, the OM-6 is valid, responsive, and reliable for otitis media, but not for acute otitis externa or other ear diseases such as mastoiditis.

Two additional attributes are important to evaluate when selecting an outcome measure. The late Dr Alvan Feinstein described the sensibility of an outcomes instrument as “enlightened common sense,” characterized by a clear purpose and framework, an easily understood and interpreted output scale, and content validity. The final attribute to consider is the burden imposed by its use. Burden, of course, is defined by the experience of the user. Lengthy health outcome surveys create a time burden; placing that burden on the patient rather than on a busy, distracted office staff relieves the staff of the time and effort necessary to retrieve medical data or compound their paperwork and may enhance their willingness to participate in clinical research studies. These five attributes are summarized in Table 4.

Medical Outcomes and Patient Outcomes

The emergence of health services and outcomes research has brought about recognition that medical outcomes and patient outcomes are not always directly correlated: a very positive medical outcome in terms of controlling disease may carry very unwelcome patient outcomes in terms of quality of life, social, or mental function. For example, tracheostomy is quite effective in controlling severe obstructive sleep apnea and some dangerous associated conditions such as cardiac dysrhythmias, hypertension, and blood oxygen desaturation. Patients, however, now have to deal with care and protection of the stoma, effect on communication, and body image factors, and those issues will impact their perceived quality of life. Patients' satisfaction with their medical care has been shown to be directly associated with how effectively that care reduces the symptoms they view as most important or troublesome, even if those symptoms are not the most medically significant.

Application of Outcomes and Effectiveness Research

Driven by geographic variations in practice patterns and utilization, rising healthcare costs, the proliferation of information technology that has motivated patients to take more active roles in the decision process about their healthcare, and the demand by payers for evidence to support the effectiveness and quality of medical and surgical interventions, medical and patient outcomes, and effectiveness research has assumed an increasingly important role in the American healthcare system. Because outcomes and effectiveness research has evolved to reflect the interests of

(A adapted from reference 2.)
Major stakeholders in the healthcare process, it offers distinct advantages to each:

- It helps healthcare providers understand the importance and therapeutic value of the patient–physician relationship, design and evaluate more efficient ways to deliver healthcare, and improve informed consent procedures.
- It helps patients develop realistic expectations about disease and treatment, participate in treatment decisions that will have an impact on their quality of life, and provide feedback to their physicians and nurses on their satisfaction with the quality of care they have received.
- It helps healthcare delivery systems develop guidelines based on relative probabilities of explicit outcomes and patient preferences; analyze the cost-effectiveness of primary care versus specialty care based on long-term outcomes; determine the most significant factors in patient satisfaction for quality improvement programs; and establish evidence-based indications for care to develop appropriate utilization rates.
- Insurance companies use the results of clinical research to standardize and validate healthcare evaluation parameters, develop objective methodologies to define “appropriate” versus “unnecessary” levels of care, and increasingly, determine reimbursement policies.
- Health regulatory agencies apply the results of outcomes and effectiveness research to develop a balanced view of quality, cost, and access for national healthcare, project societal and pathophysiology; patients were not expected to have a role in the decision process. An essential premise underlying this new paradigm is the acknowledgment of the uncertainties of clinical medicine, which continue to grow with the exponential growth of medical literature, new technologies, the linking of reimbursement to outcome and effectiveness, and an increasingly litigious society.

As the volume of literature has grown, presenting evidence for and against the effectiveness of interventions and the assessment of diagnostic tests and prognosis, a new field has emerged, focused on systematically evaluating the validity of the clinical evidence and summarizing the evidence. At the center of this new field is a hierarchy of research designs, arranged in descending order of quality and increasing probability of bias. Randomized controlled clinical trials appear near the top of the hierarchy (high quality, low bias); individual case reports and retrospective case series toward the bottom (lower quality, higher probability of bias). The steps in this hierarchy have come to be referred to as “levels of evidence,” and are widely used for a variety of applications, ranging from publications to development of practice guidelines to reimbursement criteria.

**Evidence-Based Medicine**

Evidence-based medicine is the integration of clinical expertise, patient values, and the best evidence available into the decision-making process for patient care. Clinical expertise refers to the clinician’s cumulated experience, education, and clinical skills. The patient brings to the encounter his or her own personal and unique concerns, expectations, and values. The best evidence is usually found in clinically relevant research that has been conducted using sound methodology. The evidence, of itself, is never a deciding factor, but it can be a powerful tool in supporting the patient care process and in other aspects of organized medicine.

Medical decision making based on the triad of these three factors represents a fundamental paradigm shift in medicine, requiring new skills of the physician, including efficient literature searching and the application of formal rules of evidence evaluating the clinical literature. Clinical research of all kinds is far more common today than it was 50 years ago: In 1960 randomized clinical trials were sporadic and outcomes research as a discipline did not exist. Clinical decisions were made on the basis of clinical experience and understanding of related biology and pathophysiology; patients were not expected to have a role in the decision process. An essential premise underlying this new paradigm is the acknowledgment of the uncertainties of clinical medicine, which continue to grow with the exponential growth of medical literature, new technologies, the linking of reimbursement to outcome and effectiveness, and an increasingly litigious society.

Diseases of the External Ear

Frank E. Lucente, MD
Matthew Hanson, MD

The external ear is composed of the auricle and the external auditory canal and is a frequent source of patient complaints in otolaryngology. External ear problems can range from the deceptively simple, such as earwax impactions and foreign bodies, to severe and life-threatening problems such as malignancy or invasive infection. Often the presenting symptoms of the 2 extremes may be indistinguishable; and the otolaryngologist must rely on a thorough evaluation, appropriate testing, and a high index of suspicion to ensure the appropriate treatment of the patient. This chapter presents an overview of diseases of the external ear, primarily infectious and inflammatory disorders.

ANATOMY AND PHYSIOLOGY

The fundamental function of the external ear is the conduction of sound. The shape of the auricle, or pinna, and the canal provide a small degree of amplification which is greatest at normal speech frequencies. The auricle also provides a degree of selective directionality to hearing, favoring sounds coming from in front of the listener. The entire external ear complex provides approximately 5 dB of gain (depending on the frequency) and the greatest gain is for sounds coming from a 45° angle from the front of the individual and at frequencies of 500 to 6,000 Hz.1 In addition to its acoustic function, the external ear is protective, allowing the delicate structures of the middle and internal ear to lie deeply embedded in the skull and safe from trauma and environmental insults. The auricle also has important bearing on the aesthetic aspects of facial appearance, but this is discussed in greater detail in Chapter 52, “Otoplasty for the Prominent Ear.”

The canal itself can be further divided into a lateral, cartilaginous portion and a medial, bony portion (Figure 1). The epithelium of the canal is stratified squamous epithelium, i.e., skin. Over the medial bony portion, the skin is thin and applied directly to the periosteum of the bone. In this portion, there are no skin appendages, glands or hairs; and the close approximation of the periosteum makes this area very sensitive. The lateral cartilaginous portion has considerably thicker skin with a generous adventitia and numerous appendages, including hairs, sebaceous glands, and modified apocrine ceruminous glands.

Earwax Removal

Earwax is a beneficial substance and does not routinely need to be cleaned or removed. In some persons, however, the earwax does not extrude but becomes impacted in the canal preventing the normal transmission of sound. Overzealous use of cotton-tipped swabs is the usual underlying cause, but some patients do demonstrate excessive production of wax, produce an abnormally hard or tenacious wax or have impaired migration and extrusion. A small amount of wax is not pathologic, the otolaryngologist may need to remove it to perform a complete examination of the eardrum. As such, removal of earwax is one of the most frequently performed procedures.

Many different strategies have been tried over the years for earwax removal, but they basically fall into 1 of 3 categories: manual removal,
irrigation, and chemical dissolution. Many patients will require a combination of all 3 strategies. Manual removal using suction (#5 or #7 Frazier tips) and microinstruments (ring curette, right angle hook) under microscopic visualization is the preferred method of the authors. This affords the least traumatic removal and does not risk the worsening of underlying pathology, such as cholesteatoma or tympanic membrane perforations that may lie beneath the wax. Irrigation is used frequently in both primary care and specialty settings. Lukewarm water (to prevent caloric stimulation) is instilled using a large syringe (Figure 2). The auricle is pulled back to straighten the canal and the water is directed to the roof of the ear canal, not directly at the ear canal. A basin is placed below the ear to catch the irrigant and wax. Although irrigation is a mostly effective and a time-honored technique, it does put the patient at risk for injury. The irrigation is done, of necessity, blindly, and too much force may damage the canal skin or tympanic membrane. If underlying pathology is present, such as a cholesteatoma or perforation, the introduction of water may worsen the situation and hasten severe infection. Overall, the use of irrigation for cleaning out earwax should be discouraged.

Chemical dissolution does not so much remove the wax as much as soften it. This facilitates its removal by manual disimpaction, irrigation, or the natural extrusion over time. The simplest chemical in use is over-the-counter 4% hydrogen peroxide. Cheap and readily available, hydrogen peroxide will effectively soften wax over a brief period of time. Because of its aqueous nature, it may not penetrate deeply into the wax, and its use may cause a keratinolytic epidermal reaction that may lead to infection. Carbamine peroxide is a mineral oil-based peroxide solution and is widely available over the counter under a number of brand names (Debrox being the best known). The mineral oil-base allows much greater penetration of the substance into the wax, and there is generally no epidermal reaction. Ceruminex, (triethanolamine polypeptide oleate-condensate), prescription medication, is a useful softening agent in office situations. This medication is a keratinolytic that will effectively soften earwax in about 45 minutes. It is usually recommended that it be instilled in the office and suctioned out completely with the softened wax. This medication is not meant for patient use and should never be given for home instillation. The keratinolytic action causes a severe inflammatory reaction with repeated use and frequently predisposes the patient to acute infection. Roland and colleagues compared the efficacy of carbamine peroxide and Ceruminex in a randomized, controlled trial against a placebo control and found no significant benefit of either over saline.6 Other substances have also been used for earwax dissolution, including liquid ducosate (Colace), mineral oil, and others. Most are probably safe, but there are no studies of the long-term safety and efficacy of these treatments. A Cochrane Database Systematic Review in 2003 found the data to be insufficient to make any recommendations regarding the role of cerumenolytics.7

One treatment touted for earwax removal by herbalists and other advocates of alternative medicine is “ear candling.” In this practice, a wax cone is inserted into the ear and lit on fire and allowed to burn down. It is to be extinguished when the candle has burned down to less than three inches. It is claimed that the earwax is melted and drawn up into the candle by the flame, allowing it to be removed with the extinguished candle. The efficacy of this treatment is doubtful, especially for deeply impacted wax, and it is obviously unsafe. There are reports of significant burns resulting from this practice, and it is to be strongly discouraged.8

Symptoms of External Ear Disease

Disease of the external ear can present with a limited number of symptoms: pain, pruritus, aural fullness, and hearing loss. Diplosis and autophonia can also be noted, but are rarely the presenting complaints. Otorrhea, either purulent or bloody, will often be the symptom associated with more advanced disease.

It is important to have a systematic way of evaluating the patient presenting with ear pain. Otolgia, essentially, has 3 possible sources: the ear, something else that is close to the ear, or something distant that is causing referred pain in the ear. All parts of the ear, external, middle, and inner, can be potential sources of otalgia (inner least of all). Clinical assessment of these areas by careful history and examination will usually reveal or rule out an aural source. The temporomandibular joint (TMJ), lying just anterior to the ear canal, is a frequent source of otalgia. Referred otalgia may result from a number of sources ranging from dental irritation to esophageal malignancies. As such, a complete history and otolaryngologic examination is absolutely necessary in evaluating the patient with otalgia.

Much the same can be said regarding the sensation of pruritus and aural fullness, in terms of their possible sources. Both can result from aural, adjacent, and referred sources. TMJ disease will frequently result in a “full” sensation in the ear, and itchy ears can be a referred sensation due to nasal allergies. Hearing loss, on the other hand, is obviously aural in nature and has its own diagnostic paradigm. As with otalgia, any of these symptoms would require a complete history and otolaryngologic physical examination to evaluate for distant, referred sources.

Foreign Bodies and Insects

One of the most common presenting complaints involving the external canal is the presence of a foreign body. Adults will typically know the nature of the object in the ear, whereas in children it may be incidentally found by a pediatrician. Pain is occasionally present, but more often the patient complains of hearing loss or a full feeling in the ear. In most adults, the object can be easily removed in the office under microscopic visualization using a combination of suction, alligator forceps, or a right-angle hook. Deeply impacted objects in adults or foreign bodies in an uncooperative child may best be removed in the operating room. Hard, round objects, such as beads, present a particular challenge, as they may not present an easily grasped aspect. Often a right-angle hook can be passed deep to the object or a large suction can be used to engage the object and draw it out.

One particularly disturbing foreign body is a live insect, such as a cockroach (Figure 3). More of a problem in urban areas, these patients will note severe pain in the ear. Most insects do not have the ability to crawl backward and cannot turn around in the canal. Meanwhile, the acidic wax layer may irritate them. This will usually cause them to crawl incessantly against the eardrum causing the severe pain. A great deal of relief is often obtained by just killing the insect. This can usually be done by instilling alcohol or lidocaine solution. Mineral oil can also be used but often makes the carcass brittle and difficult to remove in 1 piece. Once the insect is dead, it can be removed in the office similarly to removal of any foreign body.

Injury and Thermal Trauma

The exposed position of the pinna makes it a frequent site of trauma. Injuries fall into 4 broad categories: sharp trauma or lacerations, avulsions, blunt trauma, and thermal trauma. In dealing with any injury, one must remember the “ABCS” and

![Figure 2 Irrigation of earwax.](image1)

![Figure 3 Insect in the external canal.](image2)
consider the risks of deeper injury. An apparently simple laceration of the tragus may in fact involve laceration of the facial nerve. A auricular hematoma from a baseball bat injury may also show “Battle sign” indicating a deeper skullbase fracture.

**Lacerations and Avulsions.** Lacerations of the pinna can often be challenging to repair. It is an established surgical principle that wound edges should be cleaned and debrided back to healthy, clean tissue. In lacerations of the auricle, however, too excessive debridement may result in loss of too much tissue, possibly resulting in greater tension of the closure and risk of a poor cosmetic result. Nonetheless, wound edges must be aggressively cleaned to remove any bacteria, dirt, or debris.

Closure of full-thickness lacerations of the auricle must be planned to provide a cosmetic, durable repair. The cartilage should be reaproximated with a very fine permanent monofilament suture placed through the perichondrium and cartilage. Care should be taken to approximate all layers of tissue closely, including the inner and outer layers of skin. Even apparently clean wounds of the pinna should receive antibiotic coverage to prevent perichondritis. If the laceration is the result of a human or animal bite, this, too, should affect the choice of antibiotic coverage.

Lacerations become even more problematic if portions of the pinna have become completely avulsed. If available, the avulsed portion should be reattached, essentially making it a full-thickness composite graft. Platelet inhibitors, anticoagulants, hyperbaric oxygen, and surgical leeches have all been used to enhance the survival of these reattached pieces. If the entire pinna is avulsed, microvascular re-anastomosis may be required. If the avulsed portion is not available for reimplantation, the wound may be closed primarily or allowed to close by secondary intent, with formal reconstruction performed when the wound is stable.

**Auricular Hematoma.** Blunt injury to the auricle may result in the formation of an auricular hematoma. This is a not-uncommon injury in sports, particularly in wrestlers and boxers, and is the primary reason for use of headgear in these sports. Injury to a perichondrial blood vessel results in blood accumulation in the subperichondrial space, elevating the perichondrium off of the cartilage. If not drained, this separation of the cartilage from its blood supply may result in cartilage necrosis. The trapped blood and injured perichondrium will eventually organize into a fibrocartilagenous mass, creating the deformity known as “cauliflower ear.” Once a cauliflower ear is formed, there is little that can be done to return the ear to its prior, normal state. Therefore, auricular hematomas must be evaluated and addressed as soon as possible following the injury, preferably within 72 hours.

The long-recommended treatment involves evacuation of the hematoma and application of a pressure dressing to prevent reaccumulation of the blood (Figure 4). Wide incision with a scalpel is the preferred means of drainage. Incisions should be placed parallel to the helix in the scapha. After drainage and removal of clot and fibrocartilage, bolster dressings should be applied. This is usually done with dental rolls applied to both sides of the auricle and secured with through and through permanent sutures. These dressings are usually left in place for 7 to 10 days.

Some feel that incision and bolstering is unnecessary and an auricular hematoma can be managed by needle aspiration. Indeed, many published series have advocated needle aspiration, only using incision and bolstering for recurrent cases. A Cochrane Database Systematic Review of the literature was unable to find adequate data to suggest a clearly defined best treatment, so further study is needed.

**Burns.** Burns represent a major source of trauma to the external ear. Thermal burns are traditionally classified as first, second, and third degree. First-degree burns are essentially scald injuries and result in little necrosis, but a great deal of inflammation and considerable pain. Treatment of first-degree burn is usually minor; nonsteroidal medications for pain and emollient creams. The burn usually heals with no scar. Second-degree burns are partial thickness burns that will lead to epidermolysis and blistering. These, too, are often treated expectantly with nonsteroidal anti-inflammatory medications. Gentle cleansing and application of antibiotic ointments are recommended. Third-degree burns are full thickness and are generally anesthetic. These are treated the same way as second-degree burns but are much more likely to result in significant tissue loss and require reconstructive intervention. In all types of burns to the auricle, pressure on the auricle should be avoided, and the patient may need to wear a protective cup or bolster. A dequate analgesics should be administered to all patients with burns.

One common risk of auricular burn is the risk of perichondritis. This disorder was thought to occur in up to 25% of all second- and third-degree burns of the ear and may result in significant loss of cartilage if not recognized and immediately addressed. With the greater awareness of this issue and the use of topical antibiotic ointments, the risk of this disorder has fallen to around 3%. It is usually caused by Pseudomonas and often develops 2 to 4 weeks following the initial injury. In the initial phase there is redness, pain, and swelling, and this represents a perichondritis. Intravenous antibiotics are often successful in this stage. The later stage is characterized by abscess formation and will generally result in significant cartilage loss if not addressed. Because of the avascular nature of this stage, intravenous antibiotics alone are ineffective and surgical drainage is needed. Multiple incisions are made and aggressive local care is needed for full control.

**Frostbite.** The exposed position of the auricle also puts it at risk for frostbite. Prolonged exposure to temperatures less than 0°C results in anesthesia, pallor, and ice crystal formation within the tissue. With thawing, endothelial damage results in severe edema and sludging of blood, increasing the risk of necrosis. Still later, erythema develops around the demarcated tissue. The demarcated tissue may eventually slough and reconstructive intervention may be needed. Nonsteroidal antiinflammatory medications, corticosteroids, aloe vera, and heparinization have all been recommended in the early stages to prevent necrosis, but no controlled studies have proven their roles.

In the acute setting, it is recommended that the area be gently thawed by application of moist cotton pledgets slightly warmer than body temperature. Radiant heat is not recommended. Just as with burns, compressive dressings should be avoided and antibiotic creams should be applied.

A rare late result of auricular frostbite is auricular ossification. The results from replacement of the elastic cartilage of the auricle with bone. This results in a rigid, ossified auricle that is uncomfortable to the patient and may prevent examination of the eardrum with a speculum. A side from this, the condition is benign and there is no treatment. Repeated exposures may be a factor in this disorder.

**Inflammatory and Infectious Disorders**

The vast majority of patient complaints involving the external ear are going to involve inflammatory or infectious disorders. The close proximity of the canal skin to the exquisitely sensitive periosteum can often make this a painful disorder. Failure to diagnose and treat such a disorder adequately can result in prolonged discomfort and potentially life-threatening spread of infection.
Acute Otitis Externa (AOE). A OAE or acute external otitis is an acute, usually bacterial, infection of the skin of the external auditory canal (Figure 5). In its later stages it presents with severe pain in the affected ear and will frequently be associated with drainage and decreased hearing, but early infection may cause only itching and fullness. The clinician will usually note pain on manipulation of the pinna with erythema and swelling of the ear canal skin. Often, the skin of the bony external canal will be spared. Often the swelling of the canal skin prevents full evaluation of the drumhead, making it uncertain whether the eardrum is intact and the middle ear is not involved with the infection as well. The infection may also cause excessive skin desquamation, resulting in the accumulation of a large amount of keratin debris in the canal.

The initial therapy should include a thorough cleaning of the canal. Not only can the debris prevent an adequate examination, but the debris in the canal will harbor microorganisms and prevent adequate penetration of drops. The importance of this often-overlooked step cannot be overstated as it is a frequent cause of therapy failures. After cleaning, the treatment usually involves the use of topical treatments in drop form. In situations in which the canal swelling prevents adequate penetration of the drops, a sponge wick can be used. Placed dry and compressed in the canal, the wick will swell in response to the instilled drops. A wick provides 2 important actions: first, it draws the antibiotic down into the canal to the site of infection; second, it puts pressure on the walls of the canal to decrease the swelling. A wick, like any other packing, can turn into a nidus for infection so should be removed or changed after a few days.

Otic Antibiotic Preparations. The general treatment of AOE is with the use of antibiotic otic drops. Over the years, many preparations have been on the market (Table 1). In ancient times, ear infections were treated by the instillation of vinegar into the ear. The acetic acid lowers the pH of the ear canal and suppresses the growth of the usual AOE pathogens of pseudomonas and staphylococcus. It will also suppress the growth of most fungal microorganisms as well. A number of commercially available otic preparations are acids and are meant to work in this way, eg, Domeboro (boric acid) and A cetosal (acetic acid).

For many years, the preferred otic drop preparation was a combination drop containing neomycin, polymyxin-B, and hydrocortisone. Sold under a number of brand names, most notably "Cortisporin," this otic drop was usual sold in 2 forms: a mineral oil-based liquid and an aqueous suspension. The mineral oil-based drop had excellent penetration in small canals and those filled with debris but could be quite painful if the drop entered the middle ear through an unknown perforation or tube. The aqueous suspension was better tolerated in open ears but had a strong tendency to leave a white, filmy debris, the suspended solid crystals of hydrocortisone, which is insoluble in water. This filmy debris would often be mistaken for a fungal overgrowth, and the patient would be placed on an additional antibiotic.

These 2 antibiotics and a corticosteroid preparation have enjoyed a long history of success in the treatment of AOE. The neomycin, an aminoglycoside, had high activity against staphylococcus species and moderate activity against pseudomonas. The polymyxin B had strong activity against pseudomonas as well as staphylococcus. The hydrocortisone would lessen the inflammation, opening the ear and relieving the pain. The neomycin and polymyxin-B, however, both have a long-known toxicity to the inner ear when used systemically. This raised some concern about their extensive use in ears, often in situations in which there is perforation or a ventilating tube. No cases of certain eardrop-related ototoxicity have ever been documented, and chronic infection itself is a risk to hearing, so it is difficult to make a case that these preparations are dangerous, especially considering their decades of popular use.

Otic drops containing quinolone solutions were brought to the market in the 1990s. These contained either ofloxacin (Flacin Otic) or ciprofloxacin (Cipro- HC Otic or CiproDex, both also contain a corticosteroid). These drops offered an antibiotic with known effectiveness against the common microorganisms encountered in AOE with no known risk of ototoxicity. Heavily marketed, these drops soon became the most frequent treatment used in AOE. Unfortunately, a steady increase in quinolone resistance has been seen in both staphylococcus and pseudomonas microorganisms. In some areas, less than half of all cultures of pseudomonas aeruginosa will be sensitive to quinolones. In addition, these drops often lack other characteristics, such as a lower pH, that suppresses the growth of other microorganisms, such as fungus.

To address the issue of the appropriate treatment of AOE, a committee from the American Academy of Otolaryngology Head and Neck Surgery developed evidence-based treatment guidelines for this disorder. Although antibiotic drops were shown to give significantly higher symptomatic and bacteriologic cure rates, no difference could be demonstrated between the various preparations.

When to Use Systemic Antibiotics. Most AOE can adequately be treated with debridement and otic antibiotic preparations. In some situations, systemic antibiotics should be added. If the patient is diabetic or otherwise immune-suppressed, systemic treatment will be another barrier to deeper and more life-threatening spread of the infection. In a patient in whom the swelling of the canal has become so profound that a wick has had to be placed, systemic antibiotics will ensure adequate penetration of coverage.

"Malignant" Necrotizing Otitis Externa. Malignant otitis externa represents an invasive bone infection involving the external canal (Figure 6). The nomenclature of this disorder is confusing to patients. The traditional name, coined initially by Chandler in 1968, is "malignant" otitis externa, reflecting its life-threatening nature. The term "malignant" is usually applied to neoplasia, so there is confusion about its use in this nonneoplastic disorder. Since bone necrosis is a feature of this disorder, the term "necrotizing" otitis externa is often preferred.

Whatever name is used, it is a serious and life-threatening infection. Mortality for necrotizing otitis externa has been measured as high as 20%. With increased awareness of the disease and aggressive treatment (including the availability of effective oral antibiotics), the mortality now is less than 1%. This disease occurs when the infectious agent of AOE penetrates to deeper tissue to involve bone and deeper fascial planes. Although it is usually initially limited to the temporal bone and its adjacent structures, it can spread medially to become a full-fledged osteomyelitis of the base of the skull. As it advances, it will cause dysfunction of the cranial nerves as their foramina are involved. Infection can also spread to the subarachnoid space resulting in meningitis. Mortality is often due to intracranial
Infection or aspiration secondary to lower cranial nerve dysfunction.

Patients with necrotizing otitis externa are typically older and diabetic. They may also be otherwise immune-suppressed. They present with severe, boring pain in the ear with associated drainage. There is usually a prolonged course, and often they will have been treated with one or several courses of topical antibiotics. They may rarely present with a facial paralysis or other lower cranial nerve involvement. In diabetics, they may note an elevation in their blood sugar and increased difficulty in controlling their diabetes. On examination, granulation tissue is often seen in the canal, usually on the floor and adjacent to the bony-cartilaginous junction. Biopsy of this tissue should be taken to ensure the absence of malignancy, which can present in a similar fashion.

Further workup should begin with a culture of the drainage in an attempt to identify the offending microorganism, usually pseudomonas. Fungal culture should be obtained as well. A high-definition computed tomography (CT) scan of the temporal bones may show areas of bone erosion but is normal in many early cases. MRI has also been recommended, usually showing fatty streaking in the precondylar space but is fairly nonspecific and does not show bone detail like the CT.

In general, diagnosis is confirmed using radioisotope scanning. A technecium-99 bone scan will show increased uptake in the involved area, confirming that bone in the area is rapidly being metabolized. This may be the most sensitive test for necrotizing otitis externa, but this uptake will remain present for months to years following the resolution of the infection, making it a poor examination to monitor treatment. A Gallium-67 scan, showing areas of active infection, will have increased uptake early in the disease and will clear as the infection is controlled. Both the bone scan and the Gallium scan are ordered initially; the bone scan confirming the diagnosis by demonstrating bone involvement; and the Gallium scan to confirm the infectious process. The Gallium scan is then used to monitor the effectiveness of the treatment. The erythrocyte sedimentation rate can also be monitored to assess the resolution of infection.

The treatment, in addition to debridement of the granulation tissue and rigorous control of blood sugar, is to use topical and systemic antibiotics directed against pseudomonas. Before the availability of the quinolones, this usually meant an aminoglycoside (such as gentamicin) in combination with an antipseudomonal penicillin (such as piperacillin) or a third-generation cephalosporin. These treatments could only be given intravenously, and a 6-week course was usually required. This usually meant a prolonged hospital stay and some degree of vestibular impairment due to the aminoglycoside. The quinolones, such as ciprofloxacin, provided excellent pseudomonal coverage in an oral form, allowing most necrotizing otitis externa to now be treated on an outpatient basis. In most cases, the patient will be started on an oral quinolone for a 6-week course. This antibiotic regimen may be altered based on the results of the culture and the effectiveness of the therapy, as determined by a Gallium scan 6 weeks after starting therapy.

Surgery is required in only rare cases of necrotizing otitis externa. In earlier years, aggressive surgery had been attempted to remove necrotic bone. Results of this intervention were often disappointing as it often facilitated the spread of the disease. Nowadays, surgical intervention is avoided as it may hasten the spread of infection and is only used after failure of a more prolonged, conservative approach.

Otomycosis. Fungal infections are frequently involved in inflammatory processes of the ear canal (Figure 7). Unlike bacterial infections, pain seems to be an uncommon complaint in these disorders, where the usual complaint is pruritus. Often they are asymptomatic. A variety of fungal microorganisms are involved.

Much of the time, fungus found in the ear canal is saprophytic, meaning it feeds off of other material. This most often occurs in cases of chronic suppurative otitis media where the pus serves as a food source for the fungus. In such cases, the fungus involved, usually aspergillus, is not a true infective pathogen. The drainage and infection are due to the middle ear pathology, and the fungus a mere saprophyte. Debridement of granulation and necrotic tissue and treatment of the underlying suppuration will usually resolve the fungal overgrowth. Saprophytes, however, can become invasive infectious microorganisms when there is significant immune suppression or impaired circulation. Invasive fungal infections can be rapidly fatal and require aggressive treatment. Often their presentation is identical to that of necrotizing otitis externa. The fungal hyphae often spread in the endothelial layer of the blood vessels, causing hypoperfusion and necrosis (as seen in mucormycosis). Aggressive surgical debridement, correction of immune suppression, and high-dose amphotericin B are the only available options and a severe trial for these already frail patients.

A another common fungal infection found in the external ear is due to Candida species. Patients may complain of pruritus, a smelly discharge from the ear and a hearing loss due to the accumulated debris. Pain is uncommon and usually points to another abnormality. Candidal infections are also more saprophytic in nature. They are characterized by a large amount of cheesy, white debris in the canal. The underlying canal skin may be slightly edematous and erythematous, but it is rarely as severe as that seen in AOE. Very often, these candidal overgrowths are the result of overuse of newer antibiotic otic drops. Otic quinolone preparations will suppress bacteria and allow overgrowth of the resident Candida species. Complete debridement, acidifying drops, and, occasionally, instillation of antifungal creams or ointments, eg, nystatin, will frequently be curative.

Some external ear complaints will be due to dermatophyte infection. These microorganisms, notorious as a cause of athlete’s foot and ringworm, will cause severe ear itching and scaling of the canal skin. Dermatophytes are usually treated with acidifying drops with corticosteroid and on occasion may need more directed antifungal treatment.

One interesting aspect of dermatophyte infection is the risk of the allergic dermatophytid or
“id” reaction. This phenomenon, not uncommon with dermatophytes, is a local inflammatory skin reaction caused by an infection some distance away. This sometimes occurs in the external ear. A patient will present with chronic itching and scaling of the canal that does not respond to any local therapy. Canal scrapings viewed with a potassium hydroxide (KOH) preparation fail to show any microorganisms. Often, additional questioning will reveal the presence of a troublesome dermatophyte infection such as an athlete’s foot. Successful treatment of the primary dermatophyte infection will often result in clearing of the id reaction as well.

**Viral External Otitis.** The external ear can also be inflamed due to herpetic viral outbreaks. These generally present as a painful vesicular eruption following a dermatomal pattern. Herpes zoster and simplex are the most common microorganisms. When such a herpetic outbreak is associated with a facial paralyzis, it is termed Ramsay Hunt syndrome (see Chapter 34, “Facial Paralysis”). Tzanck preparations will often confirm the herpetic nature of the outbreak, but this is rarely needed in obvious outbreaks. Treatment is usually with an antiviral medication, such as Valtrex (valaciclovir), with analgesics being given for the pain. Outbreaks may be followed by prolonged periods of neuralgia, the care of which is largely supportive.

**Noninfectious Ear Canal Inflammation.** Not all otitis externa is due to infectious microorganisms. Often, canal inflammation is the result of an allergic or cutaneous condition. This will frequently present identically to, and be treated as, a bacterial or fungal otitis externa. Its true nature may not be determined until after multiple treatment failures or recurrences. Further complicating the distinction is the fact that these conditions may respond nicely to the corticosteroid component of antibiotic ear drops. Additionally, such cutaneous conditions lead to recurrent infection, further blurring this distinction. Seasonal or environmental variation and the associatedatomic picture will often support this diagnosis.

Unlike otitis externa, however, pain is less common than itching. Typically one will see thickening of the skin of the lateral aspect of the canal skin with hyperkeratosis and scaling. It may appear identical to a dermatophyte infection and a KOH preparation should be considered to differentiate the disorders. Such patients may have a history of psoriasis involving other areas of the body. Alternatively such cutaneous inflammation may be seborrheic or eczematous, with crusted, weepy skin. Such chronic inflammation may result in the gradual narrowing of the external meatus and stenosis of the ear canal.

For most of these cutaneous disorders, conservative therapy involves the use of corticosteroid-containing drops or creams. Since it is the lateral part of the canal and conchal bowl that are most frequently involved, a small amount of corticosteroid cream dabbed on the fingertip can be easily applied to the affected areas. If conservative therapy fails to provide significant relief, biopsy should be considered. Referral to a dermatologist should be considered for conservative treatment failures and when there are concomitant systemic lesions.

**Granular myringitis.** Granular myringitis is a poorly defined disorder characterized by chronic inflammation and weeping on the surface of the tympanic membrane. Although cultures may frequently demonstrate a dominant microorganism, it tends to recur despite appropriate antibiotic therapy. The chronic inflammation results in the gradual deposition of scar tissue, resulting in marked thickening of the tympanic membrane and gradual stenosis of the external canal (Figure 8). The disease course usually spans over many years, with frequent bouts of itching and drainage, and progressive conductive hearing loss due to the thickening drumhead. The problem often ceases when the scar tissue deposition reaches the cartilaginous canal.

Treatment of this disorder should be fairly aggressive. Granulation tissue on the drumhead should be cauterized with silver nitrate or trichloroacetic acid, and the infection treated with acetic acid/corticosteroid drops. Antifungal, antibiotic, and antiseptic drops should be considered. Cultures should be taken to direct therapy.

In situations in which the stenosis has progressed to a significant conductive hearing loss, surgical treatment may be needed. This procedure involves dissecting the deposited scar off of the canal wall and the fibrous layer of the tympanic membrane, which can usually be found intact. Denuded areas are then grafted with split-thickness skin grafts harvested from behind the ear or from the undersurface of the upper part of the arm. Packing of some sort is used to stent the canal open and maintain the skin grafts in place. When healed, this procedure often returns the eardrum to a normal appearance. Nonetheless, the patient may frequently again develop granular myringitis and start the process all over again.

**Disorders of Keratin Migration**

As mentioned earlier, the keratin layer of the ear canal skin has a migratory characteristic. As the outer layers mature, they move laterally and are finally desquamated out of the meatus by the action of the ceruminous and sebaceous glands. Occasionally this process is disrupted resulting in a neoplastic-like accumulation of keratin debris in the canal. Like cholesteatoma, this keratin accumulation can cause resorption of bone with resultant anatomic changes of the ear canal.

**Keratosis Obturans.** Keratosis obturans occurs when this migratory pattern of keratin maturation ceases or is in some way blocked. Patients with keratosis obturans usually complain only of a hearing loss, but pain, pruritus, or drainage may also be noted. The keratin plug initially appears like a “run-of-the-mill” wax impaction, but as it is removed the true keratotic nature of the lesion can be seen. In the deeper part of the canal, large accumulations of white, cheesy keratin are removed. Frequently, bone absorption will result in a dramatic widening of the medial canal, which can result in dehiscence of the fallopian canal in the external ear. As such, caution should be used as the keratin is dissected from the underlying, viable tissue.

Keratosis obturans can occur in 2 forms, a primary form and a secondary form. The patients with the secondary form are typically older and are more often male. In this form, a long-standing plug of hard, dense wax results in effective blockage of the keratin migration. Patients with the primary form typically develop the problem when younger than 40 years, and it represents a primary dysfunction in epithelial migration. There is an equal sex predilection, and it is more common in African-Americans. Removal of the keratin plug is often curative, but the patient may need to be seen on a regular basis to remove accumulated keratin before it becomes impacted.

**Canal Cholesteatoma.** Keratoma obturans must be distinguished from the much rarer entity of canal cholesteatoma. While cholesteatomas are a histologic similarity with those found in the middle ear but are not associated with middle ear disease. A canal cholesteatoma typically forms on the floor of the external canal. There is often a localized sequestration of necrotic bone with keratin accumulation often surrounding this sequestrum. There may be a cystic keratin “pearl” on the floor of the ear canal. These lesions may sometimes be small, and office debridement (often requiring local anesthesia) is curative. At other times, the lesion may be extensive and require total canalplasty and, occasionally, mastoidectomy.

The exact pathophysiology that leads to this type of cholesteatoma is unknown. One theory suggests that the process is initiated by some insult (infectious or traumatic) that results in a localized area of necrosis within the bony tympanic ring. The body wall off this necrotic area, and skin grows underneath it, resulting in the cholesteatoma. Another theory is that trauma, such as self-instrumentation of the ear for relief of pruritus, causes skin laceration and inversion of the epithelial lining. The buried keratin layer no longer migrates as in healthy canal skin and

**Figure 8** Medial canal stenosis due to granular myringitis.
gradually develops the keratin accumulation characteristic of cholesteatoma. Some other canal cholesteatomas may be caused by retraction pockets into dehiscent mastoid air cells. These cholesteatomas typically occur on the posterior wall and are associated with well-pneumatized mastoids.

**Congenital Sinuses, Cysts, and Skin Tags**

Sinuses, cysts, and skin tags are congenital lesions associated with the embryologic development of the external ear (Figure 9). The more common of these lesions are the preauricular sinuses and pits. These lesions are due to a failure of the union of the hillocks from the first and second branchial arches. Typically, a small pit is found in the skin just anterior to the tragus, and there may be an underlying cyst. These cysts may occasionally become infected or have a foul-smelling drainage, in which case surgical excision should be considered. Excision is performed with an elliptical preauricular incision with primary closure. There is usually a sinus tract found on the deep aspect of the cyst that can usually be traced to the helical cartilage. Care must be taken to dissect out the entire cyst and sinus tract to prevent recurrence.

Related to these lesions are the first branchial cleft anomalies, i.e., cysts and sinuses. These lesions are usually lined by squamous epithelium and may have sinus tracts connecting to the middle ear. These lesions were classified by Work as either type I or type II. Type I lesions usually present as a cyst located behind the meatus, sometimes within the conchal bowl. Surgical excision is usually curative but is usually reserved only for those cysts that become repeatedly infected. Again, careful dissection of the associated sinus tract is necessary to prevent recurrence. Type II lesions typically occur in the preauricular area and may involve the facial nerve and the parotid gland. Surgical excision of these lesions requires great care.

A type I congenital ear malformation, from a preauricular skin tag to complete microtia, can be a finding in branchio-oto-renal (BOR) syndrome. This autosomal dominant disorder is characterized by congenital ear abnormalities (external, middle, or inner), branchial cleft anomalies (sinuses, cysts, or pits) and renal abnormalities (ranging from mild hypoplasia to complete absence). This disorder has been linked to a mutation in the EYA1 gene on chromosome 8 (8q13.8). This gene is the human analog of the drosofila “eyes absent” gene and codes for a protein that is involved in the regulation of differentiation. Genetic testing is available for this gene and should be considered in patients with auricular and branchial anomalies, especially if they are familial or associated with sensorineural hearing loss (see Chapter 26, “Hereditary Hearing Impairment” for additional information.)

**Benign Neoplasms and Tumor-Like Soft Tissue Lesions of the External Ear**

The external ear, which is fundamentally a skin appendage, is prone to a number of neoplasms that may occur anywhere on the skin. Other lesions are unique to the ear. Identification by characteristic presentation and appearance is the rule, but biopsy should always be considered when the exact nature of the lesion is uncertain.

**Keloids.** A keloid is a very firm, round, painless mass that typically occurs at a site of trauma, most typically the site of ear piercing. It occurs as a result of such trauma in susceptible individuals, who are most often of African descent. These “hypertrophic scars” are totally benign, and the main problem that they present is cosmetic disfigurement. Small lesions can typically be treated with vigorous massage and pressure, with intralesional triamcinolone (Kenalog) injections for refractory cases. Large lesions require surgical excision, usually with primary closure. Massage and intralesional corticosteroid should be used after postoperative healing to prevent recurrence of the lesion.

**Chondrodermatitis Nodularis Chronica Helicis.** Chondrodermatitis nodularis chronica helicis presents as an exquisitely painful, discrete nodule usually involving the rim of the helix. The lesion is tender, and patients will most often complain that they cannot sleep on that side or use a telephone on that ear due to the pain induced by such activity. Similar lesions may be found in the meatus or conchal bowls of hearing-aid users and may prevent the patient from using the aid. On initial presentation, the lesion may not be easily differentiated from a basal cell or squamous cell carcinoma, but it tends not to grow larger than a few millimeters. Histologically there will be surface ulceration with pseudoepitheliomatous hyperplasia in very close contact to the sensitive perichondrium. The underlying cartilage is usually nonvital, and it is thought that the skin and perichondrial reaction is secondary to this cartilage necrosis. It is believed that perichondrial irritation due to trauma or chronic pressure is the initiating factor. Surgical excision, including the involved perichondrium and nonvital cartilage (which has a distinctly whiter appearance than normal cartilage) is usually curative.

**Gouty Tophi.** Gouty tophi may accompany systemic gout and may affect any part of the auricle. This is usually a painful, discrete nodule covered with a thin, vascular, orange skin that may discharge a white, creamy material. This is a manifestation of the systemic disease, and treatment is, therefore, medical and involves the use of urate-lowering medications.

**Inflammatory Polyps.** In most cases, inflammatory polyps do not come from the external canal but usually originate in the middle ear and extend...
into the external canal through a perforation. Exuberant, friable inflammatory proliferation with purulent discharge is the typical appearance. Histologically there is a dense infiltration of plasma cells. Although classically associated with chronic inflammatory disease of the middle ear, these lesions can be associated with more aggressive neoplasia. Imaging, usually with CT, is usually indicated and biopsy should be considered based on the results of such imaging. For purely inflammatory polyps, topical antibiotic drops, preferably containing a corticosteroid should cause their involution, but systemic antibiotics should be considered as well.

**Cystic Lesions.** Several varieties of skin cysts may present in the external ear. This includes sebaceous cysts, epidermal cysts, and dermoid cysts. They are typically nontender and largely asymptomatic unless they are infected or enlarge to the point that they affect hearing. Surgical excision is curative.

**Osteoma and Exostosis.** The most common bony tumors found in the external ear are exostoses and osteomas. These lesions can be distinguished clinically by the following characteristics: exostoses are typically found deep in the canal, often adjacent to the tympanic membrane, whereas osteomas typically occur more laterally, near the bony-cartilaginous junction; there are usually multiple exostoses, often on both sides, whereas osteomas are typically single and almost never bilateral; exostoses typically have a broad base whereas osteomas often have a single, pedunculated stalk; and exostoses are typically located more superiorly in the canal whereas osteomas typically are attached posteriorly. Histologically, they are vastly different in appearance. Exostoses have a hared, laminated appearance with multiple parallel layers of subperiosteal bone with no medullary cancellous portion. Osteomas have a more neoplastic appearance, with areas of dense, skin-covered laminar bone with a central portion of cancellous bone, bone marrow, and fibrous tissue.

Exostoses are strongly associated with participation in water sports and are sometimes called “swimmer’s nodules” or “surfer’s ear.” It is believed they result from irritation of the deep periosteum of the ear by cold water, resulting in the increased deposition of bone by the periosteum. The lesions are benign and typically need no treatment. Surgical excision should be considered if the lesions result in frequent infections or impactions, if their size affects the hearing (primarily due to wax retention), or if their presence prevents the proper fitting of a hearing aid. Caution should be taken in this surgery in regard to the facial nerve, as it may be shallow in the posterior-medial ear canal, and there are reports of iatrogenic facial nerve injury in these cases.

Osteomas, on the other hand, will almost always require removal. Their location more lateral makes them more obstructing and problematic. If they have a small stalk, as is almost always the case, they can often be easily removed in the office. The base is infiltrated with 1% lidocaine with 1:100,000 epinephrine and a small, firm tool such as a Freer elevator is used to “snap” the osteoma off at its base. Hemostasis can be obtained with a small cotton pledget or oxidized cellulose (Surgicel), and the base allowed to granulate in. Larger, more sessile osteomas will require surgical removal in an operative setting.

**Other Benign Neoplasms.** In addition to the above mentioned lesions, there may be many other types of benign neoplasms that arise from the external ear. Any benign neoplasm arising from skin or its appendages particularly glands, bone or cartilage can be found on occasion in the external canal. As would be expected, most benign neoplasms will be well-circumscribed, painless masses. Excisional biopsy is usually curative.

**Malignant Neoplasms of the External Ear**

Malignant neoplasms of the external ear are a particular challenge to the otolaryngologist–head and neck surgeon. The vast majority of these neoplasms are skin-derived, and sun exposure and fair skin are the obvious risk factors. Basal cell and squamous cell carcinomas arising from auricular skin make up about 44% of all neoplasms of the external ear. Skin cancer involving the ear makes up 6% of all skin cancers. Squamous cell carcinoma is the most common type of such malignancy, making around 60% of all external ear malignancies. This is in contrast to elsewhere on the body, where basal cell predominates and makes up 90% of skin malignancies. On the sun-exposed skin of the auricle, basal cell carcinoma is indeed more common than squamous cell. In the ear canal, basal cell carcinoma is rare. Squamous cell carcinoma of the canal may not only be a result of sun exposure but also of chronic infections, trauma, radiation, and chronic dermatitis.

Basal cell carcinoma (Figure 11) has the typical appearance of a pearly nodule, possibly with central ulceration and surrounding telangiectasia. These painless lesions rarely metastasize but may spread to deeper tissues via embryonic tissue planes. Diagnosis is by biopsy, which is often curative if the entire lesion can be easily excised. Larger lesions and biopsies with positive margins are best treated with Mohs micrographic surgery (MMS). This technique relies on intraoperative pathologic evaluations and re-resection in positive areas until margins are free of disease. This has the advantages of complete neoplasm removal and maximal sparing of normal tissue. Reconstruction of such defects is described in Chapter 57, “Scar Revision and Skin Resurfacing.”

**Figure 11** Basal cell carcinoma of the auricle.

**Figure 12** Squamous cell carcinoma of the auricle.

**Figure 13** Squamous cell carcinoma of the external auditory canal.
Squamous cell carcinoma of the auricle usually appears similar to its appearance in other areas of the body: an indurated, scaly, maculopapular area with possible ulceration (Figure 12). Wide excision or Mohs surgery is recommended, but the metastatic potential is markedly higher with squamous cell carcinoma, so selective neck dissection or sentinel node biopsy may be indicated.

Unlike squamous cell carcinoma of the auricle, squamous cell carcinoma of the canal tends to be a much more problematic disease (Figure 13). Patients with this problem in this location tend to be younger, averaging 52 to 55 years, as opposed to 65 to 70 years in squamous cell carcinoma of the auricle, are predominantly male, and have fewer skin cancer risk factors. Chronic ear complaints such as pain, drainage (bloody and/or purulent), and pruritus are not uncommon. Often, diagnosis is delayed due to prolonged attempts to treat what appears to be an infectious condition, and biopsy is recommended when putative ear canal inflammation fails to respond to appropriate therapy. The carcinoma tends to be infiltrative and poorly defined and histologically less differentiated than those found on the auricle. Facial paralysis may be a presenting symptom. These tumors are classified with the TMN system recommended by Arriaga and colleagues, commonly referred to as the Pittsburgh system (Table 2). Surgery is the preferred treatment modality and is usually extensive and disfiguring. Radiotherapy is a useful adjunct in more advanced disease. This is discussed in Chapter 92, “Chemoradiation for Head and Neck Cancer.”

In addition to basal and squamous cell carcinomas, a variety of malignant neoplasms may affect the external ear. Malignant melanoma, carcinomas, a variety of malignant neoplasms and adenocarcinoma of the cerumen glands can be considered primary malignancies of the external ear. Salivary neoplasms of the parotid gland or the middle ear may involve the external ear by direct extension. The external ear may even be the site of metastases from distant primary neoplasms. For this reason, a high index of suspicion should be maintained, and biopsy should be considered for any lesion in a situation in which a seemingly infectious process does not respond to appropriate therapy.

### Table 2. TNM Tumor Staging System for Carcinoma of the External Auditory Canal*

*Nodal stage (N) and metastases (M) are classified as elsewhere in the head and neck.

### REFERENCES

Eustachian Tube Dysfunction

Dennis S. Poe, MD
Quinton Gopen, MD

The eustachian tube performs the critical roles of aeration and drainage for the middle ear cavity. It also protects the middle ear from reflux of sound and material from the nasopharynx. Proper function of this tubular organ is required for optimal conduction of sound through the middle ear cavity. Since its initial description by Eustachius in the mid-1500s, much has been learned of its anatomy, physiology, and pathology. This chapter provides a comprehensive review of the eustachian tube anatomy, physiology, and pathology, including both eustachian tube dysfunction and patulous eustachian tube.

HISTORY

Although the eustachian tube was first mentioned by Alcmaeon of Sparta in 400 BC, Bartolomeus Eustachius is credited with its discovery in 1562 when he published a detailed description of its structure and function. Valsalva went on to characterize the eustachian tube into cartilaginous and osseous parts and was the first to describe the importance of the tensor veli palatini muscle in opening the eustachian tube. He also described the Valsalva maneuver, a technique which remains clinically relevant to this day. Toynbee furthered our understanding of the eustachian tube through an extensive investigation of the peritubal muscles, and Politzer played a pivotal role in delineating the eustachian tube and its role in middle ear pathology.

ANATOMY

The eustachian tube courses from the middle ear cavity proximally to the nasopharynx distally. The distal portion is comprised of a cartilaginous skeleton whereas the proximal skeleton is osseous. The osseous portion constitutes approximately one-third of the entire length of the eustachian tube. The osseous portion is funnel shaped with the wide end of the funnel extending from the anterior aspect of the middle ear cavity. The narrow end of the funnel, also termed the isthmus, is the narrowest point of the eustachian tube and is located just proximal to the junction of the bony and cartilaginous segments of the eustachian tube. The osseous portion is normally patent and does not open and close dynamically as does the cartilaginous portion. The cartilaginous distal two-thirds of the eustachian tube courses from the isthmus into the nasopharynx. It comprises a single segment of cartilage attached along its superior edge to the basisphenoid bone. Although the cartilaginous portion closer to the osseous eustachian tube segment remains fixed in its position, the more distal end of the cartilage as it enters the nasopharynx has dynamic movement. The distal end of this cartilage protrudes into the nasopharynx and is termed the medial cartilaginous lamina. The medial cartilaginous lamina is mobile and allows the orifice of the eustachian tube to open as it medially rotates during tubal dilation. The medial cartilaginous lamina provides the framework for the torus tubarius, a mobile structure also known as the posterior cushion or posterior medial wall which comprises part of the eustachian tube orifice. The eustachian tube orifice is mainly comprised of the lateral cartilaginous lamina, an immobile structure also known as the hook or “J” portion of the eustachian tube orifice. The remainder of the eustachian tube orifice is completed by a fibrous membrane. It is firmly attached to the basisphenoid bone. The eustachian tube orifice lies between the medial cartilaginous lamina and the lateral cartilaginous lamina. Just posterior to the medial cartilaginous lamina is the fossa of Rosenmüller, an important space containing lymphoid tissue and is medial to the internal carotid artery. The adenoid pad lies just medial to the fossa of Rosenmüller and occupies the midline of the nasopharynx.

The pediatric eustachian tube has many critical differences from the mature adult eustachian tube. Several studies have demonstrated that the pediatric eustachian tube is anatomically smaller than the adult eustachian tube. For example, the cross-sectional area including the width and the length of the cartilaginous eustachian tube lumen was significantly smaller in children than in adults. The length of the eustachian tube was nearly half as long in infants when compared to adults (21 mm at 3 months vs. 37 mm in adult). The eustachian tube reaches adult length of 31 to 38 mm typically at 7 years of age. A further important difference in eustachian tube development is the angle at which the tube courses from the middle ear space to the nasopharynx. In children, the tube courses horizontally, whereas in adults the tube is much more dependent and has an angle closer to 45° from the horizontal. Other differences include cartilage volume, Ostmann fat pad, mucosal folds, lymphatic glands, and middle ear volume in children compared to adults (Table 1).

PHYSIOLOGY

Although the osseous portion of the eustachian tube remains patent and is not dynamic, the cartilaginous portion of the eustachian tube remains closed in its resting state and only opens for brief periods of time. This blocks gastric reflux from entering into the middle ear as well as prevents autophony, an abnormally loud perception of one’s own voice, breathing, and other internal sounds. A tubal autophony of voice can be disturbingly loud when sound energy during vocalizations passes internally into the middle ear space. The tensor veli palatini muscle has significant bulk which when the muscle is relaxed serves to obliterate the eustachian tube orifice. Additionally, the mucosa and submucosa lining the eustachian tube are quite elastic and serve to decrease the eustachian tube lumen. The anterolateral wall of the eustachian tube contains a collection of fat, termed Ostmann fat pad, which also aids in closure of the eustachian tube orifice along with the rigid lateral cartilaginous lamina. The combination of mucosa, submucosa, Ostmann fat pad, and tensor veli palatini muscle, in effect, comprise a “valve” within the cartilaginous tubal lumen with the mucosal surfaces in apposition during closure. Importantly, brief intermittent periods of eustachian tube dilation must occur in normal individuals for ventilation. These brief periods of tubal dilation and patency result from contractions of...
the peritubular musculature (Figure 2). There are four peritubular muscles: tensor veli palatini, levator veli palatini, salpingopharyngeus, and the tensor tympani. The most important muscle for opening the eustachian tube is the tensor veli palatini muscle.12,13 This muscle predominantly originates from the basi-sphenoid bone and to a smaller degree from the lateral cartilaginous lamina. It courses inferiorly and anteriorly, passing mostly deep around the pterygoid hamulus, and then inserting into the soft palate. It runs longitudinally along the cartilaginous portion of the eustachian tube. When this muscle contracts, the eustachian tube is pulled open by a laterally directed force onto the membranous eustachian tube wall. An extension of the tensor veli palatini muscle, termed the dilator tubae muscle, originates along the anterolateral membranous wall of the eustachian tube and aids in opening the lumen of the tube.

The levator veli palatini muscle is also important in opening the eustachian tube. This muscle has its origin in the base of the temporal bone and inserts into the soft palate. It forms a sling and courses under the inferior aspect of the medial cartilaginous lamina and floor of the membranous eustachian tube. When this muscle contracts, it results in elevation of the soft palate as well as medial rotation of the medial cartilaginous lamina, both important steps toward opening the eustachian tube orifice.

A slow-motion video evaluation of eustachian tube opening has been performed and has identified four distinct phases involved in eustachian tube opening.14 The first phase involves elevation of the soft palate along with medial rotation of the medial cartilaginous lamina and the posteromediacl wall. This occurs by contraction of the levator veli palatini muscle and results in the initial dilation of the nasopharyngeal orifice. The levator veli palatini then remains contracted throughout all four phases of eustachian tube opening and may serve as a scaffold that aids the tensor veli palatini action to dilate the valve to the open position. The second phase occurs as the superior pharyngeal constrictor muscle contracts which results in a medial displacement of the lateral pharyngeal wall. This results in a transient narrowing of the eustachian tube orifice. The third phase involves contraction of the tensor veli palatini muscle which dilates the eustachian tube orifice from a laterally directed traction on the membranous eustachian tube wall. The fourth and final phase is when the tensor veli palatini maximally contracts resulting in an effacement of the anterolateral eustachian tube orifice with maximal opening. The eustachian tube orifice has a rounded appearance during maximal dilation. The entire four-phase process of eustachian tube opening lasts for roughly 400 ms.

Tubal dilation propagates from the nasopharyngeal orifice proximally into the “valve” toward the bony isthmus. Tubal closure reverses the process beginning proximally and progressing distally, resulting in a pumping action that clears the middle ear space and eustachian tube of secretions.13 Tubal closure occurs by sequential relaxation of the tensor veli palatini and the levator veli palatini musculature, and the eustachian tube orifice once again returns to its resting configuration with a convex bulge along its anterolateral wall.15

The eustachian tube dilates during deglutition or yawning. Investigators have suggested that the autonomic nervous system provides the control for intermittent, involuntary dilations of the eustachian tube through baroreceptors and chemoreceptors found within the middle ear cavity.16,17 When the eustachian tube is closed, an ongoing exchange of gas occurs between the middle ear cavity and the mucosa. Venous blood contains a lesser amount of dissolved nitrogen and also has a slightly lower pressure compared to atmospheric pressure. This results in a large gradient between the overall pressure and the partial pressure of nitrogen. Consequently, nitrogen slowly diffuses into the venous blood from the middle ear. This leads to a steady absorption of gas from the middle ear resulting in an increased negative pressure within the middle ear space relative to the ambient atmosphere. Each gas within the middle ear space has a different solubility constant for diffusion into the mucosa. Carbon dioxide diffuses most readily, approximately 40 times greater than nitrogen. Oxygen is roughly twice as soluble as nitrogen. Accordingly, carbon dioxide and oxygen may play a greater role in short-term pressure effects (more soluble) when compared to nitrogen which is theorized to have a more important role in long-term effects.18 19 This negative pressure formed by gases diffusing out of the middle ear and mastoid spaces and into the mucosal lining and capillaries continues to build until the eustachian tube periodically opens (Figure 3).

Surfactants have been identified in the eustachian tube and the middle ear cavity where they facilitate the exchange of gases across mucosal barriers and allow for easier opening of the eustachian tube orifice.19 Surfactants are defined as any substance which results in a decreased surface tension. Surfactants found within the body are phospholipids which serve to facilitate air-fluid exchange, most importantly in the lungs but also within the middle ear and mastoid spaces.

Aeration of the middle ear space occurs when the eustachian tube opens and nasopharyngeal air, generally at atmospheric pressure, is exchanged with the middle ear gases allowing for an equalization of pressure on both sides of the tympanic membrane. The eustachian tube opens approximately 1.4 times each minute for a duration of 0.4 to 0.5 seconds, usually with a swallow or yawn. The tube does not dilate open with every swallow or yawn. Between openings, there is a net absorption of middle ear gases that results in a progressive negative pressure in the middle ear space that ranges between 0 and –50 cm H2O in healthy awake adults.20

In addition to middle ear aeration, the eustachian tube also serves as a drainage pathway for fluid buildup within the middle ear. Middle ear secretions or infection are removed by two primary mechanisms. The first mechanism involves mucociliary clearance, much akin to the pulmonary system. The inferior or dependent portion of the eustachian tube is lined by columnar ciliated epithelium, in contrast to the osseous and superior portions of the eustachian tube which are lined by cuboidal respiratory epithelium.21 These ciliated epithelial cells provide a mucociliary elevator to push debris and secretions down the eustachian tube and into the nasopharynx. The second mechanism of clearance involves muscular pumping. Muscular pumping of the eustachian tube occurs as the tubal valve progressively closes from the isthmus toward the nasopharyngeal orifice when the tensor veli palatini muscle relaxes.13 This works synergistically
along with mucociliary clearance to propel fluids and debris down the eustachian tube and out the orifice within the nasopharynx where they can be swallowed or expectorated.

The third role of the eustachian tube is to prevent gastroesophageal reflux from penetrating into the middle ear cavity and to block the passage of sound from entering the middle ear cavity during speech. As the eustachian tube remains closed for all but brief intermittent periods of time, the primary mechanism for prevention of reflux of fluid and sound is mechanical blockage due to a closed lumen. During the brief periods of time when the tube is open, reflux of sound and fluid is limited by a back pressure of air within the middle ear space, the so-called gas cushion effect.12

**EVALUATION**

Evaluation of patients with suspected eustachian tube dysfunction begins with a comprehensive history and physical examination. History should focus on any disorders which could lead to edema or inflammation of the eustachian tube, such as laryngopharyngeal reflux, allergies, Samter triad (asthma, nasal polyposis, and aspirin sensitivity) or sinusitis. Disorders affecting ciliary motility such as cystic fibrosis and Kartagener syndrome should be diagnosed. Prior operations, particularly a history of adenoidectomy, should be elicited. In children, otitis media is associated with cigarette smoke exposure, wood burning stoves, and participation in group daycare facilities. Inquiry should be made about excessive respiratory tract infections, immune deficiency, food or environmental allergies, or a family history of eustachian tube problems. Social history should include questions about smoking and secondhand exposures to smoke which have a detrimental effect on mucosal ciliary clearance. A detailed list of medications is important and should focus on any nasal preparations including topical corticosteroids and oxymetazoline (Afrin), allergy medications, and hormonal replacement therapies.

Examination is comprehensive and includes a thorough head and neck evaluation with particular focus on otoscopy as well as nasopharyngoscopy. Oto-scopy is best performed using the binocular microscope and the tympanic membrane should be inspected for any retraction, retraction pockets, cholesteroloma, perforations, atelectasis, tympanosclerosis, or effusions. Pneumatic otoscopy is particularly important, looking for evidence of tympanic membrane retractions and the degree of retraction and negative middle ear pressure. Insufflation of a retraction helps to determine if there is active negative middle ear pressure that may indicate compromise of eustachian tube function. If the retraction has become adherent but the surrounding tympanic membrane moves equally well with positive or negative insufflation, the adhesion may be a remnant of past tubal dysfunction, a factor that could be important in deciding whether surgical intervention is indicated for the retraction. A urologic assessment is indicated and begins with pure-tone audiometry to assess for conductive or sensorineural hearing loss. Tympanograms are also obtained to ascertain the resting middle ear pressure.

Endoscopic examination of the eustachian tube is important to determine the nature of tubal dysfunction. It is best performed with an endoscope positioned close to the nasopharyngeal orifice of the eustachian tube with the view directed down its longitudinal axis, approximately 45° superiority to the floor of the nasal cavity. Examination during swallows and yawns reveals the mucosal folds within the valve of the cartilaginous portion of the eustachian tube unfolding in full view during the dilation and closing processes.

Endoscopic examination should include both nasopharyngoscopy and laryngoscopy. Nasopharyngoscopy can be accomplished with either rigid or flexible scopes passed through the nasal passages. A through rigid scopes allow for the best images and clarity, flexible scopes are often better tolerated by patients. Optimal patient position is sitting upright in a chair. The patient is anesthetized with topical spray consisting of lidocaine 4% mixed with an equal contribution of phenylephrine 4%. The initial examination is most commonly performed with a flexible endoscope to survey all of the nasal cavity, nasopharynx, pharynx, hypopharynx, and larynx. Nasal mucosa is also inspected for any signs of allergies, inflammation, granulomatous disease, or other pathology. The larynx is examined for evidence of laryngopharyngeal reflux such as inflammation of the arytenoid and interarytenoid web, false or true vocal folds, and especially the subglottic space. When using a flexible scope, the eustachian tube lumen is best seen through the contralateral naris by curving it posteriorly around the posterior edge of the vomer. The endoscope is positioned as close to the eustachian tube orifice as possible and directed along the long axis of the tubal lumen. Rigid endoscopy is then done for more directed detailed inspection. A 4 mm rigid 30° or 45° endoscope is quite useful in evaluation of the eustachian tube orifice. In the relaxed, closed state, the valve mucosa takes on an S-shaped curve within the lumen. During dilation, the valve becomes rounded. Patients with a patulous eustachian tube are seen to have a concave or scaphoid defect where the normal anterolateral wall bulge exists.

Dynamic endoscopic inspection of the eustachian tube orifice is important in differentiating whether the cause of dysfunction may be a mucosal or obstructive problem versus a muscular dilatory failure. Tubal dysfunction is classified as either an obstructive or dynamic disorder. Patients are initially asked to repeat the consonant “k” several times under direct visualization to assess the quality of palatal elevation and to assess the levator veli palatini muscle’s ability to rotate the posterior cushion medially. The valve does not dilate during this maneuver. To evaluate normal dilation, the patient is instructed to do a series of swallows. To evaluate maximal dilatory effort, the patient is instructed to do series of yawns. The tube should be seen going from the closed S position into a rounded open lumen and relax back to its resting closed state.

Slow-motion video endoscopy is also used to evaluate eustachian tube opening, particularly for patients with chronic tubal dysfunction. Images captured on video are reviewed in slow motion to evaluate the eustachian tube dynamics in detail. Each of the four phases of eustachian tube opening along with the dynamic function of both the tensor veli palatini and levator veli palatini can be isolated and evaluated using this technique.
Eustachian Tube Function Tests

A number of tests have been employed using either positive or negative pressure through the external auditory canal or nasopharynx to assess eustachian tube function. None of these tests have gained widespread use as they all lack clinical significance. The forced response test measures the pressure needed to open the eustachian tube, and a patent ventilation tube or tympanic membrane perforation is required. The external auditory canal is sealed using a tympanometry probe, and the pressure is increased until the eustachian tube opens resulting in a sudden decompression. The inflation-deflation test uses a tympanometry probe to record and vary pressure as the patient swallows in an attempt to open the eustachian tube. Both the forced response test and the inflation-deflation test were used to evaluate pediatric patients prior to tympanoplasty in one study. Although good eustachian tube function did correlate with a favorable outcome for tympanoplasty, poor eustachian tube function did not correlate with poor outcomes for tympanoplasty.

PATHOLOGY AND TREATMENT

In general, impairment of tubal function can be divided into two main categories: the tube cannot open properly or the tube remains inappropriately patent. Eustachian tube dysfunction commonly, and as used throughout this chapter, refers to tubal dysfunction when the eustachian tube cannot open properly. Patulous eustachian tube describes the condition when the tubal orifice remains inappropriately patent. Both entities are reviewed below.

Eustachian Tube Dysfunction

Eustachian tube dysfunction can result from anatomical obstructions or physiologic causes. Tubal dysfunction appears to be due to: (1) hereditary factors as seen in strong family histories of ear disease, (2) mucosal inflammation and edema with obstruction or failure of dilation, and (3) muscular problems causing dilatory dynamic dysfunction.

Anatomical obstructions must be ruled out, particularly in patients presenting with unilateral symptoms. Malignant masses resulting in obstruction include nasopharyngeal carcinoma, lymphoma, and chondrosarcoma. Serous otitis media is the second most common presentation of nasopharyngeal carcinoma after a neck mass. Benign causes of mechanical obstruction include adenoid hypertrophy, mucus retention cysts, Tornwald cysts, or synechiae from adenoidectomy and other surgical procedures.

Physiologic blockage of the eustachian tube is more common than anatomical obstruction. Physiologic dysfunction most often results from mucosal inflammation, possibly due to allergies or laryngopharyngeal reflux. The allergic response of the mucosa lining the eustachian tube results in edema, narrowing of the lumen, and consequent dysfunction. This can occur at the eustachian tube orifice or along the entire length of the eustachian tube. Laryngopharyngeal reflux into the eustachian tube orifice and lumen similarly results in mucosal edema, inflammation, narrowing, and dysfunction. Tobacco use results in a loss of the normal ciliary clearance of the eustachian tube and frequently causes eustachian tube dysfunction. Hormonal influences on the eustachian tube can be observed in pregnancy, particularly in the third trimester when progesterone levels are peaking. Progesterone has a direct effect on the mucosa with ensuing edema and occasional dysfunction.

Once eustachian tube dysfunction begins and the eustachian tube cannot longer open properly, negative pressure builds within the middle ear space. This results in the symptom of aural fullness along with varying degrees of conductive hearing loss. The negative middle ear pressure may lead to other sequelae, including retraction pocket formation, tympanic membrane perforation, atelectasis, cholesteatoma, serous otitis media, and chronic otitis media.

Chronic feeling of fullness in the ear associated with a normal-appearing mobile tympanic membrane, absence of any retraction or effusion, and a normal tympanogram should not be interpreted as eustachian tube dysfunction. Instead, a search for other causes of fullness, blockage, or otalgia is indicated and should include evaluation of the temporomandibular joint as the most common cause followed by superior semicircular canal dehiscence syndrome and endolymphatic hydrops.

Evidence is mounting that eustachian tube dysfunction results from dysfunction along the cartilaginous portion of the eustachian tube. Using slow-motion video analysis, 40 adult patients were evaluated with the identification of significant pathology and compromise of tubal dilation within the cartilaginous portion. Eighty-three percent had mucosal edema and 74% had reduced anterolateral wall movement. Muscular dysfunction was demonstrated and typically involved the tensor veli palatini muscle. Weakness of the tensor veli palatini muscle may also cause a decrease in anterolateral wall dilation. However, several cases of levator veli palatini muscle dysfunction were also identified.
Slow-motion video endoscopy has revealed examples of hyper- or hypofunction of the tensor veli palatini or levator veli palatini muscles resulting in dynamic dysfunction of tubal dilation. Weak efforts by either muscle result in incomplete dilation of the valve. Excessive contraction may create a bulky mass effect that can paradoxically block the valve dilation just at the moment it should be opening. In some cases, there is a lack of coordination between the muscle contractions. For example, the levator veli palatini may relax prematurely leaving the valve partially closed by the time the tensor veli palatini begins its contraction (Figure 6). A hypertrophic adenoid pad does not need to cover the tubal orifice at rest to cause a significant functional obstruction. During the swallowing process, contraction of the pharyngeal constrictors can compress an otherwise nonobstructive adenoid into the posterior cushion of the eustachian tube and force it anteriorly to close the tubal orifice at the time it should be dilating open.21 Nguyen and colleagues demonstrated that adenoidectomy for relief of otitis media with effusion was most effective when adenoid tissue was in contact with the posterior cushions of the eustachian tube orifices.22 These findings would be consistent with the dynamic observations of pharyngeal constriction acting to push the adenoid into the posterior cushions as a mechanism causing tubal dysfunction.

The treatment of eustachian tube dysfunction depends upon identification of the underlying causality. Laryngopharyngeal reflux should be treated with dietary modifications such as avoiding foods that relax the lower esophageal sphincter and that promote acid production. Consideration should be given to acid-reducing agents such as proton pump inhibitors taken daily or twice daily and H₂ blockers at bedtime. Refractory cases may be managed by sleeping on an inclined bed, and ultimately, fundoplication may be considered.

A history or findings of allergies should be investigated. A avoidance of the offending allergen can be effective but may not always be possible. Oral second-generation antihistamines, nasal corticosteroid sprays, or combination therapy may be effective in reducing allergic manifestations. Refractory cases may require immunotherapy.

Management of anatomical obstructions is tailored to the causality. Nasopharyngeal carcinoma is often treated with radiation therapy, and benign masses such as hypertrophic adenoid tissue can be excised. Infections are treated with the appropriate antibiotics. Recurrent infections should prompt a search for underlying nasal or sinus disease, immunosuppression or immunodeficiency, or primary mucusal disorders (eg, Samter triad, Wegener granulomatosis). Granulomatous disease is typically treated with immunosuppressants.

**Surgical Management of Eustachian Tube Dysfunction.** In the event that thorough investigation of underlying medical conditions and maximal medical therapy fail to resolve otitis media or atelectasis, surgical intervention is indicated. Tymanoprostomy tubes are effective in the treatment of serous otitis media and may prevent retraction of the tympanic membrane, atelectasis, and other sequelae of eustachian tube dysfunction. If the effusion or inflammation continues despite a tube in place, it raises the suspicion of a primary mucosal disorder rather than just a eustachian tube problem. Thick proteinaceous "glue-like" effusions that repeatedly occlude the lumen of the ventilating tube often respond to oral or topical corticosteroids and may represent a primary mucosal problem. In cases of long-term persistent eustachian tube dysfunction, repeated placement of ventilating tubes may become necessary. In such cases, larger flanged tubes such as "T" tubes or subannular semipermanent tubes may be indicated. Longer duration tubes raise the risk of permanent perforation of the tympanic membrane.

For adult cases of medically refractory eustachian tube dysfunction and need for repeated tympanostomy tubes, eustachian tuboplasty is currently being studied. It appears to be most effective when the underlying medical conditions have been brought under control but there is irreversible mucosal disease causing functional obstructive dysfunction of dilatation. Laser tuboplasty with removal of redundant edematous tissue along the postero medial eustachian tube orifice has been shown to be an effective alternative for patients with chronic otitis media with effusion who have received numerous prior tympanostomy tubes with or without significant atelectasis.26,27 The operation involves laser debulking of posterior cushion luminal mucosa and submucosa down to the medial cartilaginous lamina from the free margin at the nasopharyngeal opening and extending proximally up to the valve (Figures 7 and 8). The extent of valve mucosa treated depends on preoperative evaluation with slow-motion video endoscopy to reveal the dynamics of the obstruction. Even after successful surgery, patients must remain vigilant about continuing medical therapy for their underlying condition. If they stop allergy or reflux therapy, the effusion may recur. In general, the operation has been well tolerated and without significant complications; however, long-term results and controlled studies need to be completed to determine the ultimate role of the procedure in the treatment of refractory otitis media due to chronic eustachian tube dysfunction. Further research must be done on the physiology and pathophysiology of tubal function in children before tuboplasty surgery would be recommended for pediatric cases.

**Patulous Eustachian Tube**

The condition known as patulous eustachian tube occurs when the eustachian tube remains patent for variable periods of time outside of the normal brief interval of opening which occurs during deglutition or yawning. When the eustachian tube is inappropriately open, patients typically present complaining of loud and disturbing autophony of their voice and nasal breathing sounds as well as aural fullness. Most patients describe the symptoms as if they are speaking within a barrel and complain of severe echoing with speech. Physicians can simulate the symptoms for themselves by listening through their stethoscopes while they speak and breathe with their mouth directly over the diaphragm. Unfortunately, many patients will simply state that they have a "blocked ear," prompting their physicians to treat them inappropriately for obstructive eustachian tube dysfunction for prolonged periods of time. The condition may arise spontaneously or occur with exercise, probably from dehydration or decongestion from exercise related hormones. When patients lie down or compress their ipsilateral internal jugular vein, the symptoms usually abate due to venous engorgement and closure of the patulous tube. Symptoms are often intermittent and can last from minutes to hours, or in extreme cases, persist continuously throughout daytime hours. Patients may note that symptoms are worse with nasal decongestants and improved with upper respiratory tract infections. Often, patients follow a dramatic and substantial weight loss such as with postpregnancy, cachectic diseases, dietary weight loss, and bariatric surgery. In the senior author’s experience, one-third of cases of patulous eustachian tube have a substantial history of weight loss, one-third have an associated systemic rheumatologic disorder, and the remaining third are idiopathic.

Patulous eustachian tube must be confirmed by physical examination. Unfortunately, symptoms
are often intermittent, and if the patient is not having active autophony during the evaluation, the condition can be missed. If the patient is suspected of having patulous eustachian tube and is not having autophony on arrival for clinical evaluation, the patient should exercise (eg, walking up and down stairs) for several minutes in an attempt to elicit the symptoms. The patient can be instructed to breathe deeply in and out through the ipsilateral nasal cavity, occluding the contralateral nares during the otoscopic examination. While the autophony is present, examination will demonstrate excursions of the tympanic membrane that move synchronously with ventilations, a condition that is pathognomonic for the patulous eustachian tube. The condition often resolves due to venous congestion in the supine position, such that the evaluation should be performed while the patient is sitting upright.

Endoscopic evaluation of the eustachian tube may aid in the diagnosis. Patients with patulous eustachian tube typically have tissue loss longitudinally through the valve that can be seen as a concave or scaphoid defect along the superior aspect of the anterolateral wall. The senior author's surgical experience has revealed that the loss of tissue volume can involve mucosa, submucosa, Ostmann fat, tensor veli palatini muscle, lateral cartilaginous lamina, or any combination of these. Endoscopy will show a concave defect in the anterolateral wall at the nasopharyngeal orifice during resting examination. However, this can be misleading as many patients, particularly thin individuals, will have similar mucosal gaps on examination. The tube must be examined for the defect which continues longitudinally throughout the full length of the valve as revealed during sustained yawn efforts. Most of the time, the full length of the valve is not easily examined up to the bony-cartilaginous junction so that endoscopic examination alone is not usually reliable.

Treatment of patulous eustachian tube is centered on thickening the mucus or restoring the bulk of the eustachian tube valve. If the patient is on any decongestants or topical nasal corticosteroid sprays, these should be discontinued. Weight gain is only recommended if the patient is malnourished. Good hydration can be effective and may be supplemented with nasal saline drops or irrigations. Drops can be instilled during the day anytime symptoms occur. Patients should be instructed to direct their nose vertically, place the drops, then tilt the head 45° laterally to maximize the contact with the tubal orifice. Placing the head in a dependant position for a few minutes is usually effective, at least temporarily. Autophony may often occur during prolonged speaking and unobtrusive neck compression of the ipsilateral internal jugular vein may relieve symptoms for some time. Although not FDA approved, “off-label use” of estrogen nasal drops - [Premarin 25 mg injectable SECULE (registered trademark to designate a vial containing an injectable preparation in dry form) diluted in 30 ml normal saline] or estradiol nasal drops (Depo-Estradiol 5 mg injectable ampule diluted in 30 ml normal saline), three drops TID for a 6-week trial period can lead to localized hypertrophy around the eustachian tube orifice that may improve or resolve symptoms. Topical irritants, such as aspirin or boric acid powder insufflated onto the nasopharyngeal orifice can cause a localized inflammatory

edema around the orifice and are usually effective. Unfortunately, the benefits are generally short-lived. Ongoing daily topical irritant therapy such as chlorine-based nasal drops may prolong the efficacy if the patients tolerate the treatment. Potassium iodine [ie, saturated solution of potassium iodide (SSKI)] has been used with some efficacy to thicken mucous secretions. Ventilation tube placement may provide some relief but in only half of patients.28 Ventilating tubes are generally effective in relieving the sensation of patulous excursions of the tympanic membrane during breathing but rarely control the more disturbing symptom of autophony.

Early attempts at surgical correction of the patulous eustachian tube involved peritubal injections of tetrafluoroethylene (Teflon) paste which typically gave transient relief. Injections were directed into the posterior cushion or floor of the tubal lumen. The practice was largely discontinued after several deaths occurred after inadvertent intracarotid injections. Intranasal placement of a needle into the inferior tubal orifice brought the needle into a direct line with the internal carotid artery. Since the patulous defect has more recently been identified in the anterolateral wall, new attempts at injection have been made. However, since the tissue planes around the anterolateral wall, especially around the tensor veli palatini muscle, are very loosely applied, they do not hold the material in place resulting in spread of material from the basisphenoid to the parapharyngeal space.29

Complete occlusion of the eustachian tube is very effective in relieving patulous symptoms, but an effusion occurs that generally must be managed with long-term ventilation with tympanostomy tubes. Occlusion can be accomplished by transnasal or middle ear approaches.

More recently, endoscopic approaches are being developed for reconstruction of the patulous defect while preserving eustachian tube function. The authors have found that a combined endoscopic transnasal and transoral approach can provide reliable long-term resolution of symptoms. The technique implants conchal cartilage grafts into the concave anterolateral defect to create a normal convex shape that will restore the competency of the valve (Figure 9). The mucosal incision is sutured closed to maintain the graft position and special instrumentation is recommended for the technique (see Figure 9).

Although long-term data are not yet available, patients followed for 5 years demonstrate that the procedure is efficacious and does not lead to recurrence of symptoms or the development of eustachian tube dysfunction. In the senior author’s series, 14 patients, most of whom were treated with cadaveric dermal implants (Alloderm), had 93% efficacy in reducing symptoms resulting in 43% of patients completely satisfied. For the 57% of patients not completely satisfied, an additional procedure to bulk up the anterolateral wall further was offered to the patients.20 Alloderm is known to lose a significant amount of volume over time, and much improved results are now being seen using cartilage grafts. This patulous eustachian tube reconstruction provides an efficacious low-risk alternative for patients suffering from patulous eustachian tube which prove refractory to medical management (Figure 10).

Finally, it is important to recognize that another common cause of autophony is superior semicircular canal dehiscence syndrome (third window syndrome). Patients describe a “blockage” or fullness of the ear and autophony in terms indistinguishable from patulous eustachian tube symptoms. The perception of bone conducted sounds are abnormally enhanced in superior semicircular canal dehiscence syndrome creating autophony which can also include sounds from chewing, footsteps, and even eye movements. An important point of differentiation is that nasal breathing is not typically amplified in superior semicircular canal dehiscence syndrome but is amplified and equally bothersome to patients with patulous eustachian tube. Furthermore, autophony in superior semicircular canal dehiscence syndrome is often sudden in onset followed by a persistence of the symptoms except at night. Patulous eustachian tube patients usually have more intermittent or fluctuating symptoms with some periods of relief.

A more interesting similarity between the two disorders is that in both the autophony can be relieved by supine or head-down positioning. The most critical distinction between superior semicircular canal dehiscence syndrome and patulous eustachian tube is made on the physical examination of the tympanic membrane while the patient reports ongoing active autophony. Excursions of the tympanic membrane will be pathognomonic for patulous eustachian tube while the absence of the excursions during autophony effectively rules out that condition. Other causes for autophony must be sought and superior semicircular canal dehiscence syndrome would be a prime suspect with endolymphatic hydrops a distant alternative. Superior semicircular canal dehiscence syndrome...
may also be associated with low-frequency conductive hearing loss, a supranormal bone conduction threshold above 0 dB in low frequencies, intact stapedius reflex, vertigo, hearing distortion, Tullio phenomenon, and torsional nystagmus with a fistula test. In the senior author’s series of 18 patients with superior semicircular canal dehiscence, the most common presenting symptom was autophony occurring in 94% of patients. Conductive hearing loss was present in only 72% of patients.29

**CONCLUSIONS**

The eustachian tube plays a central role in maintaining aeration and preventing reflux into the middle ear cavity as well as draining secretions from the middle ear cavity into the nasopharynx. Dysfunction of the eustachian tube occurs when the tube cannot open properly or when the tube remains patent at inappropriate times (patulous eustachian tube). In a search for an underlying cause, laryngopharyngeal reflux, allergies, primary mucosal disease such as Samter triad or granulomatous disease, and mechanical obstructions such as hypertrophic tissue, benign tumors, and malignant neoplasms should be considered. When the eustachian tube cannot open properly, negative pressure builds within the middle ear resulting in aural fullness and a conductive hearing loss. This can lead to other sequelae such as retraction pockets, tympanic membrane perforation, atelectasis, serous otitis media, and cholesteatoma. Treatment should be directed toward the underlying medical condition and will successfully relieve the dysfunction in the majority of cases. Medically refractory dysfunction is managed with tympanostomy tubes. If eustachian tube dysfunction persists in spite of multiple tube placements over time or adequate medical management, irreversible mucosal disease is probably responsible; and eustachian tuboplasty surgery may be indicated for adults.

Patulous eustachian tube can cause disturbing but physiologically harmless autophony and aural fullness. A concave defect in the anterolateral wall of the tubal valve and patulous excursion of the tympanic membrane will be seen during autophony symptoms. Medical therapies for patulous eustachian tube include weight gain if appropriate, hydration, saline- or estrogen-based nasal drops, chlorine-based nasal drops, and mucus thickening medications. Tympanostomy tubes often fail to control patient symptoms. A novel surgical technique for the treatment of patulous eustachian tube refractory to medical management has been developed and involves augmenting the anteromedial eustachian tube orifice with cartilage or alloplastic materials.

Semicircular canal dehiscence syndrome can also present with autophony, aural fullness, and commonly conductive hearing loss. Patients with superior semicircular canal dehiscence syndrome will not have autophony to respirations. There will be absence of excursions of the tympanic membrane with nasal breathing during autophony.

Joseph E. Kerschner, MD

The Problem of Otitis Media

The late Sylvan Stool, MD, aptly summarized the area of otitis with the term “Otitis media (OM) with confusion.” While intensive clinical and basic studies have begun to clarify this common disease, many areas of controversy remain. These areas include the following: Do patients with acute otitis media (AOM) require antibiotic therapy? Does chronic OM adversely impact development of speech and language? and When should surgical intervention be considered? The treatment of otorrhea is controversial, and the relationship between allergy and OM is completely muddled. There is a fundamental disagreement as to whether chronic OM is primarily an inflammatory or an infectious process. The terminology is not standardized, and the accuracy of diagnosis in the hands of primary care providers is around 50%. This chapter will highlight these areas of controversy, while attempting to provide the practitioner with practical guidelines regarding the management of patients OM and middle-ear (ME) effusions.

OM is a worldwide pediatric healthcare problem. OM is the most common reason that an ill child visits a physician in the United States. Children from age 6 months to 2 years are most commonly affected, and almost all children will have an episode of OM by age 3 years, with over half having three or more episodes. The incidence of OM increased 250% from 1975 to 1990, an increase attributable to improved diagnostic efficacy, the increased number of children in daycare and, perhaps, the increased prevalence of allergic children. The American Academy of Pediatrics states that over 5 million AOM cases occur annually in US children, with about 30 million annual visits to healthcare providers.

OM is the most common indication for prescribing antibiotics, which results in more than 10 million annual antibiotic prescriptions representing 25% of all antibiotic prescriptions. Fifty percent of antibiotics for preschoolers in the United States are prescribed for ear infections. The overprescription of antibiotics is considered a major driver of the development of antibiotic resistance and there is a great concern regarding the overprescribing of antibiotics. The combination of multiple independent antibiotic selective pressures, together with the high rates of transmission within the daycare population generates an environment which is conducive to the development of multiple drug-resistant bacteria.

Surgical management of OM is the most common reason to administer a general anesthetic to a child. Treatment of OM costs over 5 billion dollars a year in the United States. While the majority of cases of OM are self-limited, OM can result in hearing loss, language delay, or serious extracranial or intracranial complications. Thus, there exist important public health reasons to develop alternate antineffective strategies, that is, vaccines, which can be used to combat ME pathogens.

There is little consensus concerning risk-benefit ratios of available medical and surgical treatments. Legitimate concerns regarding the overprescription of antibiotics have led to a bias for beneficial societal outcomes, that is, reduction of antimicrobial-resistant microorganisms, at the expense of the individual patient and family. Studies that evaluate treatment strategies use limited outcome measures and often fail to include important considerations, including the pain and suffering of the sick child, the role OM plays in limiting women’s participation in the workforce, loss of wages as the result of caring for a sick child, parental distress and familial disruption, the disproportional adverse impact on lower socioeconomic and minority populations, the likelihood of long-term consequences of OM, and even the potential for decreased lifetime earning potential of a child with cognitive delays associated with prolonged, inadequately treated OM.

OM is the most common cause of acquired hearing loss in the pediatric population. The role of OM, and the associated hearing loss, in adversely impacting speech and language development, school performance, psychosocial development, and cognitive ability has been the focus of intense study, resulting in over 100 publications. While the results of these studies have been mixed, it is clear that the adverse impact is disproportionately large for children with developmental delay, special populations, or children with existing hearing loss not due to OM. There is a school of thought that the risk of cognitive and functional damage is not as great as previously believed. Unfortunately, these beliefs have translated into a more nihilistic approach to the treatment of OM, without much thought being given to the impact on the child’s overall well-being. Fortunately, a growing number of researchers are evaluating the impact of OM on the overall health and well-being of the child, rather than taking a more proscribed course.

Studies indicate that children with chronic OM have significantly decreased quality of life (QOL) scores when compared with unaffected controls.

The epidemiology, pathophysiology, treatment, and impact of OM have been widely studied, but several fundamental issues challenge almost every effort in each of these areas (Table 1).

Chile, Iran, Egypt, and Central Europe, with some of the skulls over 8,000 years old. Hippocrates described the disease in 450 BC.

Treatments for OM have been known since Byzantine times, and included herbs, animal and mineral substances applied as eardrops or poultices. Ventilating the ME space has long been recognized as beneficial in the treatment of OM. Valsalva described the eponymous maneuver in 1704, and Toynbee’s realization that eustachian tube (ET) dysfunction was associated with negative ME pressure and hearing loss led to efforts to aerate the ME actively via the ET, generally with catheterization of the ET. Politzer’s method of insufflation of the ME through the ET with the Politzer bag without the use of a catheter was a great advance.

Tympanocentesis as a treatment for OM came about when Jean Riolan the Younger inadvertently punctured a patient’s tympanic membrane (TM) while attempting to clean the canal, which fortunately resulted in the patient’s hearing improving. Given the recognition of the spontaneous healing tendencies of the TM, many techniques were devised to obtain a more permanent opening. A wide variety of materials, including catgut, whalebone rods, and gold foil were placed into the TM in efforts to maintain patency. Unfortunately, TM perforation was performed indiscriminately by unprincipled and inexpert practitioners and fell into disfavor for decades. Tympanocentesis was reintroduced by Schwartz, the director of the 25-bed Königliche Universitäts-Ohrklinik (the Royal University Ear Clinic) in Halle, and Armstrong popularized the use of ear tubes in the twentieth century.

Nasopharyngeal irradiation has been used to reduce hypertrophied lymphoid tissue, with the goal of treating ET dysfunction or OM in groups as disparate as military aviators, submariners, and children. A ferry World War II, nasopharyngeal irradiation became a popular treatment for pediatric hearing loss and chronic ear infections. Estimates of the number of children treated range from 500,000 to 2.5 million. This treatment modality is no longer used given the potential for the development of malignancies.

DEFINITIONS, ETIOLOGY, AND PATHOGENESIS OF OM

Confusion regarding terminology continues, and care must be taken to strike a balance between differentiating among clinically significant diagnoses and splintering the diagnoses into numerous varieties with insignificant differences. OM is best thought of as representing a continuum of disease states, all characterized by the accumulation of fluid in the ME space. OM can be broadly divided into three major types: (1) AOM, a purulent effusion with constitutional symptoms such as fever or pain; (2) OM with effusion (OME), the presence of fluid in the ME in the absence of constitutional symptoms other than hearing loss or balance problems; and (3) chronic suppurative OM (CSOM), drainage (otorrhea) through a perforated TM or tympanostomy tube (TT). AOM and OM are interrelated, in that most episodes of OME are preceded by an episode of AOM. In both AOM and OME, ME effusion is present, which may be serous, a thin, watery liquid, mucoid, a thick, viscous, mucus-like liquid, or purulent.

The most likely cause of OME is a sequence of events: acute OM is initiated by a viral infection which damages the ciliated mucosa of the upper respiratory tract and permits pathogenic bacteria to invade the ME space through retrograde movement from the nasopharynx through the ET. These bacteria elicit potent inflammatory responses from the ME mucosa as well as infiltrating leukocytes. Compromise of the ET is a major component of OM. The ET ventilates the ME by equilibrating the pressure between the ME space and the nasopharynx, drains the ME of secretions, and protects the ME from excessive sound pressure and reflex of secretions. ME effusions can result from nasopharyngeal secretions entering the ME space and can also result from inadequate ventilation of the ME. ME underpressures can lead to the development of effusions, that is, the hydrops ex vacuo theory. The relatively horizontal positioning of the ET in the young child’s skull base is thought to increase the child’s susceptibility to reflex of secretions from the nasopharynx into the ME cleft.

OME generally takes place in young children with a relatively immature immune system. This lack of development in this patient population, coupled with anatomic disadvantages in the developing ET explains the susceptibility of young children to OM. In older children selective IgG2 and IgG4 subclass deficiencies can predispose to repeated episodes of OM, and patients with persistent OM should be evaluated for deficits in immunoregulatory function.

A variety of viruses can be isolated from ME effusions, including rhinovirus, respiratory syncytial virus, influenza virus, adenovirus, parainfluenza virus, and enterovirus. The major role of viruses in OM appears to be setting the stage for a subsequent bacterial infection. Viruses can invade the ME space, generating an inflammatory response, which results in effusion. Viruses also compromise the ET’s ability to protect the ME by impairing mucociliary clearance and, in addition, enhance bacterial adherence and provoke the production of inflammatory mediators. It is not clear that viruses alone can cause AOM, and studies that rely solely on viral culture techniques have presented an incomplete picture. Not surprisingly, it is clear that the use of nucleic amplification techniques greatly enhances the yield of bacterial identification in ME effusions. Using culture, antigen detection and nucleic acid amplification, a co-infection with bacteria and viruses can be found in almost all cases of OM. Increased exposure to viral and bacterial pathogens is felt to be the reason that daycare attendance increases a child’s risk of developing OME.

AOM elicits potent inflammatory responses from the cells of the ME mucosa as well as from infiltrating leukocytes. These mediators have a wealth of inter-related biological effects and play an active role in ME inflammation. Inflammatory mediators can impair mucociliary clearance, produce fever, increase bacterial adherence, activate leukocytes, and regulate antibody formation. A large number of inflammatory mediators have been studied in association with AOM, including prostaglandins, and cytokines such as interleukin (IL)-1beta, IL-6, and IL-8, IL-10, and tumor necrosis factor alpha (TNF-alpha). Local inflammatory mediators such as inflammatory cells, lysozymes, and oxidative metabolic products, also play a role. Chapter 3, “Molecular Biology of Hearing and Balance,” contains a broader discussion of the molecular biology of OM.

While allergic events, may lead to congestion, there is no convincing evidence that upper respiratory allergies are a primary etiologic event in the development of OM. Allergies can lead to nasal congestion and obstruction and ET edema and dysfunction, with resulting negative pressure in the ME and compromised ventilation of the ME space. Inflammatory mediators can be released by mucosal mast cells following the interaction of antigen and specific IgE antibody, resulting in ET obstruction and subsequent transudation of fluid into the ME space.

Microbiology of AOM

Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis are the predominant bacterial species isolated from the effusions of AOM. Other pathogens that are isolated from AOM effusions include group A Streptococcus and Staphylococcus aureus. Alloilococcus otitidis is a bacterium that is being isolated from effusions of AOM and OME with increasing frequency. Alloilococcus otitidis is most readily identified by the polymerase chain reaction, as it grows poorly in culture. While the role of this bacterium in otitis is unclear, a recent report that specific ME immune responses are induced suggests that the microorganism may be a true pathogen. Young infants can have gram-negative enteric microorganisms such as Escherichia coli, Klebsiella, and Enterobacter species, and Pseudomonas aeruginosa. M. microorganisms that are rarely involved in OM include Mycoplasma pneumoniae, Chlamydia trachomatis, Corynebacterium diphtheriae, Mycobacterium tuberculosis, nontuberculous Mycobacteria, and Clostridium tetani.

Microbiology of Chronic OME

OME has historically been considered to be an inflammatory process, as only 30% of effusions were positive for bacteria by culture using standard techniques. Over the past decade, there has been a growing body of evidence that “no growth” by culture does not equate with “absence of microorganism.” Using nucleic acid amplification strategies, it has been shown that the majority of “sterile” ME effusions actually contain DNA and messenger RNA from the three major pathogens of OM, as well as A. otitidis. These findings led to the advancement of the mucosal biofilm
paradigm, which postulates that chronic OME is due to the persistence of a bacteria biofilm on the ME mucosa. A recent report has demonstrated the presence of mucosal biofilms with confocal laser scanning microscopy in the vast majority of OME and recurrent OM ME mucosa biopsy specimens, while no biofilms were found in control specimens.6

Epidemiology

Understanding the epidemiology of OM serves as a foundation to help the clinician in making good management decisions, particularly surgical decisions, for the individual child. Consequently, the epidemiology of OM has been the focus of much investigatory effort. Despite the difficulties in OM research mentioned previously, considerable progress has been made, providing information that allows clinicians to help families identify mutable risk factors and assist with changing or ameliorating these risk behaviors. Clearly, the clinician would be more apt to intervene surgically in a child who had the first episode of OM at age 3 months, spends 40 hrs a week in daycare, and has significant hearing loss with language delay (Table 2).

DIAGNOSIS OF OM

As a group, otolaryngologists–head and neck surgeons are more accurate in the diagnosis when compared to pediatricians and general practitioners. Using video-recorded otoscopic examinations, including pneumatic otoscopy of the TM, to ascertain the ability to differentiate among AOM, OME, and normal, pediatricians and general practitioners made the correct diagnosis only half the time.7 Pediatric residents perform even more poorly. Given the recent trend toward withholding antibiotics, it is imperative that better diagnostic acumen be developed.8 A cloudy, bulging or clearly immobile TM are some of the most useful signs for diagnosing acute OM, and a distinctly red TM increases the likelihood of OM significantly.9 Tympanometry, acoustic reflectometry, and selective use of tympanocentesis can be helpful in establishing the diagnosis and guiding therapy in refractory cases.

History

The diagnosis of OM is frequently not as straightforward as might be thought. The history is generally obtained, not from the patient, but from the caregiver, the symptoms of fever and irritability are neither sensitive nor specific, the physical examination can be hampered by cerumen occluding the external auditory canal, and the patient is often uncooperative. An upper respiratory infection may precede the onset of OM. Signs and symptoms include fever, ear pain, irritability, inconsolable crying, changes in eating or sleeping habits, malaise, vomiting and diarrhea, and occasionally tugging at the ear. A recent meta-analysis demonstrated that ear pain is the most useful symptom, while fever, upper respiratory tract symptoms, and irritability were less specific. The older child may note fullness in the ear as well as decreased hearing in the affected ear. Children with OME are generally asymptomatic except for hearing loss or problems with balance.

Physical Examination

It is time well spent to gain the trust of the child before proceeding with the examination. Ensure that you have washed your hands; not only is this good infectious disease practice, but warm hands will elicit less of a response from an apprehensive child. Rest assured that the caregiver takes note if you do not wash your hands. Correct

*Note that understanding these aspects of the OM epidemiology suggest strategies to reduce or prevent OM: breastfeeding, avoidance of upper respiratory infections, avoidance of tobacco smoke, and vaccination with a pneumococcal vaccine. The most important sociodemographic risk factors for otitis media appear to be low socioeconomic status and repeated exposure to large numbers of other children. Other epidemiological aspects, including gender, race, pacifier use, and feeding practices, are less clear.
positioning of the child is essential. Most children can be easily examined if they are held in the caregiver’s lap, with the child’s back against the caregiver’s front. Instruct the caregiver to hold the child’s arms and body with one arm, and the turned head with the other. Holding the child’s feet between the caregiver’s knees provides an extra margin of safety for the examiner. Conversely, infants can be placed in the prone position on the examining table. Have an assistant hold the infant’s arms extended on each side of the head, parallel to the long axis of the body, this way one person can hold both the infant’s head and arms simultaneously. If the child is small, the examiner can hold the child’s body secure by gently leaning on the child’s torso and hips. Occasionally, a third restrainer is necessary. The use of a papoose or other restraining device becomes less frequent with experience. Cerumen can be cleaned from the external canal by use of a curette, or by lavage, if you are certain that the TM is intact. Most cerumen impactions are the result of misguided parental efforts to clean the external auditory canal with cotton swabs, displacing the wax medially.

Examination of the TM. The most common method for diagnosing OM is examination of the TM with an otoscope. Otoscopes are of two basic types, surgical or operating and diagnostic. Surgical otoscopes have a moveable lens that allows access to the external auditory canal. This type of otoscope allows for cerumen removal using a curette, and for tympanocentesis. The diagnostic otoscope has a lens and light source enclosed in a larger head and has an attached tubing and rubber bulb for the performance of pneumatic otoscopy. This type of otoscope provides for an airtight seal when the speculum is placed into the external auditory canal. Care must be taken not to place the speculum too deeply into the canal, to avoid causing the child pain. If a satisfactory seal cannot be obtained, the use of a rubber-tipped speculum or sheathing the tip of the speculum with a sleeve of rubber tubing can help.

A normal TM is translucent, with the observer able to distinguish the short and long processes of the malleus and occasionally the incus. The TM may be the observer may note either air-fluid levels or nonerythematous, unless the child is crying. Air bubbles deep to the TM. The TM may be the observer should look for abnormalities of color, translucency, contour, and mobility. Thus, the TM may appear erythematous, whitish, or yellow. The drumhead may be opaque or bulging. Purulent otitis media is indicative of a TM that ruptured as the result of AOM. In OME, the observer may note either air-fluid levels or air bubbles deep to the TM. The TM may be retracted, and the TM will be dull gray or amber, and nonerythematous, unless the child is crying.

Common sources of error in diagnosis include mistakes an erythematous TM due to the child’s crying for an infection, failure to perform insufflation, failure to perform insufflation correctly, pumping the bulb of the pneumatic otoscope as though the observer were trying to inflate a truck tire is contraindicated, and failure to restrain the uncooperative patient adequately.

An assessment of the TM mobility by pneumatic otoscopy will greatly enhance the accuracy of diagnosis. To perform pneumatic otoscopy, hold the otoscope in one hand with the bulb under your thumb and rest your hand against the child’s head, so that if the child moves, the tip of the speculum does not lacerate the ear canal. Using the other hand to steady the child’s head, ensure that a seal is achieved between the tip of the speculum and the external auditory canal. Gently squeeze the bulb with your thumb. As the bulb is alternately squeezed gently and released, the response of the TM to both positive and negative pressure can be assessed. A normal TM will readily move medially in response to positive pressure, and laterally in response to negative pressure. If an effusion is present, the TM movement will be dampened.

While complete immobility almost guarantees the diagnosis of otitis, in the absence of a TM perforation, decreased mobility is a more common finding. Unfortunately the technique is operator-dependent and is often not used by pediatricians or general practitioners. Diagnostic accuracy is improved with a structured approach to teaching otoscopy and by validating clinicians either with myringotomy or videotaped otoscopy examinations.

Tympanometry is an objective measurement of the compliance of the TM and is analogous to TM mobility during pneumatic otoscopy. Tympanometry can be a useful adjunct in the diagnosis of otitis but cannot distinguish between AOM and OME. Tympanometry is a simple, rapid, non-invasive test that provides information about TM compliance in electroacoustic terms, using a tympanometer. A known sound pressure is applied in a sealed volume between the external auditory canal and the TM, and the air pressure in the ear canal is varied above and below atmospheric pressure. The TM reflects the sound pressure, and the tympanometer measures the energy of the reflected sound signal at these different pressures. The mobility of the TM is maximal when air pressures are equal medially and laterally. In the normal condition, the air pressure on each side of the TM is already equalized via the ET, and the TM mobility (compliance) will be at its maximum when the tympanometer provides no change in pressure to the external auditory canal (0 decapascal pressure). If the ME has an effusion, the TM mobility is dampened, and the compliance will be decreased. If the ME has negative pressure, the compliance will be greatest when the tympanometer provides no change in pressure to the external auditory canal (0 decapascal pressure). If the ME has an effusion, the TM mobility is dampened, and the compliance will be decreased. If the ME has negative pressure, the compliance will be greatest when the tympanometer provides no change in pressure to the external auditory canal (0 decapascal pressure). If the ME has an effusion, the TM mobility is dampened, and the compliance will be decreased.

Tympanograms are generally classified into one of three categories: Type A, a normal curve characterized by a steep gradient, with a sharp peak. Type B, a flat tracing that indicates decreased TM compliance across a broad range of air pressures. The most common reason for a Type B tracing with a "normal" volume is ME effusion. A Type B tracing with a "large" volume indicates a TM perforation or patent ear tube. Normal volume for a child is around 1 mL. Type C indicates significant negative pressure in the ME space, which correlates with a retracted TM. A type C tympanogram is suggestive of impaired ventilatory function of the ET and may indicate a transition between a normal ear and an ear with a ME effusion. Overall, a Type C tympanogram is relatively nonspecific.

Tympanometry is not as accurate in infants (6 months of age and younger), as the skin and cartilage in the external auditory canal are quite lax and will move in response to changing air pressure (producing a Type A tympanogram), even though the ME may have an ME effusion.

Future Diagnostic Modalities. A variety of new technologies are being investigated to determine their role in the diagnosis of otitis. A-mode ultrasonography has been used to detect ME effusion. In one preliminary study, ultrasound identified the presence or absence of effusion in 96% of cases and could distinguish between serous and mucoid effusions with 100% accuracy. However, it could not distinguish between mucoid and purulent effusion.

MEDICAL MANAGEMENT OF OM

The treatment of OM continues to undergo transformation. From the days of unbridled antibiotic use for acute disease and month after month of "treatment" for OME, there is an increasing emphasis on a more nuanced approach, with a decreased reliance on antibiotic use in uncomplicated OM and an increased emphasis on the clinical setting rather than a "one-drug-fits-all" approach. The decreased emphasis on antibiotics is directly related to the increasing rates of bacterial antimicrobial resistance, particularly in young children attending daycare.

Guidelines have been developed by the American Academy of Pediatrics and the American Academy of Family Physicians to help the clinician choose the appropriate course of action. The Institute of Medicine defines guidelines as "systematically developed statements to assist practitioners and patient decisions about appropriate healthcare for specific clinical circumstances." The goals of the OM guidelines are to promote the judicious use of antibiotics in an effort to protect their therapeutic advantage. It is also thought that several million antibiotic prescriptions can be avoided annually by the use of guidelines. While these guidelines are helpful, they tend to be narrowly drawn and couched with disclaimers and leave great latitude in the practice pattern of the individual physician (Table 3).
Several considerations argue against the withholding of antibiotics from children with AOM: (1) children will resolve their symptoms more quickly with antimicrobial treatment; (2) antimicrobial treatment reduces the number of suppurative complications and withholding antibiotics can lead to an increase in suppurative complications (Table 4); (3) primary care physicians lack diagnostic precision and follow-up may be variable; (4) multiple follow-up visits are not possible for many families; (5) leaving the final decision to administer antibiotics in the hands of lay people is an abdication of the responsibilities of the physician; and (6) in today’s medico-legal climate, the onus of responsibility for a child developing a devastating complication as the result of an easily treatable disease may fall directly on the individual physician.

### Bacterial Resistance

Bacteria have evolved multiple mechanisms to develop resistance to antimicrobial agents, including reducing antibiotic penetration through the bacterial membrane, metabolic bypass, active efflux pumps to eliminate antibiotics from the bacteria, inactivation of antibiotics by specific enzymes, for example, beta-lactamase, and alteration of the antibacterial target site. Bacteria can develop antibiotic resistance via nucleic acid mutation, bacterial generations are measured in minutes, or horizontal transfer of genetic material occurs via plasmids or transposons. Bacterial biofilms also provide phenotypic resistance to antibiotics, and enhance nucleic acid transfer among bacteria.

In the United States, approximately 40% of strains of nontypable H. influenzae and almost all strains of M. catarrhalis are resistant to amoxicillin because of the production of beta-lactamase, or less commonly, alterations in penicillin-binding proteins. This resistance can be overcome by the use of a beta-lactamase inhibitor, such as clavulanate, or by using a beta-lactamase-stable antibiotic. Approximately half of the strains of S. pneumoniae are penicillin-nonsusceptible, mediated by alterations in penicillin-binding proteins. This mechanism of resistance can be overcome by increased concentration of antibiotic. Selection of Antimicrobials for AOM

Studies have shown that antibiotic treatment of AOM shows a modest but significant impact on the disease, with earlier resolution and a reduction in the frequency of persistent disease and suppurative complications. Having said that, antibiotic use varies from 31% of patients in the Netherlands to 98% in the United States, although there are some indications that this percentage of patients receiving antibiotics for AOM in the United States is dropping. Given that tympanocentesis is generally not used in the management of uncomplicated AOM, the infectious agent in the individual case can only be surmised. Thus, the treatment of the vast majority of AOM episodes is empiric, based upon a historic knowledge of the major pathogens in AOM, that is, S. pneumoniae, H. influenzae, and M. catarrhalis, and their antimicrobial resistance patterns (Table 5). Other considerations include the clinical setting, tolerability, concentrations achieved in the ME, and cost. Compliance with antibiotic regimens is enhanced by selecting agents that require less frequent dosing, such as one or two times a day, and by prescribing shorter, 5 days or less, treatment courses, although shorter courses of antibiotics are still controversial.

A. amoxicillin remains the drug of choice for the treatment of uncomplicated OM. Limitations of amoxicillin include inactivation by the beta-lactamases, eg, nontypable H. influenzae and most strains of M. catarrhalis, and penicillin-resistant strains of S. pneumoniae. Indications for second-line medications include failure, or history of failure, to respond to amoxicillin, penicillin allergy or culture results indicating the presence of a resistant microorganism. A Therapeutic Working Group convened by the United States Centers for Disease Control and Prevention recommended that children who fail initial therapy with amoxicillin be treated with amoxicillin-clavulanate, cefuroxime axetil or intramuscular ceftriaxone, although there was criticism of the group’s methodology and conclusions. Tympanocentesis and culture can help guide effective therapy in recalcitrant cases. The follow-up interval for AOM should be individualized. Young patients and patients with continued pain should be seen within a few days, while 2 to 4 weeks may be adequate for older children. Parents should be educated that the presence of fluid in an asymptomatic child at the initial follow-up visit is not an indication for additional antibiotic treatment.

A number of other antibiotics that have been used in the past for the treatment of AOM. These include trimethoprim sulfa, clarithromycin, cefalexin, cefaclor, erythromycin ethylsuccinate and sulfisoxazole acetil, and azithromycin, all of which have fallen out of favor due to high rates of antimicrobial resistance in common OM pathogens. The use of macrolides should be avoided in the treatment of OM. A variety of other treatments have been tried in the past, including decongestants, antihistamines, prostaglandin inhibitors, corticosteroids, and various methods of ME insufflation, however good evidence for efficacy is lacking. Although there is likely some small advantage, antibiotic treatment is no longer recommended in resolving OME.

### Table 3 Guidelines on the Management of Acute Otitis Media from the American Academy of Pediatrics and the American Academy of Family Physicians

<table>
<thead>
<tr>
<th>Points to Consider</th>
</tr>
</thead>
<tbody>
<tr>
<td>To reliably diagnose acute otitis media, the physician should confirm a history of abrupt onset (&lt;48 h) of middle-ear effusion and inflammation.</td>
</tr>
<tr>
<td>The management of acute otitis media should include assessment of pain. If pain is present, the clinician should provide treatment to reduce it, eg, acetaminophen or ibuprofen.</td>
</tr>
<tr>
<td>Observation without antibiotics is an appropriate option for selected children with uncomplicated acute otitis media based on diagnostic certainty, age, severity of illness, and certainty of follow-up.</td>
</tr>
<tr>
<td>If the decision is made to treat with an antibiotic, amoxicillin remains the initial antibiotic of choice for most children.</td>
</tr>
<tr>
<td>Lack of response within 48–72 h requires reassessment to confirm acute otitis media. If confirmed in a child initially managed with observation, an antibiotic should be prescribed. If initial management was with an antibiotic, an alternative antibiotic should be prescribed.</td>
</tr>
<tr>
<td>Physicians should encourage acute otitis media prevention through reduction of risk factors.</td>
</tr>
</tbody>
</table>

*The guidelines are limited to otherwise healthy children from 2 months to 12 years of age, who have not had a recurrence of acute otitis media within 30 days or AOM with underlying chronic otitis media with effusion. The diagnosis of AOM should include recent onset of illness, presence of middle-ear effusion, and signs or symptoms of middle-ear inflammation. A antibiotics should be used for children age six months or younger, or for older children with severe symptoms, generally defined as temperature greater than 39° with severe otalgia. Note that the key to success of these guidelines is accuracy in diagnosis, particularly the use of pneumatic otoscopy and close follow-up of the child.

### Table 4 The Use of Antibiotics for the Treatment of Acute Otitis Media Markedly Reduced the Incidence of Suppurative Complications

<table>
<thead>
<tr>
<th>Points to Consider</th>
</tr>
</thead>
<tbody>
<tr>
<td>Historically, acute otitis media has had a high complication rate, major morbidity, and frequent mortality.</td>

A. 213
at the time of their tube placement. This post-operative otorrhea is not uncommon after the tympanic antibiotics may be beneficial. Postoperative fungal infection, and occasionally systemic antibiotic drops alone. In refractory cases, Otorrhea is generally well treated with ototoxic drops. Pathogens associated with acute otitis media are those associated with AOM, particularly in younger children, while Pseudomonas spp. are more common in older children. Chronic otitis media is more commonly associated with Pseudomonas spp. and Staphylococcus aureus. Medical treatment, including topical medications, systemic antibiotics, and aural toilet is generally adequate. However, mastoidectomy should be considered in refractory cases or if a cholesteatoma is present. Repair of chronic perforations should be performed once the infectious process has been resolved.

### Complementary and Alternative Medicine Treatments of OM

Our society is increasingly interested in complementary and alternative medicine (CAM) treatments for medical conditions, and OM is no exception. Given the propensity of otitis to spontaneously resolve, these treatments may appear to be successful, however, well-designed studies demonstrating efficacy are few in number, and the results are inconclusive. Homeopathy, chiropractic manipulation, acupuncture, Qigong, that is, an ancient Chinese breathing exercise with meditation, and a large number of herbs have been recommended for OM, including garlic and Sai-rei-to, that is, a herb used in Kampo or Japanese herbal medicine. Herbal eardrops include calendula (marigold flowers), St John’s wort, mullein flower, and garlic, while Echinacea is widely believed to alleviate upper respiratory symptoms, despite several studies to the contrary. Dietary manipulations include adding foods rich in antioxidants and omega-3 fatty acids. Probiotics such as lactobacillus and xylitol, a sugar alcohol, that may interfere with bacterial adherence have been advocated, and may actually be of value in reducing bacterial adherence to mucosa.

### Vaccine Strategies

Otolaryngology has a history of diseases vanquished by vaccination, including diphtheria and epiglottis, as two examples. It is hoped that OM will one day be added to this list. A diminution of the pneumococcal conjugate vaccine results in a fairly substantial reduction in OM secondary to the included serotypes, and a more modest reduction in total episodes of OM. Use of the pneumococcal vaccination has now made H. influenzae the most frequently isolated bacteria in AOM. It is likely that the frequency of nonvaccine serotypes being isolated from children with OM will increase. Development of effective vaccinations against nontypable H. influenzae and M. catarrhalis have proven more challenging. Viral vaccinations may prove useful in the prevention of OM, particularly against respiratory syncytial virus (RSV), influenza virus, and parainfluenza virus.
SURGICAL MANAGEMENT OF OM

Patient Selection

The surgical treatment of OM can be extremely efficacious in patients refractory to medical management. Using a validated instrument, children with OME or recurrent OM had improvement in their QOL after placement of TT.12 Surgery offers a treatment pathway for the child that does not contribute to the emergence of antibiotic-resistant bacteria.13 Parents overwhelmingly perceive that their child’s health has improved after the placement of tubes and are satisfied with the results of the operation.20 To the extent possible, clinicians may have relatively asymptomatic disease and allergies to antibiotic therapy, craniofacial structural changes, including persistent perforations, the greatest risk to the child revolves around the risk of general anesthesia. Otolaryngologists should have a low threshold for performing myringotomy in immunologically compromised children or as a part of a septic workup in infants. Myringotomy alone as a treatment for OM is not effective, as the myringotomy site will rapidly close.

Myringotomy with TT Placement

Myringotomy with TT placement is the most common operation performed on children requiring general anesthesia in the United States. In one study, almost 7% of US children had tubes inserted by age 3 years.21 Indications for tubes include chronic OME, recurrent AOM, ET dysfunction, and persistent TM retraction pockets. Tubes are also used to ensure adequate drainage in the treatment of supplicative complications of OM. With careful patient selection, the placement of tubes can be expected to resolve conductive hearing loss due to fluid, treat the balance disorders associated with OM, reduce the frequency, severity and duration of OM episodes, and reduce the incidence of long-term sequelae of chronic ear disease. The greatest risk to the child revolves around the risk of general anesthesia. Other factors to weigh include the cost and chronic TM changes, including persistent perforations, the percentage of which is low.

The timing to placement of TT for patients with chronic OME and recurrent OM will be affected by a number of factors. These include risk factors for OM, family history, tolerance or allergies to antibiotic therapy, craniofacial structure, underlying hearing loss, and associated developmental status. In OME, some patients may have relatively asymptomatic disease and can be monitored for a period of time with close follow-up to assess for development concerning anatomic abnormalities, that is, retraction pocket, TM adhesion, cholesteatoma, or hearing loss. In patients with OME, hearing loss frequently develops, and even small levels of persistent bilateral hearing loss has the potential to impact negatively patient development, especially those with underlying developmental concerns or speech delay. Interestingly, most studies which have demonstrated a smaller impact of OME on development have specifically excluded patients with underlying developmental or anatomic considerations or socioeconomic disadvantages and have focused on patient populations with less severe disease such as unilateral OME.22 Patients who tend to be referred to otolaryngologists—head and neck surgeons for consideration of TT placement often have more severe disease as well as considerations related to development and language. There has been a great deal of interest in performing the myringotomy with various lasers, including the carbon dioxide and ND-Yag lasers. A laser myringotomy can provide relatively short-term ventilation of ME space. Proponents tout the advantage of performing the laser myringotomy with a local anesthetic in the office setting without general anesthesia, thus reducing the risk and cost of the procedure. Variable success of disease resolution and family satisfaction seem to have limited the appeal of this procedure. There is no evident clinical benefit to using the laser to perform a myringotomy and then placing a tube. Additional indication for laser myringotomy include elimination of ME fluid before auditory testing, barotraumas, ET construction, or tympanocentesis to obtain a culture of ME fluid.

Adenoidectomy

There is good evidence that adenoidectomy is an effective treatment for recurrent or persistent OM. A adenoidectomy should not be chosen as the initial surgical treatment for OM until there are clear indications, such as persistent nasal obstruction or chronic adenoiditis. Most otolaryngologists—head and neck surgeons will recommend an adenoidectomy if a second set of TT is needed. A adenoidectomy is thought to be effective either by improving ET function or by removing a reservoir for bacteria. Recent work demonstrating the presence of bacterial biofilms in the adenoid lends credence to the latter.

COMPLICATIONS OF OM

Impact of OM on Language Development

A child’s language development is a wonderfully complex interweave of genetic and environmental factors. The impact of OM, or more precisely the hearing loss associated with OM, on a child’s development has been the subject of intense investigation and passionate debate for years. While it is clear that language development can be hindered by moderate or profound hearing loss, or by lesser degrees of loss that are permanent, the exact impact of mild or fluctuating hearing loss on language development remains unclear. The average hearing loss associated with OM is 15 to 50 dB between 500 and 4,000 Hz, which are the most important frequencies for speech reception. There are many challenges to research in this area, including accuracy of diagnosis, determination of outcome measurements of language and cognition, influence of gender, and short-term duration of follow-up. Controlling for other influences of language development, including a nonnurturing environment and cognitive deficits, is difficult. The effects of intermittent hearing loss associated with OM may be subtle and long term. Deleterious effects on phonological representations and working memory have been noted, along with degradation of communicative skills, particularly in a noisy background. A long-term study of over 1,000 children from the United Kingdom demonstrated that the developmental sequelae of OM remained significant for a decade.

Other complications of OME include dizziness, clumsiness, and balance problems which generally improve with the insertion of tubes. Children with bilateral OM did poorly compared to controls on the Peabody Developmental Motor Scales, which tests balance and locomotion skills. There is also an association between OM and learning disabilities.

Children with cleft palate, mental retardation, educational difficulties, or underlying sensorineural hearing loss are particularly at risk for the adverse effects of OM on language and social development. Children with Down syndrome and cleft palate benefit from aggressive management of their ear disease, but families should be counseled that they will have more episodes of otosrhea with tubes.

Central auditory processing disorder (CAPD) is an auditory-specific perceptual deficit located in the higher auditory pathways that underlies many learning problems in school-age children. CAPD cannot be identified by standard audiometric evaluations, and diagnosis requires specific tests employing temporal and frequency distortion and dichotic challenges. The conductive loss associated with OME may play a role in the development of CAPD.

Given our current inability to identify the child with the potential for long-term problems, the prudent clinician will ensure that a child with a prolonged history of OM is evaluated for hearing acuity and will have a high degree of suspicion regarding language delay. Speech and language intervention should be considered once the hearing loss has been corrected. Conversely, children with language or speech problems should be evaluated for OM and aggressively managed. Children from lower socioeconomic backgrounds or with mothers with marginal communication skills are at particular risk.

Additional complications of OM are considered in Chapter 17, “Chronic Otitis Media and
RESEARCH DIRECTIONS IN OM

As outlined in this chapter, there are many aspects of OM that are incompletely understood. Challenges abound in diagnosis, treatment, and management. Controversies exist in the timing of intervention or even the need for intervention at all. The basic pathophysiology is beginning to be understood, but there is a great deal of work to be done.

Animal Models of OM

A variety of animal models have been developed to investigate various aspects of OM, including the chinchilla, rat, guinea pig, gerbil, cat, ferret, and cynomolgus (Macaca fascicularis), and rhesus monkeys. While there is no one perfect animal model of OM, these models are often used for focused investigations and sequential observations. The chinchilla’s suitability to OM research has made it perhaps the most widely used animal model for this disease although its wide palatal ET makes it a poor choice for ET studies. The gerbil is an important model for the study of cholesteatoma. The rat is a useful model for secretory OM in studies investigating the role of allergy in OM, and in vaccines trials while its high incidence of naturally occurring OM mandates that results be interpreted with caution. The guinea pig is useful in studying immune-mediated OM, while the cat is used to study ET function and ME changes secondary to OM. Monkeys are excellent models for studying ET function, with rhesus monkeys useful in studying gas absorption process in the ME cavity and the cynomolgus monkey used to study chronic supplicative OM. The ferret’s susceptibility to influenza A virus and the close similarity of its ET function to that of the human make a good model to study the relationship of upper respiratory infections and ET dysfunction.

Genetics of OM

The fact that almost every child will have an episode of OM was taken by most observers to indicate that there was not a genetic predisposition to the development of the disease. However, the broad recognition that susceptibility to infectious disease can be genetically determined along with OM-specific evidence from twin studies, particularly the landmark Casselbrant and colleagues studies, as well as epidemiological, immunological, and animal studies, have led to the recognition that susceptibility to OM is, at least in part, determined by the genetics of the host. The identification of susceptibility genes will help identify children at increased risk, will provide a clearer understanding of the pathophysiology, and inform new treatment modalities.

Some of the challenges of identifying the OM genes include: (1) It is most likely that numerous genes influence the development of OM, that is, there is not one “OM gene;” (2) multi-generational families with clear diagnoses of OM are not common; and (3) there is likely a high degree of heterogeneity in phenotypes, particularly among various population groups. Despite these challenges, several factors work in the investigators’ favor: (1) no a priori knowledge of specific susceptibility genes or inheritance patterns is necessary; (2) the human genome sequence is known; (3) genetic markers such as single nucleotide polymorphisms are available; and (4) multiple small families, rather than a few large families, can be used for mapping.

Relationship Between the Host and Bacteria

The relationship between infectious agents and the host is a complex one. The nasopharynx of children is colonized by bacteria that can interact in both an antagonistic and synergistic fashion by a variety of mechanisms, including the production of bacteriocins (a protein toxin produced and released by bacteria that inhibits the growth of similar bacteria). These interactions help maintain balance in the normal endogenous flora. Many children tolerate colonization of the nasopharynx with S. pneumoniae, H. influenzae, or M. catarrhalis without developing OM. How these bacteria change from colonizers to pathogens is poorly understood, but the changes appear to be triggered by viral infections. Preferential colonization of the nasopharynx with microorganisms that have interfering capability, such as alpha-haemolytic streptococci, Peptostreptococcus anaerobius, and Prevotella melaninogenica, may help prevent the establishment of pathogenic bacteria in the nasopharynx.

In all, these current directions in OM research and an approach based on molecular and cellular techniques will not only provide a broader understanding of the pathogenesis of OM but also novel intervention strategies.

Chronic Otitis Media and Cholesteatoma

Richard A. Chole, MD, PhD
Robert Nason, MD

Otitis media (OM) is broadly defined as inflammation from any cause of the middle ear. This process may involve any of the contiguous pneumatized portions of the temporal bone such as the mastoid or petrous apex. In the United States, it is the most common reason for visits to the pediatrician and is the disease most commonly treated with antibiotics. Overall, healthcare costs related to OM account for approximately $4 billion annually.1

In light of this broad definition, OM is classified along a temporal continuum. A cute otitis media (AOM) refers to the rapid onset of middle ear inflammation with its attendant signs and symptoms; this process is termed recurrent AOM (RAOM) when four or more acute episodes occur in a one year period. If fluid accumulates behind an intact tympanic membrane (TM), this process is referred to as otitis media with effusion (OME), secretory otitis media, or “glue ear.” The etiology of OME is unclear, but evidence points to eustachian tube dysfunction (primary or secondary), viral infection, or inflammatory sequelae of AOM as probable causes. OME is defined as chronic should the effusion persist for more than 3 months. Chronic OME should be distinguished from “chronic otitis media” (COM). The latter term refers to intractable pathology of greater than 3 months duration within the middle-ear system in the setting of a permanent TM defect.

If persistent otorrhea is present, the term chronic suppurative otitis media (CSOM) is applied. TM defects include retraction pockets, atelectasis, and perforations secondary to infection, trauma, or surgery, for example, tympanostomy tubes. COM can be further subclassified into those cases with or without aural cholesteatoma. Cholesteatomas, the majority of which are complications of COM, are epidermal inclusion cysts within the pneumatized portions of the temporal bone. Cholesteatoma can be classified as either congenital or acquired with the latter variant being further divided into primary or secondary forms to be defined later in the chapter.

**Epidemiology and Risk Factors of COM**

OM is most common in the winter and least common in the summer months.1 Some studies have demonstrated male predominance while incidence rates of OM among white and black American children have shown no differences.2 Native American and Eskimo populations, however, do experience higher rates of OM. The highest incidence of AOM occurs in the 6- to 11-month age group with ~75% of all infants experiencing an episode by 12 months of age. Furthermore, those children who have their first episode of AOM before 12 months of age are significantly more likely to experience RAOM compared to those who do not. Despite prevalence rates of OME that approach 90% in some populations, studies have demonstrated that the vast majority of cases of AOM and OME resolve spontaneously and without sequelae.3

Epidemiological data on COM is elusive due to varying definitions by authors. In regard to CSOM, the highest prevalence rates are found in children of Alaskan Inuits, Native Americans, and Australian Aborigines (7 to 46%). Industrialized countries such as the United States and the United Kingdom boast rates of less than 1%.4 Sade and others demonstrated that only half of the 200 patients that they studied could remember an acutely painful ear associated with otorrhea; rather, 40% of patients noticed only a slow, gradual onset of otorrhea and possible hearing loss.5 This explained an average elapsed time of 10 years before disease onset and consultation with an otolaryngologist. Interestingly, one-third of these patients were found to have disease in the contralateral ear. In following 493 patients an average of 6.5 years after surgery for COM, Vartainen and others determined that only 37% of patients had structurally normal contralateral ears whereas only 64% of contralateral ears exhibited normal hearing.6 Tympanosclerosis and atrophy of the pars tensa were the most common physical findings in the contralateral ear. These findings underscore the morbidity and insidious nature of COM.

Risk factors for OM include mechanical obstruction of the eustachian tube (eg, sinusitis, adenoid hypertrophy, nasopharyngeal carcinoma), immunodeficiency (primary or acquired), ciliary dysfunction, congenital facial anomalies (eg, cleft palate, Down syndrome), and gastroesophageal reflux.1 Environmental factors such as number of hours spent in child daycare, passive exposure to smoke, lack of breastfeeding in infancy, and low socioeconomic status have all been implicated in higher OM rates.1 Significant risk factors for CSOM include history of RAOM, parents with histories of COM, and crowded daycare settings.6 No studies have established links between CSOM and breastfeeding, gender, or smoke exposure. Allergy has been implicated as a risk factor since some studies have demonstrated allergens to cause eustachian tube and nasal obstruction; however, middle-ear effusions were never seen to develop. Furthermore, studies involving antihistamines, directed at an allergic cause for OM, have failed to show any benefit in alleviating OME.2

Recent studies now highlight genetic predisposition to OM. Casselbrant and colleagues, in a prospective study of 168 sets of twins and 7 sets of triplets, have demonstrated a significantly higher correlation for proportion of time with middle-ear effusion in monozygotic twins compared to dizygotic twins.8 Furthermore, in patients suffering from RAOM due to Streptococcus pneumoniae, polymorphisms have recently been found in antibody receptors to certain IgG subclass molecules which inhibit leukocyte phagocytosis of antibody-coated bacteria.10 Failure to kill invading bacteria would permit both disease establishment and progression. Other studies point to polymorphisms in cytokine production as predisposing to OM. Respiratory syncytial virus (RSV) is commonly found in OME and AOM isolates and is regarded as a copathogenic factor in OM from the standpoint of specific eustachian tube dysfunction and generalized upper airway edema. In one study of 77 infants with RSV, Gentile and others demonstrated an association between low interferon-gamma (IFN-γ) production and OM.11 Thus, patients with this polymorphism would possess increased risk of developing OM and its sequelae.

**Microbiology of COM**

Bacteria reach the middle ear via the external auditory canal in the presence of a TM defect or retrograde through the nasopharynx. It is well established that Streptococcus pneumoniae is the most common microorganism isolated from AOM samples, followed by Haemophilus influenzae, Moraxella catarrhalis, and group A streptococci. These same microorganisms have been isolated from chronic OME samples with polymerase chain reaction (PCR) techniques, demonstrating at the very least the presence of bacterial genomic DNA in effusion samples.
The bacteria isolated in COM and infected cholesteatomas differ markedly from those found in AOM or chronic OM E. In CSOM isolates, aerobic and anaerobic bacteria are involved, coexisting in half of cases. The most common aerobic bacteria isolated are Pseudomonas aeruginosa, Staphylococcus aureus, and other gram-negative bacilli, for example, Escherichia coli, Proteus species, and Klebsiella species. Pseudomonas aeruginosa is known to reside in the moist environment of the external auditory canal, whereas S. aureus is universally harbored within human nares. The proximity of these bacteria reflects the likelihood of their eventual presence within the middle ear, either as contaminants or bonafide pathogens. Bacteroides spp. and Fusobacterium spp. are the most common anaerobic bacteria isolated. Furthermore, fungi are frequently found within CSOM samples, specifically Aspergillus spp. and Candida spp. There is some speculation that fungi may result as overgrowth after initial treatment with antibiotic drops.

**PATHOGENESIS OF COM**

COM is characterized by pathological findings consistent with irreversible inflammatory changes within the middle ear and mastoid. The sequence of events which result in these changes are unclear mostly due to the silent nature of this disease and, hence, the amount of time that elapses before attention is sought. In a temporal bone study of chronically infected ears with either intact or perforated TMs, da Costa and colleagues demonstrated almost universal presence of both granulation tissue and ossicular bony changes in either group.13 This highlights the fact that significant disease may exist despite the presence of an intact TM.

Undoubtedly, dysfunction of the eustachian tube plays a prominent role in both AOM and COM. The eustachian tube opens to the contraction of the tensor veli palatini muscle during swallowing and, under physiologic conditions, is responsible for clearance of middle ear secretions into the nasopharynx, prevention of nasopharyngeal secretions from refluxing into the middle ear, and pressure equalization between the middle ear and the external environment. Obstruction of the eustachian tube functionally (eg, cleft palate, paradoxical constriction) or mechanically (eg, mucoid secretions, edema, neoplasm, nasogastric tube, adenoid hypertrophy) results in lowering of the normally negative middle ear pressure due to increased nitrogen absorption into middle ear subepithelial mixed venous blood. This results in transudation of serous fluid into the middle ear cleft. Also, nasopharyngeal bacteria are more readily introduced into the middle ear upon tubal opening as they are in the settings of a shorter tube (eg, infant) or a perforated TM. Other factors thought to promote tubal dysfunction are gastroesophageal reflux or virally induced ciliary transport deficiencies of middle ear secretions by middle ear epithelium.

Once bacteria enter the middle ear via the nasopharynx or a TM defect, bacterial replication ensues within a serous effusion. Concomitantly, an immune response is triggered within an intact host, releasing inflammatory mediators into the middle ear space. The hyperemia and polymorphonuclear leukocyte-dominated acute inflammatory phase gives way to a chronic phase, characterized by a shift toward mononuclear cellular mediators (eg, macrophages, plasma cells, lymphocytes), persistent edema, and granulation tissue. Furthermore, metaplasia of the middle ear epithelium may occur, converting cuboidal epithelium to a pseudostratified columnar epithelium capable of increased mucoid secretion.14 Granulation tissue becomes increasingly fibrotic, eventually forming adhesions to important structures within the middle ear. This can disturb aeration of the antrum and mastoid by decreasing space between the ossicles and mucosa which separate the middle ear from the antrum. Chronic obstruction leads to irreversible changes within both bone and mucosa of these structures.

Whether COM results as a continuation of AOM is a matter of debate. On one hand, AOM is much more prevalent than COM and most perforations secondary to AOM resolve spontaneously without consequences. On the other hand, studies have shown degeneration of the fibrous layers of the TM lamina propria in the setting of OM E or RAOM, thereby weakening this structure.3 In a study by Yoon and colleagues of temporal bones with or without OM, retraction of the TM was not found at all in those samples without OM.15 In the OM group, however, retraction was present in the OM E group (2.1%) and to a significantly greater degree in those samples with COM (19.5%). Exposure of a progressively weakening TM to increased negative middle ear pressure in the setting of eustachian tube dysfunction would drive the TM medially, causing retraction pockets (see Figure 1). Further TM weakening or destruction may result in middle-ear atelectasis, adhesive otitis, perforation, and acquired cholesteatoma.

**MIDDLE EAR ATELECTASIS AND ADHESIVE OM**

Middle ear atelectasis is a variant of COM and refers to TM retraction onto the promontory and ossicles of the middle ear (see Figure 2). The most likely reason for this phenomenon is increased negative middle ear pressure from eustachian tube dysfunction. To accommodate for an increase in negative middle ear pressure, the drumhead moves medially to decrease middle ear volume. This action is in accordance with Boyle’s law which states that pressure multiplied by volume must be constant. Further medial displacement is possible if TM atrophy occurs with loss of the fibrous layer; this is usually secondary to repeated infection or persistent middle ear effusion.3 Obliteration of the middle ear space may be complete or partial but, importantly, is potentially reversible and does not involve changes to the lining middle ear mucosa. Should a medially retracted TM completely obliterate the middle ear space and irreversibly replace the normal mucosa by adhering to the bony promontory, the term adhesive OM is applied. Several authors have included atelectasis and adhesive OM in a staging system of TM retraction with each stage representing progressive loss of the TM fibrous layer: stage I, retracted TM; stage II, retraction with contact of the incus; stage III, middle ear atelectasis; stage IV, adhesive OM.5,16 Ossicular contact from such retraction may cause bony erosion, particularly of the long process of the incus and the stapes.

Another important factor in the development of atelectasis and COM is mastoid pneumatization. The mastoid is a pneumatized space connected to the middle ear which is invariably hypopneumatized in the setting of COM. Like the middle ear, it also behaves as a pressure buffer to counteract pressure changes within the middle ear (ie, Boyle’s law). In this closed system, Sadé and others have demonstrated that smaller mastoids

---

**Figure 1** Severe chronic otitis media with effusion with extreme pars flaccida retraction and an attic retraction pocket (arrows). In this photo there is also retraction of the inferior portion of the pars tensa.

**Figure 2** Severe middle ear atelectasis due to chronic eustachian tube dysfunction. In this case, the thinned tympanic membrane is adherent to the stapes (1), the round window niche (2) and the promontory (3). (Adapted from reference 17.)
are the weakest pressure buffers, thereby increasing the sensitivity of the TM to increased negative middle ear pressures. Thus, the TM is more prone to displacement in COM which may help explain why atelectatic drums can also balloon out in the same patient. Unequivocally, patients with chronic middle ear disease have poorly aerated mastoids. Controversy exists as to whether chronic infection leads to mastoid maldevelopment or whether smaller, maldeveloped mastoids predispose to COM. In support of the former theory, a recent 5-year follow-up study of infants with RA OM or chronic OME treated with tympanostomy tubes demonstrated that those requiring increased numbers of ventilation tubes, increased frequency of tubes, and with pars tensa retraction had significantly decreased mastoid air cell system sizes.

**COM with Tympanostomy Tubes**

Tympanostomy tubes have been used as a means of mitigating middle ear effusions, retractions, and atelectasis in the hope of achieving return of the TM to its normal physiologic position. As defined earlier, COM can occur from a spontaneous TM perforation or as a result of a tympanostomy tube placement. As many as 80% of patients experience at least 1 episode of otorrhea after tube placement and approximately 5% of patients experience chronic tympanostomy tube otorrhea. Antibiotic topical solutions administered at the time of tube placement decreases the incidence of postoperative otorrhea. Furthermore, silver oxide-impregnated tympanostomy tubes have been shown to decrease subsequent otorrhea by 50%. In cases of CSOM, the same microorganisms as found in COM populations are isolated. Unfortunately, it remains unclear whether ventilation tubes propagate chronic infections. In support of this possibility, a small percentage of TM perforations persist after tympanostomy tube removal. Also, the recent identification of biofilms within tympanostomy tubes would invariably lead to chronicity and difficulty in eradicating any established infection.

**CHOLESTEATOMA**

The term cholesteatoma was first coined by Johannes Müller in 1838 to describe what we now understand to be epidermal inclusion cysts of the pneumatized portions of the temporal bone. As such, keratinizing stratified squamous epithelium is found ectopically within the middle ear, an area typified by low cuboidal epithelium. The squamous epithelium comprises the “matrix” of the cholesteatoma which rests above the “perimatrix” that contains inflamed fibrous tissue. In contrast to the name, cholesteatomas do not contain fat or cholesterol within their matrices. Their appearance, described as “peary tumors” by Cruveilhier in 1829, relates rather to the desquamated keratin debris produced by the squamous epithelium which lines these cysts. Other than the congenital variant, cholesteatomas are usually the result of COM and, therefore, possess its attendant inflammatory changes such as granulation tissue. In studies by da Costa and Sade, approximately 10% of COM ears were complicated by cholesteatoma. The significance of cholesteatoma is based upon its propensity to erode the bony structures of the temporal bone.

**Epidemiology of Cholesteatoma**

The exact prevalence of cholesteatoma is not known. A acquired cholesteatoma complicates approximately 10% of COM cases and is more likely to arise from COM ears with TM perforations than those without perforations. The annual incidence of cholesteatoma is low, ranging from 3 to 12 cases per 100,000 population. It is slightly more common in males and Caucasians and rarely seen in Asian populations. Although the Alaskan Inuit population has a large predilection for COM, they, interestingly, have low prevalence rates for cholesteatoma. Reasons for this are unclear. Children typically present approximately at 5 years of age with congenital variants and at 10 years with acquired cholesteatomas.

**Pathogenesis of Cholesteatoma**

Cholesteatoma can be classified as either congenital or acquired. Aquired cholesteatomas are further divided into primary or secondary forms. Cholesteatomas can also be classified according to their sites of origin. Attic cholesteatomas begin from pars flaccida retraction and usually spread to the aditus or mastoid. Sinus cholesteatoma refers to those arising from posterosuperior retraction or perforation of the pars tensa. Tensal cholesteatoma refers to cholesteatoma arising from retraction of the entire pars tensa.

**Congenital Cholesteatoma.** When cholesteatoma arises behind an intact TM without history of otorrhea, the term congenital cholesteatoma is used (see Figure 3). Congenital cholesteatomas arise from keratinizing epithelium within the middle ear cleft. Unfortunately, the origin of this epithelium is the source of much speculation; furthermore, proof of causation has not been established from any of the proposed theories. It is possible that middle ear mucosa may undergo squamous metaplasia or that external canal squamous epithelium may migrate through TM microperforations. Another possibility is that of middle ear space deposition of desquamated epithelial cells from amniotic fluid during fetal development. Yet another theory proposes that squamous epithelial cells may implant onto the malleus or incus from early TM retraction. The most widely accepted theory is that of failure of involucration of keratinizing epithelium. It has been established that small tufts of squamous epithelium are normally found within the anterosuperior portion of the middle ear cleft; furthermore, these tufts undergo normal transition into normal middle ear mucosa. In support of this theory, Michaels discovered squamous tufts that he termed “epidermoid formations” in the anterosuperior portion of the middle ear in 37 of 68 temporal bones from fetuses between 10 and 33 weeks of gestation. These epidermoid formations have also now been found in infants and children. Failure of the epidermoid formation to involute could possibly account for the anterosuperior location of most congenital cholesteatomas.

Congenital cholesteatomas typically develop in the anterosuperior quadrant of the middle ear; thereafter, they spread to the posterosuperior quadrant and gain access to the antrum and mastoid. A useful classification system developed by Potsic and others exists in which stage advancement correlates directly with risk of residual disease: stage I, cholesteatoma limited to one quadrant; stage II, involving multiple quadrants without ossicular involvement; stage III, ossicular involvement without mastoid extension; stage IV, mastoid involvement. A primary acquired cholesteatoma refers to cholesteatoma that arises from simple retraction of the pars flaccida (see Figure 4). Secondary acquired cholesteatoma refers to cholesteatoma that arises in the setting of TM perforation, usually in the posterosuperior quadrant of the middle ear (see Figure 5). There are 4 main theories proposed to account for acquired cholesteatoma etiopathogenesis: (1) TM invagination; (2) migration of epithelium through a TM perforation; (3) basal cell hyperplasia; and (4) squamous metaplasia (see Figure 6). A fifth mechanism, implantation, is also established and requires little explanation. In the case of implantation, squamous epithelial cells are displaced into the middle ear space either iatrogenically (eg, tympanoplasty, tympanostomy tube placement) or traumatically. This is an uncommon mechanism; for example, the prevalence of cholesteatoma following ventilation tube placement is less than 1%.

**Invagination Theory.** This theory is widely accepted as the most likely mechanism for primary acquired or attic cholesteatomas. In this setting, the TM becomes retracted further medially into the middle ear secondary to increased negative middle ear pressure. The reasons for
medial displacement are the same as those that have been established for COM in general: eustachian tube dysfunction, inflammation, TM atrophy, and poor mastoid pneumatization. Wolfman and Chole, for example, demonstrated cholesteatoma development in 75% of gerbils 16 weeks after experimental bilateral eustachian tube obstruction.31 Although this process typically occurs in the pars flaccida due to its inherent weakness from lack of a fibrous layer, any portion of the TM can be involved. As the retraction pocket progressively deepens, the squamous epithelial cells lining the retraction pocket continually release keratin debris into its center. This is compounded by alteration of normal epithelial cell migration that results in a functionally closed cyst that can no longer drain its desquamated keratin debris. Instead, the growing cyst expands into the middle ear system and gives the prototypical appearance of a posterosuperior TM defect. Although the TM is intact in the case of a retraction pocket, it may give the appearance of a marginal perforation. Retraction pockets, especially of the attic, must be considered precursors to cholesteatoma and demand close observation.

Epithelial Invasion. Squamous epithelium of the external auditory canal and the outer margin of the TM has the ability to migrate into the middle ear across TM perforations. It has also been established that epithelium will advance until confronted by another epithelial surface, a term called contact inhibition. If middle ear mucosa either along the medial portion of the TM or further into the middle ear space were to be disrupted by inflammation, infection, or trauma in the setting of a TM defect, the mucocutaneous junction could theoretically shift into the middle ear space. In support of this theory, van Blitterswijk and others determined that cytokeratin (CK) 10, an intermediate filament protein and marker of squamous epithelium, could be found in external meatal epidermis and cholesteatoma matrix but not in middle ear mucosa.32 Marginal perforations are understood to be more likely to lead to epidermal ingrowth than central perforations, most likely because perforation at this site exposes the middle ear mucosa and bony canal wall structures to the external ear canal. Central TM perforations, however, should not be disregarded as safe ears. In a recent analysis of central TM perforations from COM patients, 38% of perforations were found to have significant epidermal growth with the mucocutaneous junction located beyond the inner surface of the perforation.33 This rate is comparable to studies involving both marginal and central perforations.

Basal Cell Hyperplasia. In 1925, Lange observed that keratinizing epithelial cells of the pars flaccida could invade the normally inaccessible subepithelial space to form attic cholesteatomas.34 Furthermore, Huang and colleagues have shown that TM injury via propylene glycol application results in middle ear epithelial ingrowth in a chinchilla model.35 For keratinizing epithelial cells to reach the lamina propria of the TM and form epithelial cones, they must travel through disruptions of the basal lamina.36 Once within the subepithelial connective tissue, entrapped epithelial cones are equivalent to microcholesteatomas, essentially keratin-producing cysts with the potential to expand and form larger cholesteatomas. Upon secondary perforation of the TM, a typical attic cholesteatoma would be seen.

Squamous Metaplasia. Chronically infected or inflamed tissues are known to undergo metaplastic transformation (eg, esophagus, bronchus). Similarly, the cuboidal epithelium of the middle ear may undergo transformation into keratinizing epithelium. Keratinizing squamous epithelium has been found in middle ear biopsies of pediatric patients with OM as well as in middle ears of rats deprived of vitamin A.37 However, progression to cholesteatoma has yet to be established.

Inflammation and Hyperproliferation. The epithelium of cholesteatoma, while not neoplastic, is hyperproliferative. Involutin, the precursor to cornified envelope formation at the uppermost layers of the epidermis, is found only in high suprabasal layers of normal skin. In cholesteatoma, however, involucrin is found in all suprabasal layers, resulting in much higher accumulation of keratin within a larger portion of the epidermis. Studies have also demonstrated increased expression of proliferative markers in basal and suprabasal layers of the epidermis: CK 4, CK 5/6, CK 10, CK 13/16, epidermal growth factor receptor (EGFR), keratinocyte growth factor (KGF), and Ki-67.28 A normal distribution of p53, c-jun, and c-myc expression are also implicated in the hyperproliferative process. Recently, studies using cDNA array technology have identified many more genes with possible roles in cholesteatoma development.38 These include calgranulin A/B, thymosin, and extracellular matrix protein-1.

Another important factor in the hyperproliferative process is the invariable presence of chronic inflammation. The stroma of the cholesteatoma possesses fibroblasts, Langerhans cells, mast cells, activated lymphocytes, macrophages, and keratinocytes. Furthermore, keratinocytes produce large amounts of keratin. Inflammation with or without infection recruits these cell types to create a milieu with increased concentrations of proinflammatory cytokines. Such an environment is known to stimulate basal keratinocytes.
Biofilms. In addition to being found within tympanostomy tubes, biofilms have also recently been demonstrated within human cholesteatoma and COM middle ear epithelium. Biofilms are bacterial aggregates in which planktonic, free-floating bacteria join other bacteria to form sessile, stationary communities. In the environment, most bacteria exist as biofilms. Via quorum sensing genes, bacteria communicate with one another to express genes and products that afford protection to the community as a whole. This translates into lower total energy requirements, increased ability to survive in otherwise inhospitable niches, and encasement in matrices composed mostly of polysaccharides and extracellular DNA. This community is in constant flux, with microorganisms detaching and rejoining when opportunities or energy needs arise. The extracellular matrix dramatically decreases antibiotic penetration, thereby minimizing bacterial exposure to these drugs. Furthermore, bacteria in biofilms are capable of altering their individual phenotypes, switching to those possessing increased antibiotic resistance. In turn, the presence of a biofilm within an infection leads to extreme difficulty in cure and invariably chronicity, as antibiotics usually prove ineffective in the long run.

In the setting of a biofilm infection, antigenic bacterial components such as lipopolysaccharide (LPS) or peptidoglycan would be intermittently reintroduced into the middle ear system by re-entrant bacteria, establishing chronicity of infection and inflammation. This scenario, for example, could explain why, after antibiotic administration, purulent otorrhea typically recurs in infected cholesteatomas or colonized tympanostomy tubes. This inflammatory microenvironment would exert its effects on downstream middle ear and cholesteatoma components, further propagating the well-known consequences of COM and cholesteatoma.

Bone Resorption

It is estimated that 10% of the total bone content is replaced per year in adult humans. Bone is a dynamic organ constantly being remodeled to achieve both calcium homeostasis and structural integrity. Matrix synthesis is carried out by osteoblasts while osteoclasts dictate resorption. Osteoclasts are multinucleated specialized cells of the macrophage/monocyte family which arise from the fusion of mononuclear precursors that have attached to bone. More importantly, they are the cell capable of bone resorption in the human body. Pathologic conditions which favor inappropriate osteoclast activation overturn this balance and result in excess erosion of bony structures. In established cases of COM with or without cholesteatoma, bone erosion is almost invariably present and represents the major source of morbidity. As opposed to pressure necrosis or proteolytic factor secretion by components of the cholesteatoma matrix, it is now clear that resorption occurs, as in other inflammatory conditions, via the action of osteoclasts.

Recently, osteoclast formation from precursor cells has been discovered to be under the control of 2 essential cytokines: receptor activator of nuclear factor-κB ligand (RANKL) and macrophage colony-stimulating factor (M-CSF). Normally, osteoblasts produce M-CSF and RANKL to initiate osteoclast formation by engaging the c-Fms and RANK receptors on osteoclast precursors, respectively (see Figure 7).

In pathologic conditions, other cell types participate in the production of these cytokines. An important inhibitor of this process is osteoprotegerin (OPG), a soluble decoy receptor of the tumor necrosis factor (TNF) superfamily that competes with RANK for RANKL (see Figure 7). Jeong and others have recently demonstrated nonspecific overall higher counts of RANKL-producing cells in cholesteatoma compared to normal postauricular skin; conversely, normal skin had a significantly higher rate of cells expressing OPG. These results reveal that cholesteatoma tissue possesses an increased RANKL/OPG ratio due to inflammation and very likely potentiates osteoclastogenesis.

A hallmark feature of COM with or without cholesteatoma is chronically inflamed tissue near bony structures. As such, inflammatory cytokines (eg, interleukin-1 (IL-1), IL-6, tumor necrosis factor-alpha (TNF-α)) and prostaglandins are elaborated in a microenvironment composed of keratinocytes, macrophages, lymphocytes, fibroblasts, osteoblasts, and other cell types. These cytokines are upregulated in cholesteatoma tissue and are also known to promote osteoclastogenesis by either direct or indirect effects on osteoclasts. IL-1 and TNF-α, for example, promote osteoclast formation, increase osteoclast survival, and increase bone resorption by mature osteoclasts. In addition to osteoblasts, lymphocytes (eg, B and T cells) contribute largely to inflammatory osteolysis by generating RANKL themselves (both soluble and membrane-bound) in the inflammatory microenvironment.

Infected cholesteatomas are known to act aggressively and erode bone more quickly. Elevated levels of bacterial virulence factors likely...
play key roles in this phenomenon. Biofilms also contribute to increased concentrations of virulence factors since they represent a safe niche from which bacteria or their antigenic components can re-emerge (see Figure 7). In support of this, TLR4 and others have recently demonstrated higher concentrations of LPS in samples from patients with otitis media and bone resorption secondary to cholesteatoma. LPS is the main antigenic component of gram-negative bacterial cell walls (e.g., Pseudomonas aeruginosa) and is a well-characterized virulence factor known to powerfully stimulate the immune system.

Eukaryotic microorganisms use a family of receptors called toll-like receptors (TLRs) to sense diverse populations of microbial pathogens. TLRs recognize common bacterial structures, allowing quick tailor-made responses to pathogens. Studies have recently demonstrated that TLR4 is the TLR responsible for detecting LPS from gram-negative bacteria. Via TLR4, LPS is known to promote the release of inflammatory cytokines from monocytes, osteoblasts, and lymphocytes (see Figure 7). LPS is also known to induce RANKL release by certain cell types and to promote osteoclast formation. The mechanisms by which this occurs is currently under investigation.

COMPlications OF COM AND CHOLESTEATOMA

The most common complication of COM is conductive hearing loss, typically ranging from 20 to 60 dB. This may be caused by one of many noninfectious sequelae of COM, namely TM perforation, middle-ear atelectasis, tympanosclerosis, ossicular disruption, and cholesteatoma. Although conductive hearing loss predominates, infectious and inflammatory components may also be transmitted to the inner ear via the round window resulting in cochlear damage and hearing loss. Other important noninfectious sequelae include facial paralysis and cholesterol granuloma. Infectious complications include subperiosteal abscess, mastoiditis, CSOM, labyrinthitis, petrositis, and intracranial infection, e.g., encephalitis, meningitis, brain parenchymal abscess, subdural effusion, sigmoid sinus thrombophlebitis, extradural abscess. The significance of hearing loss and subsequent auditory deprivation, especially in children, remains a major topic of interest. Although poorer attention, speech perception, and expression skills have been demonstrated in children, the final impact on their language and cognitive development remains unclear.

The main complications accounting for the morbidity of cholesteatoma arise from destruction of nearby bony structures. These include the ossicles, the otic capsule, facial nerve canal, tegmen tympani, and tegmen mastoideum. Infections of cholesteatomas are also a common complication and tend to be recurrent. This results in purulent otitis media and inflammatory damage to structures that infected cholesteatoma tissue may abut. Conductive hearing loss typically results from erosion of the incus. Erosion of the otic capsule, most commonly involving the lateral semicircular canal, can result in labyrinthine fistula, vertigo, or infectious sequelae such as suppurative labyrinthitis. Fistula, labyrinthitis or cochlear erosion may result in sensorineural hearing loss. Facial nerve paralysis may result from nerve invasion after erosion through the facial nerve canal or from infectious involvement of cholesteatoma tissue that abuts the facial nerve. Cerebrospinal fluid leakage and brain herniations can result from erosion of either tegmen.

Diagnosis of COM

The diagnosis of COM with or without cholesteatoma is usually made based on the history and physical examination. Evaluation should elicit prior history of middle ear disease and surgical interventions. Although COM and cholesteatoma may be diagnosed incidentally in asymptomatic patients, symptoms including hearing loss, otitis media, nasal obstruction, tinnitus, and vertigo may prompt the patient to seek medical attention. Of these presenting symptoms, hearing loss and otorrhea are by far the most common. CSOM presents with a profuse, viscous otorrhea that is intermittent in nature. On the other hand, patients with infected cholesteatoma present with small amounts of foul-smelling, purulent otorrhea. Otorrhea usually represents a secondary external otitis, and will conceal underlying pathology of the middle ear. For this reason, follow-up evaluation with thorough canal debridement is imperative after an acute flare-up to properly visualize middle-ear pathology. Alternatively, pain may represent an intracranial sequel of a cholesteatoma. Other symptoms of possible sequelae include bloody otorrhea in advanced disease, vertigo from a labyrinthine fistula, facial nerve paralysis, or neurologic symptoms from intracranial spread.

The diagnosis of COM and aural cholesteatoma can usually be made on otomicroscopic examination given that the ear is properly cleansed of debris and drainage. It is also important to evaluate the nasopharynx in these patients, as eustachian tube dysfunction is a common cause of COM in many cases. In regard to the ear, the microscope will allow visualization of the drumhead to identify perforations, retraction pockets, cholesteatoma, and granulation tissue. If a TM perforation is present and large enough, middle-ear mucosa may be assessed for evidence of inflammation and infection; furthermore, some or all of the ossicles may be visible and assessed for erosion, fixation, or disruption. A primary acquired cholesteatoma will be seen in the posterosuperior portion of the TM as a pearl-white defect containing keratin debris, whereas a secondary acquired cholesteatoma will be found next to a TM perforation (see Figures 4 and 5). Alternatively, a congenital cholesteatoma may be seen as a white mass behind the anterosuperior quadrant of an intact TM if discovered before secondary TM perforation (see Figure 3).

Granulation tissue is the most common finding associated with COM and is a consequence of inflammation (see Figure 5). Sometimes polyps herald the presence of cholesteatoma; they represent granulation tissue at the junction between the cholesteatoma and eroding bone and may be seen extending as far as the external meatus in advanced cases. Most commonly, patients complain of progressive unilateral worsening of their hearing status. Audiometric evaluation, including air and bone thresholds as well as speech discrimination testing is imperative. Test results can additionally be correlated with Weber and Rinne tests performed with a 512 Hz tuning fork. The reduction in hearing is determined by the extent of middle ear disease as related to the status of the TM, ossicles, and the middle-ear mucosa. A perforation of the TM will result in a conductive hearing loss of about 15 dB, whereas a loss of 50 dB is possible if a TM perforation is accompanied by disruption of the ossicular chain. Perforations of the posterior TM that expose the round window membrane will also result in more severe conductive hearing loss because the TM no longer shields the round window from sound, the so-called “baffle effect.” Conductive hearing loss will also result from
changes to the ossicles. Erosion of ossicles with subsequent discontinuity may result from atelectasis, adhesive OM, inflammation, or cholesteatoma growth. Alternatively, ossicular fixation may be the root cause. Fixation of the stapes footplate is well known to occur in cases of middle ear tympanosclerosis that has reached the oval window. Additionally, fixation of the incudostapedial joint arises commonly as a postinflammatory consequence. If granulation tissue within the middle ear space inhibits ossicular mobility, conductive hearing loss can also be expected. Of note, granulation tissue or cholesteatoma that has eroded much of the ossicular chain may only cause minimal hearing loss if sound is able to be transmitted through these lesions to reach the inner ear via the stapes or footplate.

In any patient with findings suggestive of COM or cholesteatoma, and especially those presenting with vestibular symptoms, pneumatic otoscopy is imperative. A positive fistula test characterized by vertigo and nystagmus suggests inner ear involvement and need for urgent intervention.

**Imaging.** Although imaging is usually unnecessary for uncomplicated cases of COM or cholesteatoma due to eventual surgical exposure, high-resolution computed tomography (CT) and magnetic resonance imaging (MRI) of the temporal bones may provide supplementary information. In addition to complementing the clinical examination, imaging characterizes the extent of disease and may also identify cholesteatoma in asymptomatic patients. Although CT is considered the “gold standard” for imaging cholesteatoma, it lacks specificity due to difficulty in distinguishing cholesteatoma from granulation tissue or edema, especially when bone erosion is absent. On CT, cholesteatoma will appear as a lesion with smooth, sharp margins that does not enhance upon intravenous contrast administration (see Figure 8). When bone erosion is concurrently identified, CT can identify a nondependent mass as cholesteatoma with 80% specificity. CT is also useful in highlighting surrounding anatomical features such as temporal bone pneumatization or the presence of a low-lying tegmen mastoideum. Furthermore, it is extremely useful in revision cases in delineating altered anatomy and recurrent disease.

On MRI, cholesteatoma will appear with low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (see Figure 9).

In addition to being nonspecific in diagnosing cholesteatoma like CT, air and bone are indistinguishable on MRI making delineation of bony details difficult. However, if intracranial complication is suspected, e.g., lateral sinus thrombosis, MRI with gadolinium is extremely valuable due to its superiority in visualizing soft tissue densities. It is also effective in diagnosing disease extension into the petrous apex.

**Tympanosclerosis**

Tympanosclerosis refers to the deposition of acellular hyalin within the TM or middle ear submucosa as a result of COM or trauma. Sometimes, tympanosclerotic lesions are also calcified. If the process is isolated to the TM, the term myringosclerosis is used. On otoscopic examination, white crescent- or horseshoe-shaped plaques are seen in the TM (see Figure 9). Most cases are incidentally identified and asymptomatic. If tympanosclerosis extends into the middle ear cleft, however, the ossicles are at risk and conductive hearing loss may occur (see Figure 10).

**Pathogenesis.** Tympanosclerosis results as a consequence of RAOM, COM, or tympanostomy tube placement. In one study by Jaisinghani and others, 52 (35%) of 150 temporal bones from COM patients demonstrated myringosclerosis.46 In a study of 146 children with bilateral OME who were treated with adenoectomy, right-sided tympanostomy tube placement, and left-sided myringotomy, Tos and Stangerup demonstrated that 59% of right ears that underwent tube placement had tympanosclerosis while only 13% of left-sided ears had the same finding.47

The exact pathogenesis of tympanosclerosis remains unclear. Microscopically, tympanosclerosis is characterized by acellular hyaline degeneration of the lamina propria of the TM, middle ear, and mastoid mucosa. This may progress to calcium deposition. Furthermore, both cartilage and bone formation may occur within these lesions. It is generally accepted that infectious or inflammatory injury to the TM or mucosa is the inciting event in the pathogenesis of tympanosclerosis. One possible mechanism is degeneration of fibroblasts which are known to progressively accumulate in these plaques. Fibroblasts accumulate cytosolic matrix vesicles rich in calcium, phosphate, and alkaline phosphatase. These vesicles eventually merge with the cell membrane and are released extracellularly upon fibroblast cell death. Continued accumulation leads to calcification of the collagen matrix.

Hypercalcemia in itself may be a contributing factor since de Carvalho Leal and others recently demonstrated that rats given a calcium-rich diet developed tympanosclerosis more frequently after S. pneumoniae middle ear infection than rats maintained on normal calcium content diets.48 A nother possible mechanism is dystrophic calcification of degenerated collagen fibers after an infectious or inflammatory insult (eg, AOM, OME). In contrast to the belief that tympanosclerosis arises from infectious or inflammatory insult, Wielinga and colleagues showed that sterile middle ear effusions secondary to eustachian tube obstruction was enough to incite tympanosclerotic plaque formation.49 In their study, infected effusions caused almost complete replacement of the lamina propria with a dense connective tissue of normal cellularity; hence, no plaque formation was seen. Another possibility is autoimmune injury. Schiff and colleagues induced tympanosclerotic plaque formation after iatrogenic TM trauma in guinea pigs that were passively immunized with antisera to lamina propria.50

**Treatment.** Tos and Stangerup demonstrated that tympanosclerosis secondary to tympanostomy tube placement resulted in an inconsequential conductive hearing loss of less than 0.5 dB.49 Should tympanosclerosis involve the middle ear cleft, however, involvement of the ossicles and middle ear mucosa is likely to occur. New bone growth usually involves the attic where fixation of the malleus and incus may occur. Tympanosclerosis involving the oval window leads to stapes fixation and conductive hearing loss.

Tympanoplasty and ossicular reconstruction may be performed to treat tympanosclerosis. Vincent and others reported recently that stapled tympanostomy with reconstruction resulted in reduction of the air-bone gap to less than 20 dB in 70% of patients and 10 dB in 39% of patients.51 In a review of 135 cases of tympanosclerosis with an average preoperative air-bone gap of 30.9 dB treated mainly by-stage operations, Teufert and De La Cruz reported that the air-bone gap was reduced to less than 20 dB in 65% with ossicular fixation even after 10 years of follow-up.52 There were no dead ears in this group of patients, and only patient experienced partial sensorineural hearing loss. Gormley, however, showed that...
dead ears resulted from stapedectomy and only 7% of patients had an air-bone gap of less than 21dB on long-term follow-up, citing recurrence of disease as problematic.\(^{31}\) Significant risk of sensorineural hearing loss may result from either cochlear erosion of the disease process or from surgery due to the extensive dissection required in affected ears.

**Cholesterol Granuloma**

Cholesterol granuloma of the temporal bone is a brownish-yellow and mucoid lesion first described by Manasse in 1894.\(^{54}\) Also called cholestrin pseudocyst, or black cholesteatoma by some experts, cholesterol granuloma of the temporal bone arises as a consequence of COM in as many as 20% of temporal bones. In a study of 144 temporal bones from patients with COM, 21% of the 28 samples with TM perforations and 12% of the 116 samples without TM perforations revealed tympanosclerosis.\(^{33}\) Although it may occur in any pneumatized portion of the temporal bone, it is most commonly found in the petrous apex and represents the most common primary lesion of this site. It is essentially a sterile foreign-body reaction to cholesterol crystals and, therefore, may arise in any part of the body. Although most common in the temporal bone, it has also been demonstrated in sites such as the paranasal sinuses, jaw, lungs, pleura, mediastinum, orbit, testes, and kidney.

**Pathogenesis.** Although the etiology is unclear, cholesterol granuloma arises from the same factors which lead to COM. It commonly coexists with both mucoid middle ear effusion and TM retraction, likely the result of increased negative middle ear pressure from disrupted aeration and drainage. Negative pressure and inflammation lead to hemorrhage into the area. Breakdown of erythrocyte membranes releases cholesterol, initiating crystal formation and a sterile inflammatory reaction. Microscopically, multinucleated foreign-body giant cells are seen engulfing and surrounding cholesterol crystals. Inflammation leads to eventual granulation tissue formation, and repeated hemorrhage results in a lesion which grows in size.

**Diagnosis.** Cholesterol granuloma may be completely asymptomatic. Conversely, it may present by mass effect with symptoms such as hearing loss, tinnitus, vertigo, or facial twitching. Otoscopic examination may reveal a brownish-yellow, viscous lesion in the middle ear. If the lesion is not visible within the middle ear and likely involving the petrous apex, radiographic imaging greatly aids in diagnosis and preoperative planning. On CT, cholesterol granuloma has smooth borders, is isodense to brain parenchyma and does not enhance with intravenous contrast due to its avascularity. MRI is most helpful and usually establishes the diagnosis. The lesion is characterized by hyperintensity on both T1- and T2-weighted images and does not enhance after gadolinium administration. The unique hyperintensity on T1-weighted images is thought to be related to crystal presence, protein content, and hemorrhage. Should cholesterol granuloma coexist with cholesteatoma, it might be differentiated by the fact that cholesteatoma shows high signal intensity only on T2-weighted images.

**Treatment.** The form of treatment for cholesterol granuloma is based upon its location within the temporal bone as well as the patient’s hearing status. Recurrence of surgically excised cholesterol granuloma is not uncommon, and, therefore, conservative treatment is generally warranted for uncomplicated cholesterol granuloma of the middle ear cleft or mastoid. If aeration of the middle ear system is unaffected, observation may be employed. Should cholesterol granuloma exist in the setting of poor middle ear ventilation and drainage, ventilation tubes are warranted. Small, asymptomatic lesions of the petrous apex may be followed with serial CT or MRI. Surgical approaches for symptomatic lesions of the petrous apex include middle cranial fossa, infratemporal fossa type B, infralabyrinthine, transcanal infracoillear, transphenoidal, and retrosigmoid approaches. Goals of surgery are to achieve drainage and aeration.

**Management of COM**

**Medical.** Most infected perforations can be managed conservatively with topical antibiotics and regular aural toilet. A clean external meatus is needed to ensure proper drug penetration into the middle ear mucosa. The antibiotics chosen should have efficacy in eradicating Pseudomonas aeruginosa and Staphylococcus aureus, the most common pathogens in COM cases. Importantly, studies have recently shown that approximately 20% of Pseudomonas isolates in European and American hospitals now demonstrate ciprofloxacin resistance.\(^{55}\) In a recent review, Macfadyen and others determined that topical quinolone antibiotics were superior to systemic antibiotics in the management of otitis in patients with uncomplicated CSOM.\(^{56}\) Also, topical quinolones have been shown to be superior to topical nonquinolones in several reviews; a recent evidence-based review by Macfadyen demonstrated at least equal efficacy to topical aminoglycoside antibiotics.\(^{57}\)

Topical antibiotics offer the advantage of minimizing possibility of bacterial resistance because their concentration at the site of infection exceeds the pathogen’s minimal inhibitory concentration to such a degree that eradication is faster and more complete. Furthermore, topical antibiotics bypass the systemic circulation and result in significantly fewer adverse systemic effects. Topical antibiotics combined with corticosteroids in suspension form are also frequently employed. However, this combination has never been formally compared to antibiotic treatment alone. It is believed that corticosteroids alleviate edema, thereby allowing increased penetration of the antibiotic. Topical antiseptics such as boric acid, aluminum acetate, and povidone-iodine have also been used with good results. Antiseptics such as borate and antibiotics including chloramphenicol, sulfamethoxazole, and amphotericin may also be applied via insufflation in powder form; this technique is particularly useful in the setting of epithelium and moist mastoid cavities.

In those with recurrent or chronic infections, cultures should be obtained to direct antimicrobial therapy; if possible, cultures should be obtained from the middle ear to avoid possible contaminating flora, particularly P. aeruginosa from the external auditory canal. Systemic antibiotics may be administered according to culture and sensitivity results. A nother useful option in patients with recalcitrant otorrhea is irrigation of the affected ear with half-strength acetic acid solution (eg, distilled vinegar diluted 1:1 with water) prior to otic antibiotic drop application. The status of the round window and the risk associated with potentially ototoxic agents must be appreciated in the clinical decision-making process. The round window membrane serves as the major route by which toxins reach the inner...
Tympanoplasty is often accompanied by conservative mucosa, removing granulation tissue, and a mastoidectomy with or without facial recess correction of conductive hearing loss as a result of cholesteatoma or progressively destructive injury to the tympanum and are presented in Chapter 17, “Reconstruction of the Middle Ear.”

Reconstruction of the hearing mechanism in intact canal wall procedures leads to a more physiologically normal middle ear. This procedure has the drawback of potentially leaving keratinizing epithelium in a closed mastoid which is not amenable to physical examination. The judgment as to whether or not to leave a canal wall intact depends on the surgeon’s estimate of the adequacy of removal of the cholesteatoma matrix as well as patient reliability factors.

When extensive cholesteatomas involve the antrum and mastoid and an intact canal wall procedure cannot be performed safely, the posterior ear canal may be removed and the surgical procedure converted into canal wall down procedure with an open mastoid cavity. Recurrences of cholesteatomas when the canal wall is down are visible to the examining surgeon and are more easily detected and treated than in the intact canal wall procedure. Indications for the canal wall down procedure include destruction of the posterior canal wall by cholesteatoma, an extremely small sclerotic mastoid, calcific or calcifying recurrent cholesteatoma and “cholesteatosis” (widespread patches of keratinizing epithelium in which the cholesteatoma matrix has interdigitated into so many areas in the mastoid that physical removal is impossible).

Tymanoplasty. Tymanoplasty for TM perforation and ossicular reconstruction is usually performed when chronic inflammation is controlled or sometimes in conjunction with a procedure to remove pathological mucosa and granulation tissue from the mastoid. The techniques of TM repair and ossicular reconstruction do not differ from those used in cases of traumatic or postoperative injury to the tympanum and are presented in Chapter 19, “Reconstruction of the Middle Ear.”

Compete Mastoidectomy. Complete mastoidectomy is performed on patients with suspected mastoid cholesteatoma or in COM without cholesteatoma in the presence of blockage (ie, attic, aditus ad antrum), chronic unrelenting inflammation, cholesterol granuloma or when chronic granulation tissue is present.

A cortical mastoidectomy is performed with exposure of the antrum and incus (see Figure 11).51

Figure 11: A complete mastoidectomy is performed by removing the cortex of the mastoid bone and exposing the antrum. A dequate exposure requires visualization of the incus (arrow). (Adapted from reference 61.)

Atticotomy for Cholesteatoma. Cholesteatomas that are limited to the attic region may be removed through either an atticotomy approach with reconstruction of the attic defect or by an intact canal wall mastoidectomy. If an atticotomy procedure is used, the entire cholesteatoma sac must be exposed and removed meticulously (see Figure 12). The defect must be reconstructed with a tragal or conchal cartilage graft.

Intact Canal Wall Mastoidectomy. An intact canal wall mastoidectomy has the advantage of preserving the normal anatomy of the entire posterior ear canal without need for scutum removal and reconstruction (see Figure 13). This procedure is most often performed in cases of primary acquired cholesteatoma when the cholesteatoma involves the attic and antrum. Complete cortical mastoidectomy is performed, and the mastoid antrum is entered. Care is taken to preserve the cholesteatoma matrix as dissection is continued around the periphery of the matrix. Ideally, a primary acquired cholesteatoma can be removed.
without interrupting the matrix until final removal is appropriate. This minimizes the chance of leaving small fragments of keratinizing epithelium which may lead to recurrence. When the cholesteatoma is extremely extensive, the matrix is attenuated and there is difficulty in removing the matrix from underlying bony tissues. The surgeon may often elect to perform a “second look operation” for recurrences 6 to 12 months later. Alternatively, a canal wall down procedure may be selected when complete removal of the matrix is not possible.

When performing an intact canal wall procedure, there is no necessity for removing all air cells and mucosa, nor is there a requirement for smoothing the margins of the cavity (saucerization). The surgical approach for the intact canal wall procedure, therefore, is quite different from the canal wall down procedure in that the former preserves normal mucosa and trabecular anatomy that aid in healing and re-pneumatization of the mastoid. This is in contrast to the canal wall down procedure in which all air cells should be exenterated and the mastoid cavity widely saucerized to minimize compartmentalization of the cavity (see Figure 14).

Canal Wall Down Mastoidectomy. When a canal wall down mastoidectomy is chosen, it is critical to exenterate all possible air cells since mucosa originating from air cells can harbor and trap disease. Furthermore, this mucosa can become secretory and form a moist and troublesome mastoid cavity. The bone lateral to the fallopian canal should be removed (the so-called facial ridge) to minimize the possibility that debris and inflammatory material can be harbored within the cavity posterior to the facial nerve (see Figure 15).

Additionally, the mastoid cortex lateral to the sigmoid sinus should be thinned to obliterate any air cells which may lie lateral to the sigmoid sinus. In most cases of canal wall down mastoidectomy, the mastoid air cells of the mastoid tip are exenterated completely and the tip removed. Removal of the mastoid tip in a canal wall down mastoidectomy minimizes the possibility of forming a deep troublesome mastoid cavity inferiorly.

The mastoid cavity can be further minimized with closure techniques utilizing bone chips (“bone pâté”). Bone can be used to obliterate deeper portions of the mastoid cavity, especially behind the labyrinth. These bone chips must be covered by viable tissue. The surgeon may also choose to employ a Palva flap (postauricular subcutaneous tissue), rotated over the bone chips, to provide a smooth lining for the mastoid cavity (see Figure 16). Meatoplasty is always performed with a canal wall down mastoidectomy and is often appropriate for intact canal wall procedures.

The ultimate goal of a canal wall down mastoidectomy is to create an ear in which the meatus...

is large enough for easy examination and provides appropriate ventilation of the external canal and mastoid cavity. Furthermore, the resultant mastoid cavity should be small and lined with healthy keratinizing epithelium. A canal wall down mastoidectomy is often accompanied by reconstruction of the middle ear and a tympano-

Cranial and Intracranial Complications of Acute and Chronic Otitis Media

David R. Friedland, MD, PhD
Myles L. Pensak, MD
John F. Kveton, MD

Inflammation and pains of the ear lead sometimes to insanity and death.—Celsus, 25 AD

The European and American otologic literature of the nineteenth and preantibiotic twentieth centuries well document the fear and anxiety provoked by intracranial complications associated with aural infection of either acute or chronic nature. Reading before the California State Medical Society in April of 1916 and subsequently published in the California State Journal of Medicine, the prominent otologist Edward Sewall presented a detailed assessment of otitic meningitis.1 Included in this seminal text is a detailed review of the regional anatomy, confounding factors, and ultimately the need for prompt assessment and management. “The purulent process in the temporal bone that causes brain disease begins in the tympanum, labyrinth, or adjacent pneumatic cavities. Prompt evacuation of pus that has accumulated here is the safeguard that the surgeon must bear in mind while using his best judgment for the advantage of the patient.” Although the advent of antibiotics has greatly reduced the incidence of such disease, it is precisely because they are rare and potentially fatal that the clinician must be familiar with complications of acute and chronic otitis media (Table 1).

ANATOMY

Temporal bone anatomy is discussed in detail in Chapter 1, “Anatomy of the Auditory and Vestibular Systems;” however, we emphasize that the irregular and complex osteology of the bony skull base produces a number of preformed pathways that enable the extension of disease into the intracranial compartment. The multiple neural and vascular structures that traverse the temporal bone and petrous ridge provide avenues for infectious extension which we will discuss briefly in this section.

Osteology

Infection of the ear canal or middle ear may expand beyond the confines of the local environments through preformed pathways. The fissures of Santorini allow for external auditory canal infections to extend anteriorly into the parotid gland. From there passage may provide for extension into the infratemporal fossa, parapharyngeal space, masticator space, and neck along with the lymphatic drainage from the parotid system.

Medially, infections within the mesotympanic space may pass into the adjacent tympanic recesses and cavities, including the hypotympanum where the jugular bulb and jugular fossa may be seeded. Anteriorly, these infections may extend into the prot tympanum and track along the internal carotid artery and eustachian tube. Should the roof of the eustachian tube become violated, spread into Glasscock triangle (bounded by the greater superficial petrosal nerve, the mandibular division of the trigeminal nerve and a line between the foramen spinosum and the arcuate eminence) along the middle fossa floor may occur. Continued anterior extension may track along the route of the greater superficial petrosal nerve while posterior extension may involve the geniculate ganglion (Figure 1).

If a significant air cell tract is present in Kawase triangle (actually a quadrangular area bounded anteriorly by the mandibular division of the trigeminal nerve posteriorly by the arcuate eminence, laterally by the greater superficial petrosal nerve, and medially by the superior petrosal sinus), anterior extension may involve the trigeminal nerve while involvement of the apex and Dorello canal may precipitate a classic Grendelberg syndrome resulting in abducens nerve paralysis. Medial extension within Kawase triangle may result in invasion of the superior petrosal sinus. Propagation of infection anteriorly may seed the cavernous sinus while posterior extension will result in sigmoid sinus involvement. Finally, with aggressive destructive processes, violation of the internal auditory canal and otic capsule may result in suppurative labyrinthitis and anacusis.

Mesotympanic pathology extending posteriorly may involve the sinus tympani within the roof of which lays the fallopian canal and facial nerve. Cephalic extension into the epitympanum may seed the aditus ad antrum, the central mastoid air cell tract and, thus, the air cell system of the petrous ridge. Infection leading from the central mastoid air cell system will track along well-defined pathways including the pre- and postsigmoid tracts, the sinodural, retrolabyrinthine, infralabyrinthine, supralabyrinthine, retrofacial, subarcuate, and apical cells. Extra temporal involvement may ultimately invade accessory air cells including the zygomatic root, styloid process, and occipital bone.

Vascularity

Knowledge of the venous anatomy of the petrous architecture is of vital importance (Figure 2). The sigmoid sinus and jugular bulb...
occupy central positions within the temporal bone and thus involvement of these structures may result in a thrombophlebitis. A retrograde extension of infection propagates inferiorly into the jugular vein itself. Mastoid involvement may extend to the sigmoid sinus and it is not uncommon to find granulations over an exposed sigmoid sinus in coalescent mastoiditis. Such a finding may be an early process in the progression to sigmoid sinus thrombophlebitis. Continued retrograde involvement may impact the transverse sinus, torcular, and the vein of Labbé (inferior anastomotic vein). Emissary veins along the posterior petrous ridge may be sources of spread of infection to the posterior fossa dura. Furthermore, temporal venous channels may result in temporal lobe seeding by either retrograde propagation of infected clot or emboli.

The carotid sheath is relatively resistant to infection but may serve as a conduit for skull base osteomyelitis. The carotid canal represents a preformed pathway as the artery enters the skull base anterior to the jugular bulb, rises superiorly ventral to the cochlea, turns along the floor of the eustachian tube and the temporal fossa before entering the intradural intracranial compartments at the level of foramen lacerum. Natural dissections along the artery’s osseous course provide areas for entry of infection leading to abscess, osteomyelitis, and extradural seeding.

**Neural Structures**

Infection spreading along neural pathways may follow the glossopharyngeal, vagus, or spinal accessory nerves as they pass through the pars nervosa of the jugular foramen before entering the upper cervical neck. The hypoglossal nerve and hypoglossal canal are rarely involved with intracranial infection and paralysis of this nerve portends an ominous course in cases of skull base osteomyelitis. In general, the facial and vestibuloclear nerves remain fairly protected through their course within the internal auditory canal. However, the facial nerve is at risk in the tympanic segment because of frequent dehiscences in the bone of the fallopian canal. There is also potential involvement of the vertical facial nerve due to either mastoid disease or involvement of the sinus tympani.

**MICROBIOLOGY**

The microorganisms involved in cranial and intracranial complications of otitis media generally reflect the bacteriology of the primary infection (Table 2). Bacteria commonly associated with acute otitis media are well documented and include Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis. Other microorganisms causing acute otitis media include Staphylococcus aureus, S. pyogenes and, in infants under 6 months of age, Escherichia coli. Complications of acute otitis media are more likely to remain intratemporal, and treatment of such disorders should focus on these microorganisms. Mastoiditis, the most common complication of acute otitis media, has similar causative microorganisms, but the clinician must also direct treatment toward Pseudomonas aeruginosa, coagulase negative staphylococci, Proteus species, and anaerobes. Meningitis, the most common intracranial complication of acute otitis media is most commonly caused by S. pneumoniae. The advent of multivalent pneumococcal vaccines may shift this microbiological spectrum as nontypeable H. influenzae becomes a more prevalent cause of acute otitis media.

Chronic otitis media has a different microbiological profile than acute ear infections (Table 2). S. aureus and P. aeruginosa are the typical infective agents. Coagulase negative staphylococci and Proteus species are also frequently seen. Klebsiella species and mixed gram-negative microorganisms and anaerobes may also be found. A significant percentage of cultures of acute and chronic otitis media and their associated complications are sterile. Biofilms in chronic otitis media may also affect culture results and require polymerase chain reaction techniques to identify the pathogens. Many patients with complications of aural infections have been on antibiotics prior to presentation with a cranial or intracranial process and this may affect culture results. The choice of antibiotic should take into account the susceptibility of the microorganism and the ability of the antibiotic to cross the blood-brain barrier.

**DIAGNOSIS**

**Physical Examination**

The history and physical examination remain the cornerstones of an early diagnosis of cranial and intracranial complications associated with otitic infections. A history of a change in alertness or behavior may indicate extratemporal extension of disease or infection. Diminished cognitive responses such as alterations in arousal, somnolence, wakefulness, reduced response to verbal or physical stimulation, or impaired consciousness require emergent assessment. New onset seizures or emesis should also be addressed with haste.

The patient may give a history of an ear infection that has been treated with antibiotics and even myringotomy and tube placement. A history of chronic perforation may be present but does not ensure that the mastoid is aerated. Masked mastoiditis can occur if the antrum is blocked by inflammatory tissue, yet the middle ear may appear relatively free from disease. New onset otorrhea, headache, vertigo, and hearing loss despite treatment are symptoms and signs of severe otitis and impending or early complication. Facial weakness, spiking fevers, vomiting, and changes in alertness suggest extension of disease beyond the tympanum and require urgent evaluation.

The physical examination must include a general head and neck examination and a thorough

Cranial complications of otitic infection is the mainstay of evaluation of cranial and intracranial involvement. Nystagmus or a positive head-thrust refixation test indicates uncal herniation, which suggests intracranial involvement. Cerebellar signs should also be checked with rapid alternating hand movements and finger-to-nose testing. Nystagmus or a positive head-thrust refixation test may indicate labyrinthine involvement.

Radiographic Imaging

The mainstay of evaluation of cranial and intracranial complications of otitic infection is the computed tomography (CT) scan. The CT scan should be performed with contrast to delineate areas of abscess and inflammation as well as reveal flow voids in thrombosed vessels. Aeration of the mastoid should be noted. A sclerotic mastoid suggests an acute exacerbation of chronic ear disease which should increase suspicion for underlying cholesteatoma and focus attention on direct or disseminated intracranial extension. A well-developed mastoid may be found in acute otitis media with associated mastoiditis, and local cranial complications are more likely. Meningitis is more common with acute otomastoiditis. Meningitis is not readily apparent on CT scan, and magnetic resonance imaging (MRI) should be performed before lumbar puncture (LP).

CT bone windows will delineate the osteology of the temporal bone and demonstrate coalescence in the mastoid, dehiscence of the tegmen tympani or tegmen mastoidea, erosion into the sigmoid sinus, and extension of disease through the lateral or medial cortex of the mastoid cavity. The clinician should not focus solely on the temporal bone disease and must also evaluate the entire scan. The brain and intracranial cavity should be examined for intraparenchymal brain abscess, abscess around the dural layers, venous dilatation, and abscessed lymph nodes, deep neck space infections, or Bezold abscess. Localized edema and inflammation of tissue around the temporal bone may suggest a skull base osteomyelitis.

MRI is useful in evaluating for the intracranial complications of acute or chronic otitis media. MRI is usually along the side of ear involvement. Brain abscesses may be difficult to see in the early stages but localized cerebral edema may suggest an impending abscess. In later stages, brain abscesses are easily seen on MRI. Intracranial and venous abscesses are also quite apparent. A magnetic resonance venogram (MRV) can also be included in the MRI evaluation and helps to identify venous thrombosis and the extent of involvement. Localized tissue edema and cellulitis from skull-base osteomyelitis can be more impressive on MRI as compared to findings on CT.

### Lumbar Puncture

Suspicion of infection within the spinal fluid compartment requires a LP. Prior to the LP the patient should undergo neuroradiographic evaluation to assess for hydrocephalus or brain compression from intracranial abscess or pneumocephaly. On physical examination, the presence of papilledema is an ominous finding and necessitates caution and neurologic consultation before the LP is done. LP performed in the face of elevated cerebrospinal fluid (CSF) pressure may lead to brain herniation and death. An opening pressure should be obtained to assess for increased intracranial pressure. In meningitis, normal CSF flow and reabsorption is inhibited, and intracranial pressure increases. The CSF in meningitis typically shows a low glucose level but elevated white blood cell count and protein levels. Culture should be performed for bacterial and fungal growth. Polymerase chain reaction techniques can be used for detection and identification of the microorganism causing the infection including viruses, prions, and tuberculosis.

### Radionuclide Bone Scans

In cases of malignant otitis externa, skull base osteomyelitis, or osteoradionecrosis of the temporal bone with attendant infection, both gallium-67 and technetium-99 scans have been used. These scans provide evidence of an acute inflammatory process and the ability to monitor response to treatment. Gallium will provide a short-term assessment for the response to acute-phase antibiotics and/or surgical drainage, while the technetium scans will provide a longer-term evidence of the resolution of infection. Bone scans are not commonly used in current management as CT and MRI provide high-resolution images of bone involvement and tissue inflammation.

### Cranial Complications

**Mastoiditis**

Mastoiditis denotes inflammation with the mastoid air cell system. Almost all cases of acute otitis media will have radiographic evidence of mastoid fluid or mucosal thickening which represent inflammation. In uncomplicated middle-ear infection, concurrent mastoid involvement should not be considered a complication of acute otitis media and is not a surgical disease. If inflammatory tissue obstructs the aditus ad antrum itself, acute mastoiditis may be followed by chronic mastoiditis. The incidence of acute mastoiditis may be increasing due to resistant bacterial strains.

A cute mastoiditis can cause systemic signs of infection such as fever and malaise. Mastoid tenderness and localized reactive lymphadenopathy is commonly present. In the child with a thin mastoid cortex there may be erythema and/or edema of the overlying mastoid soft tissue. This leads to an unilateral protuberant ear characteristic of this disease. In the adult with a thicker cortex,
local pain may occur, and tenderness may be the only external sign. Typically, in the early stages of mastoiditis, there are concurrent signs of acute infection in the middle ear, and antibiotic therapy alone may be all that is necessary. A aggressive intravenous antibiotic use, especially in children, should be considered. Myringotomy will release pus from the middle ear, remove the nidus of inflammation and should be strongly considered on initial presentation. A complete head and neck examination is critical to identifying impending otosclerosis and intracranial complications and establishing a baseline upon which to gauge response to therapy.

If the aditus block and mastoid inflammation persist, fluid within the mastoid air cells will become increasingly purulent and lead to worsening mucosal edema and venous stasis. The subsequent acidosis and osteoclast activity causes calcification of bone septae and coalescence of air cells into a confluent cavity (Figure 3). This coalescent mastoiditis may develop despite antibiotic treatment and myringotomy. The middle ear infection may appear to have resolved by this time, but the blocked antrum walls off the mastoid from drainage. A antibiotic therapy may be less effective under these circumstances, and the clinician must be attuned to signs and symptoms of such a masked mastoiditis.13 In the patient with chronic otitis media, antral block may lead to acute or coalesce mastoiditis despite the presence of a perforation or resolution of otitis media. Cholesteatoma in chronic otitis media may cause mastoid outlet obstruction and serve as the potential nidus of infection.

There is no definitive algorithm for the treatment of acute or coalescent mastoiditis. The efficacy of modern antimicrobials and the relative efficiency in which disease progression can be radiographically monitored make initial medical therapy of uncomplicated acute and coalescent mastoiditis the preferred option. The early performance of a myringotomy may prevent the development of complications of acute mastoiditis and need for further surgery.4 Failure to improve despite aggressive medical management (including myringotomy with or without tympanoplasty tube placement), the development of other cranial or intracranial complications, or the presence of complications on admission is an indication for mastoid surgery.4 For uncomplicated mastoiditis, the need for mastoidectomy despite admission and intravenous antibiotic therapy is about 10%.21,22 In patients with intracranial complications, the mastoidectomy rate is much higher and can be up to 70%.21,22

The mastoidectomy for complicated acute or coalescent mastoiditis is a difficult operation. There is typically friable granulation tissue throughout the mastoid, antrum, and middle ear. The granulations may be so thick as to prevent the insertion of a ventilation tube. The abundant tissue distorts the anatomy, makes visualization difficult and can cause local bone erosion. Dehiscence of the sigmoid sinus, facial nerve, or labyrinthine fistulae is not uncommon. Cholesteatoma is commonly encountered in chronic otitis media and may cause similar bone destruction and involvement of vital structures.21 Drainage of the mastoid, removal of granulation tissue, and restoration of normal ventilatory pathways should be the goal of the operation. Continuation of antibiotic therapy postoperatively for weeks can eradicate residual disease.

**Facial Paralysis**

Facial nerve paralysis secondary to acute or chronic otitis media represents only about 3 to 5% of all occurrences of acquired facial weakness.24,25 Paralysis from Bell palsy, trauma, herpes zoster oticus, ie, Ramsay Hunt syndrome or Borella burgdorferi, ie, Lyme disease, is more prevalent.24 Nevertheless, it is imperative that the physician carefully inspects the ear for the presence of middle-ear infection or masked mastoiditis.24 The facial nerve paralysis in acute otitis media has usually been present for less than a week whereas facial paralysis in chronic otitis media may have been present a much longer period.24 The severity of the facial palsy in acute and chronic otitis media varies with almost all patients having at least House-Brackmann grade III and 30 to 50% having total facial paralysis.24,27

The cause of facial paralysis with acute otitis media is not clear. Historically, direct pressure on an exposed nerve has been considered a principal cause. However, formal explorations do not consistently reveal fallopian canal dehiscences.22 A neurotrophic effect of the infection, entering the fallopian canal through natural dehiscences or vessel channels, is considered a more likely cause.22 Alternatively, there may be recrudescence of latent herpes virus in previously exposed individuals. In chronic otitis media with facial paralysis, there is a high incidence of cholesteatoma.23,25,29 Direct exposure and pressure on the facial nerve by cholesteatoma are commonly seen. The rate of development of facial paralysis may be rapid if there has been an acute infection but may be slow in onset if secondary to gradual expansion of cholesteatoma.23 In acute otitis media, treatment should consist of systemic antibiotics and myringotomy with or without tympanostomy tube insertion. There does not appear to be a need for mastoidectomy and facial nerve decompression in acute otitis media.24 In chronic otitis media, however, surgical exploration is indicated as the vast majority harbor cholesteatoma.23,29,30 Decompression of the facial nerve is performed in most series, however, finding at mastoidectomy an entirely intact fallopian canal may result in a similar outcome.23,25,27 Removal of cholesteatoma and granulation tissue along the course of the tympanic and mastoid segments of the facial nerve early in the infectious process may improve recovery.24,25

The outcome in patients with acute otitis media is generally excellent with the vast majority returning to a House-Brackmann grade I with appropriate treatment. In chronic otitis media, the outcomes are more variable.24,29 Factors that may determine final facial function include the duration of facial paralysis before presentation and the presence of cholesteatoma at exploration. Facial palsies of greater than 1 year may not show any appreciable improvement after surgical intervention, and the presence of cholesteatoma increases the incidence of residual weakness.24 Involvement at the geniculate ganglion has a worse prognosis than isolated tympanic or mastoid infection.31 Facial paralysis and its management are discussed in Chapter 34, “Facial Paralysis.”

**Subperiosteal Abscess**

Infection within the mastoid can extend through the cortex and form a subperiosteal abscess in the upper neck.32 The absence of full mastoid development in young children may make this age group more resistant to the development of this complication.33 However, hematogenous spread through venous perforators may provide...
Petrous Apicitis

The progressive inflammatory processes that lead to acute mastoiditis can also affect the petrous pyramid (Figure 5). When the pneumatized and narrow containing spaces of the petrous apex become infected, potential routes of drainage can become obstructed and lead to persistent infection. Even if the middle ear and mastoid have been cleared of infection, the petrous apex may still harbor walled-off infection. The lower incidence of acute petrous apicitis as compared to mastoidectomy is attributable to the lower incidence of petrous apex pneumatization in the normal condition thus restricting one route of potential extension of infection.37 Venous channels to the petrous apex may provide additional pathways for dissemination of infection.34

Petrosus apicitis should be suspected if an ipsilateral retrobulbar or deep aural pain persists despite clearance of disease from the middle ear and mastoid.35 The pain of petrous apicitis may be from local dural involvement or proximity to M eckel cave and the trigeminal sensory ganglion. The classic triad of Gradengo syndrome consisting of retrobulbar pain, abducens palsy, and suppurative otorrhea is rarely fully present.35,36 Horner syndrome may also be present due to involvement of sympathetic nerves around the petrous portion of the internal carotid artery. One or more of these symptoms in association with cochleo-vestibular findings, facial weakness or signs of systemic infection should prompt careful evaluation. A CT scan can demonstrate petrous opacification, coalescence, or disruption of local architecture.37

The postcontrast T1 MRI can demonstrate granulation tissue in the petrous apex and around the carotid artery or involving M eckel cave.17

The treatment for petrous apicitis is expedient removal of the source of infection. M yringotomy with or without tube placement, mastoidectomy, and intravenous antibiotics are recommended.36,38 Corticosteroid use may be beneficial if cranial neuropathies are present although this had not been definitively studied. If drainage of the petrous apex becomes necessary, several routes have been defined. These include transnasal/transsphenoidal drainage if the anatomy is favorable, although a transstympnic sub-cochlear drainage is the least invasive route via the petrous ridge. Because numerous cell tracts will allow passage to the petrous apex, CT scanning of the temporal bone will provide preoperative visualization for potential routes of access.

Labyrinthitis

Inflammation within the labyrinth associated with acute and chronic otitis media produces hearing loss and vertigo. The two principal forms of labyrinthitis that may develop are serous labyrinthitis and suppurative labyrinthitis. Serous labyrinthitis is thought to involve the translocation of bacterial toxins or inflammatory mediators to the inner ear without invasion of the labyrinth by the bacterial pathogen. In contrast, suppurative labyrinthitis is a fulminant bacterial infection within the inner ear. Labyrinthitis is more commonly associated with acute otitis media.39

Serous labyrinthitis typically presents with sudden onset vertigo in the setting of acute otitis media. It is less commonly found with chronic otitis media but can also be secondary to meningitis. Infectious or inflammatory elements in meningitis can follow the cochlear aqueduct to enter the inner ear and lead to labyrinthitis ossificans.40 The most common microorganism in meningitis-induced hearing loss is S. pneumoniae.41 The diagnosis of labyrinthitis is typically clinical, but inflammation in the labyrinth can be visualized with postcontrast T1-weighted MR scans.17 The treatment of acute serous labyrinthitis secondary to acute otitis media is myringotomy and antibiotics. M astoidectomy may be necessary if disease persists or progresses to suppurative labyrinthitis. Hearing loss with serous labyrinthitis is rarely profound and can improve following the resolution of infection. Vertigo and imbalance, as in vestibular neuritis, may persist for several months but is rarely permanent.
Suppurative labyrinthitis represents invasion of the inner ear by the bacterial organisms. It is thought that entry to the inner ear is via the round window membrane although other potential routes include otic capsule fistulae and venous channels. Suppurative labyrinthitis can progress to meningitis and intracranial abscess. The hearing loss with suppurative labyrinthitis is usually severe to profound and has a poor prognosis for recovery. Treatment for this condition includes myringotomy and intravenous antibiotics with a low threshold for mastoidectomy based upon clinical examination. In rare occasions the labyrinth may require surgical drainage to control intracranial disease. Corticosteroids are a consideration in labyrinthitis to reduce inflammation, improve hearing outcomes, and prevent labyrinthitis ossificans (Figure 6). Their use depends on the entire clinical picture.

### Labyrinthine Fistula

Labyrinthine fistula is almost exclusively reported in association with chronic otitis media and cholesteatoma, although otic capsule defects have been seen in noncholesteatomatous ear disease. The incidence of labyrinthine fistula in chronic otitis media is approximately 10%, although the most commonly affected canal is the lateral (or horizontal) semicircular canal, but involvement of the posterior and superior canals as well as other regions of the labyrinth and cochlea have been reported. The existence of a labyrinthine fistula is highly correlated with concurrent involvement of the facial nerve, with tegmen defects, and with ossicular erosion.

The clinical history is typical for chronic otitis media and cholesteatoma with only subtle differences between patients with or without labyrinthine fistulae. While a labyrinthine fistula may cause dizziness, most patients with labyrinthine fistulae do not have imbalance. Rather, patients may present with intermittent vertigo or with the Tullio phenomenon in which they report vertigo and oscillopsia with loud noises or aural pressure changes. Signs of a fistula may be evoked clinically by the application of pressure to the ear with pneumatic otoscopy, ie, Hennebert sign. The direction of eye movements during the fistula test may help identify which semicircular canal is involved, but a high-resolution CT scan will provide better definition of the extent of the cholesteatoma and otic capsule defects.

Management of a labyrinthine fistula due to chronic otitis media and cholesteatoma is surgical and typically requires a canal wall down mastoidectomy. The region of suspected fistula should be approached carefully, and the cholesteatoma matrix left over the area until the rest of the operation is completed. This protects the inner ear from inadvertent suctioning and from the debris created by the drill. Once the remainder of the cholesteatoma and infection has been removed, the fistula is addressed. Typically, the cholesteatoma can be gently elevated off the membranous labyrinth, and constant irrigation will prevent excess perilymph leakage. The defect can be sealed with combinations of fascia, perichondrium and bone dust. Alternative management is to leave the cholesteatoma matrix over the fistula and externalize the matrix of the cholesteatoma by radical mastoidectomy. This approach is not preferred as the Tullio phenomenon may persist if the dehiscence is not addressed, and the remaining matrix may have continued toxic effects on the inner ear.

### CSF Leak and Encephalocele

A tegmen dehiscence sufficient to cause a CSF leak or encephalocele is a rare complication of acute otitis media. More commonly, a spontaneous CSF leak is mistaken for acute otitis media and identified after myringotomy and tube placement. In chronic otitis media, however, the recurrent episodes of inflammation may lead to thinning of the tegmen and ultimately tearing of the middle or posterior fossa dura. A tegmen dehiscence is more common in the presence of cholesteatoma and may allow for encephalocele formation. Following appropriate antibiotic coverage, the leak should be sealed via a translabyrinthine or intracranial approach. For leaks managed via the intracranial route, either extradural or intradural repairs may be performed.

### Intracranial Complications

#### Meningitis

Meningitis is the most common intracranial complication of acute otitis media in children and adults. In recent years, S. pneumoniae has replaced H. influenzae type B as the most common organism identified in childhood meningitis. This change in microbial profile is likely secondary to the introduction of the Hib vaccine. Access to the intracranial space and CSF may be by any of the aforementioned anatomical pathways. In acute otitis media, entry into the CSF via the labyrinth and cochlear aqueduct is more likely in congenital abnormalities of the inner ear such as Mondini malformation. Infection may also spread hematogenously through venous channels or directly through bony dehiscences in the middle and posterior fossa plates. Dehiscences predisposing to bacterial meningitis may arise from chronic otitis media, cholesteatoma, encephalocele, or trauma.

The mortality from bacterial meningitis ranges from 5%, to as high as 30%, in some series. Factors associated with an unfavorable outcome are advanced age, a positive blood
culture, tachycardia, a low CSF leukocyte count, and severe mental status changes on admission. The occurrence of meningitis from complications of otitis media or sinusitis portends a worse outcome. M. meningitidis from S. pneumoniae carries a worse prognosis for survival than meningococcal meningitis.62

Patients with meningitis typically complain of severe headache but this is not a particularly specific symptom. More specific for meningitis are complaints of fever, neck stiffness, and altered mental status which comprise the classic triad of meningitis. This triad is not usually present in its entirety on initial presentation.63,64 However, at least two of four symptoms, ie, headache plus the triad, can be found in over 95% of patients with bacterial meningitis.62 In addition to assessing temperature and general mental status, examination for meningitis typically focuses on identifying meningeal irritation and its effect on neck mobility.

Nuchal rigidity can be assessed by asking the patient to touch the chin to the chest or to move the chin alternately from shoulder to shoulder. Kernig sign is the presence of back or leg pain when the patient is in the supine position and one leg is passively flexed at the hip and then extended at the knee. Brudzinski sign is also performed in the supine position and involves passively flexing the neck. A positive sign is the observation of reflex bilateral hip and knee flexion to lift the legs. These tests are commonly used but appear to have poor sensitivity for detecting meningitis.63 Therefore, the absence of these findings should not influence the decision to perform further evaluation in the patient suspected of having meningitis.

Meningitis signs in association with acute or chronic otitis media may also reflect other intracranial complications such as brain abscess or venous thrombophlebitis. Obtaining a CT scan with contrast is critical for evaluating a patient for these conditions and also serves to determine whether the performance of a LP is contraindicated. MRI scans can also rule out other intracranial pathology and demonstrate dural enhancement and thickening suggestive of meningitis.

The LP is the mainstay of diagnosing meningitis. CSF should be sent for cytology, chemistry, and smear and culture. The CSF may be turbid. Opening pressures may be elevated due to alterations in CSF circulation with meningeal inflammation. Cytology shows elevated white cells (generally >100 cells/µL) and increased neutrophils in bacterial meningitis. Microorganisms may be tentatively identified on Gram stain and the chemistry may demonstrate a low glucose and high protein in bacterial infections as opposed to viral meningitis. The cultures can demonstrate and identify the microorganism but may show no growth if antibiotics have been previously administered. Treatment consists of early administration of intravenous antibiotics. A delay in antibiotic administration may be associated with an increased long-term mortality.63 The antibiotic should be broad spectrum and cover potentially resistant microorganisms. The usual initial regimen consists of ceftriaxone or cefotaxime which have good CSF penetration in the presence of inflammation. Vancomycin is recommended to cover resistant microorganisms but may be discontinued if culture and sensitivity so indicate. In older patients without penicillin allergy, ampicillin is recommended to cover for Listeria monocytogenes, but this is more likely in community-acquired meningitis rather than otitic meningitis.

Corticosteroids are strongly recommended early in the course of meningitis to reduce the incidence of subsequent hearing loss and overall mortality in children and adults, respectively.63,65,66 Dexamethasone dosing varies in reports but is between 0.4 and 1.5 mg/kg/d in children and about 10 mg every 6 hours in the adult over the first 4 days of treatment.66 Timing appears critical, and the first dose should be administered just before, or with, the initial dose of antibiotics. Corticosteroids may alter the blood–brain barrier and affect antibiotic levels in the CSF. The cephalosporins do not appear to be affected, but vancomycin levels may be reduced. Few adverse side effects have been noted from corticosteroid use in meningitis.

In acute otitis media, antibiotic therapy alone can control the meningitis and clear the middle ear of infection.21 Myringotomy should be performed immediately in the patient with a sudden change in mental status. Surgical management of the mastoid should be undertaken to remove the nidus of infection in cases of chronic otitis media or additional cranial and intracranial complications. Continued assessment clinically and radiographically during the course of treatment is necessary to identify further complications and ensure that surgical intervention is undertaken expeditiously.

Venous Thrombosis

Septic thrombophlebitis may obviate the venous drainage system adjacent to the petrous pyramid. Sigmoid sinus thrombosis is the second most common intracranial complication of otitis media and has a mortality rate of about 10%.60,67,68 The process generally starts with an acute or chronic otitis media that progresses to involve the sigmoid sinus directly. Erosion of bone over the sigmoid sinus should be removed. Sigmoid sinus thrombosis is associated with sinusitis, and clot may involve the transverse sinus and torcular. Distal propagation can cause obstruction of the jugular bulb and jugular vein. The thrombus commonly progresses to involve one or more of these sites by the time of diagnosis.63 In the rare occasion when obstruction crosses the midline, an acute intracranial event may lead to severe and rapid central venous obstruction, hydrocephalus, intracranial edema, and death.

Presenting symptoms and signs are variable, and the classic picket fence spiking fevers may not be present. Headache and otalgia are usually present with rare exception.69–71 Other symptoms include otorrhea, mental status changes, nausea or emesis, and photophobia. The examination may reveal an intact or perforated tympanic membrane, purulent drainage, edema of the skin of the ear canal, and soft tissue changes over the mastoid. Griesinger sign is erythema, edema, and tenderness over the posterior part of the mastoid process due to septic thrombosis of mastoid emissary veins indicating thrombophlebitis of the sigmoid sinus.68–71 Involvement of the jugular foramen may cause paresis of the glossopharyngeal, vagus, and spinal accessory nerves. Rarely, abducens palsy has been observed.

Neuroradiographic evaluation with contrast-enhanced CT or MR is available. Venous thrombosis may be identified radiographically during the course of treatment.69–71 CT and MR should also be used to evaluate the patient for other cranial and intracranial complications as these are commonly found in conjunction with sigmoid sinus thrombosis.69 LP should be performed to assess intracranial pressure and to evaluate for concurrent meningitis. Digital pressure over the nonoccluded internal jugular vein may cause a rise in CSF pressure whereas compression of the occluded side will have no effect, ie, Toly–Ayer–Queckenstedt test. Elevated intracranial pressure with sigmoid sinus thrombosis is characteristic of otic hydrocephalus.

Treatment consists of broad-spectrum intravenous antibiotics and an urgent complete mastoidectomy. In addition to covering the usual aerobic pathogens such as Staphylococcus species and Staphylococcus species, therapy should include coverage for mixed flora such as Bacteroides species and Proteus species.69,70 During mastoidectomy, granulations and inflammation overlying the sigmoid sinus should be removed. Sulfuric intervention directed at the thrombosed vessels is controversial. Some authors have recommended thrombectomy, ligation, or resection of the sigmoid sinus.68,70 Others have noted that conservative management of the sinus is equally effective.69,72 Additionally, the employment of anticoagulation remains controversial.71 In patients in whom there appears to be a seeding of the distal venous architecture and the potential for embolic phenomenon impacting the cardiovascular system, utilization of anticoagulant medication is warranted. A ditionally, septic emboli that continue to shower distal sites may necessitate the extirpation or ligation of the involved venous structures in the neck.

Intracranial Abscess

Bacteria can spread from the temporal bone to the intracranial compartment and establish distinct loci of infection. A bcesses can form in the epidural space, between the dura and arachnoid.
land, MD, PhD.)

Published with permission, copyright © 2007 D.R. Friedland, MD, PhD.)

Epidural Abscess. Direct extension of middle ear or mastoid infection tissue through the bony confines of the temporal bone into the middle or posterior fossae leads to an epidural abscess (Figure 8). Bone erosion can be caused by coalescence, cholesteatoma, or granulation tissue. Localized granulation tissue and purulent material may remain fairly quiescent for a protracted period of time before manifesting as an epidural abscess. Silent epidural abscesses, found only at exploration, have been reported. The abscess may form along either the posterior fossa dura or adjacent to the superior petrosal vein and the middle fossa dura. Epidural abscess formation around the sigmoid sinus is referred to as a perisinus abscess.

Symptoms are variable and can be quite mild. Chronic low-grade fevers and a dull headache are often the only clinical symptoms. Resolution of acute otitis media may occur inspite of persistent mastoid infection and provide a false sense of improvement. Granulation tissue in the tympanicum should raise the suspicion of an impending complication. Exacerbations of infection may lead to invasion of venous structures around the epidural abscess. On the left side, inflammation around the vein of Labbé may occur with the patient presenting with speech difficulties and aphasia. CT scan with contrast can demonstrate bone erosion along the posterior or middle fossae and rim enhancement of the epidural abscess. Gadolinium enhanced MRI can be used to identify intracranial abscess and thrombosis of surrounding vessels. Treatment is surgical and entails mastoidectomy with direct drainage of the abscess. Cultures should be taken to direct antibiotic therapy.

Subdural Empyema. Infection in the potential space between the dural and pia-arachnoid layers can produce a localized collection of pus more accurately referred to as subdural empyema rather than an abscess (Figure 9). Subdural empyema is the least common complication of otitis media and is seen more commonly with sinusitis and trauma. It was found in only 1 of 70 patients with complications of chronic otitis media and 1 of 68 patients with complications of acute otitis media. Although rare, it is one of the most serious of the otitic intracranial complications. Mortality rates are as high as 15% in recent years, and permanent morbidity in the form of seizures and neurological deficits can occur in over 30% of survivors.

The clinical presentation is usually rapidly progressive and severe. Menigitis signs of fever, headache, altered mental status, and emesis are typically present and can progress within 48 hours to seizures, focal neurological deficits, and coma. Contrast-enhanced CT scan can demonstrate a widened subdural space and resultant flattening of surrounding cerebral sulci. Subdural empyema of otitic origin will generally form along the tentorium cerebelli and the interhemispheric fissure. MRI may demonstrate changes in the surrounding cerebral cortex which can become edematous or necrotic and cause a mass effect. Diffusion weighted images can distinguish subdural empyema by its high signal from the mixed signal appearance of epidural abscesses.

Surgical drainage of the abscess and decompression of the brain should be undertaken by a neurosurgeon emergently. Concurrent mastoidectomy and myringotomy are performed to address the source of infection. Parenteral antibiotics should provide broad coverage and, based upon findings in subdural empyema from sinusitis, be directed at microorganisms more common in chronic rather than acute ear disease. Cultures obtained during drainage of the subdural empyema should direct further antimicrobial treatment.
Brain Abscess. Spread of otitic infection beyond the meninges can lead to the formation of cellitis (cerebritis) and abscess within the brain parenchyma (Figure 10). Generally resultant from retrograde thrombophbites, brain abscesses consist of a focal mass and localized signs reflective of the site of invasion. Cerebellar, as well as, temporal lobe abscesses have historically been reported as resulting from uncontrolled and untreated mastoiditis.80 Brain abscesses due to otitic media form almost exclusively ipsilateral to the ear infection. Otitic sources account for 10 to 20% of all brain abscesses.10,81,82 Age of presentation appears to be bimodal with brain abscesses of all causes occurring most commonly in children younger than 10 years and in adults between 30 and 50 years.81,82 Mortality from brain abscesses is about 10% in the modern era of CT and antibiotics.80,83,84

Symptoms and signs of brain abscess are dependent on the stage of development of the abscess. There is a period of early and late stage cerebritis which occurs over the first week to 10 days following entry of bacteria to the brain.80,83,85 During the early period, an inflammatory response develops around the thrombophilebitic vessels and, as the infection progresses, the late stage heralds the body’s attempt to restrict the infection to one region of the brain. The cerebritis stage may present with headache, fluctuating temperatures, depressed mental status, and generalized malaise. The late stage cerebritis, when the infection is being isolated by the body, can be mistaken for recovery as symptoms may seem to improve or abate. In the second week following infection the localized inflammation becomes purulent and is encapsulated forming a discrete abscess. The encapsulation stage is heralded by signs of suddenly increased intracranial pressure due to the mass effect of the abscess.79,80

![Figure 10](image-url) Magnetic resonance imaging showing a well-encapsulated brain abscess of otitic origin in the left temporal lobe. The coronal image shows an abscess in the early encapsulation phase (arrows) forming over an inflamed mastoid. Brain abscesses of otitic origin typically form in the ipsilateral temporal lobe or cerebellum. (Published with permission, copyright © 2007 D.R. Friedland, M.D., PhD.)

The complete classic triad of headache, fever, and focal neurological deficits is rarely seen, and other findings are vomiting, seizures, change in mental status, papilledema, and meningism. As with other intracranial complications, immuno-compromised patients, including diabetics, those being treated for active HIV infection, and those individuals on chemotherapeutic regimens may have a paucity of symptoms.

Typically, otitis media has been identified and treated by the late cerebritis stage and may appear to improve along with the clinical symptoms. A sudden worsening of symptoms should prompt radiographic evaluation with contrast-enhanced CT scan. A reas of low attenuation may be all that is seen in the cerebritis stage. Rim-enhancing abscess will be apparent as disease progresses to the encapsulation stage. CT will also demonstrate mass effect, hydrocephalus, and other intracranial complications of otitis media. MRI imaging can demonstrate surrounding areas of edema, dural changes suggestive of meningitis, flow in the venous system, and CSF flow in the ventricular system. Diffusion weighted MRI scans can distinguish abscesses from other lesions of the central nervous system (CNS) due to restricted diffusion in pyogenic lesions.79 LP is not useful in evaluating for brain abscess and rarely provides a microorganism for identification.82

Treatment of brain abscess of otitic origin requires mastoidectomy to address the source of infection. M yringotomy or tube placement can be performed concurrently. Otologic surgery should be performed after the patient is neurologically and medically stabilized. Broad-spectrum antibiotics should be started as aerobic and anaerobic microorganisms are commonly seen.81,82,84 Neurosurgical consultation should be sought urgently regarding management of the abscess. Medical therapy in the early stage may abort encapsulation and abscess formation. Small abscesses, high risk patients, multiple abscesses, or those with a good response to initial therapy may be managed without neurosurgical intervention.80–82 Serial CT or MRI scans should be performed to monitor for abscess growth. A spiration of the abscess is the most common surgical intervention and can be performed stereotactically, through a burr hole, or open craniotomy.10,81,86 A spiration is primarily to decompress the abscess and provide a sample for microorganism identification. Surgical excision of the abscess is rarely necessary but cerebellar abscesses should be aggressively managed as they portend a worse outcome due to potential CSF obstruction.80

Oitic Hydrocephalus. Oitic hydrocephalus is an increase in CSF pressure in the presence of acute or chronic otitis media. By definition, otitic hydrocephalus is not secondary to brain abscess or meningitis. It is, however, almost exclusively associated with sigmoid sinus thrombosis although not all cases of venous thrombosis show increases in intracranial pressure. Thrombosis of the central venous sinuses can impede absorption of CSF and raise intracranial pressures.87 Ventricular dilation does not occur as the pathways for CSF circulation remain patent.

Patients typically present with headache, visual changes, and emesis. They may also exhibit changes in mental status, changes in wakefulness, and dizziness or imbalance. On physical examination, there is evidence of acute or chronic otitis media and commonly an abducens nerve palsy.86 Fundoscopic examination reveals papilledema, but the presence of papilledema does not always imply an increased CSF pressure. An MRI should be performed to assess other intracranial complications, and the MRI or MRV will clearly demonstrate a sigmoid sinus thrombosis.89 LP should be performed in suspicious cases and an opening pressure of greater than 240 mm H2O with normal CSF chemistry and cytology is diagnostic.88

Treatment should be directed at the underlying otitic media and sigmoid sinus thrombosis. There may be potential benefit to reestablishing flow in a fully thrombosed sigmoid sinus by thrombectomy, but this is controversial. Regulation of intracranial pressure and protection of the optic nerve with corticosteroids, diuretics, or serial LPs should be considered. Ophthalmologic consultation and monitoring of visual acuity and visual fields are recommended.

Reconstruction of the Middle Ear

Saumil N. Merchant, MD  
John J. Rosowski, PhD  
Clough Shelton, MD

INTRODUCTION

Tymanoplasty is a surgical procedure designed to reconstruct the sound transmission mechanism of the middle ear. The modern era of tymanoplasty was ushered in during the 1950s with the pioneering work of Wullstein1 and Zollner.2 Subsequently, many other otologic surgeons contributed to the development and refinement of techniques of tymanoplasty. The most common indication for tymanoplasty is to repair a defect of the middle ear caused by chronic otitis media (COM). Tymanoplasty is also indicated for the repair of middle ear defects resulting from other causes such as trauma and neoplasms. Tymanoplasty may be combined with mastoidectomy performed for control of infection in COM. Techniques to repair traumatic lesions of the middle ear are described in Chapter 21, “Trauma to the Middle Ear, Inner Ear, and Temporal Bone” and mastoidectomy procedures are described in Chapter 17, “Chronic Otitis Media and Cholesteatoma.” This chapter focuses on tymanoplasty in COM.

PHYSIOLOGIC PRINCIPLES OF TYMANOPLASTY

It is helpful to review the functions of the normal middle ear to understand the physiologic basis of successful tymanoplasty. The tympanic membrane (TM)-ossicular system of the normal ear amplifies the sound pressure at the oval window compared to the sound pressure in the ear canal; this amplification is termed “the middle ear gain.” The gain provided by the average normal ear is only about 20 dB (a factor of 10).3 Most of the gain is a result of the TM to stapes footplate area ratio: the TM gathers force over its surface and the ossicles couple the gathered force to the smaller footplate of the stapes. Only about 2 dB of gain is provided by the ossicular lever that results from the difference in length of the rotating malleus and incus lever arms, (manubrium vs. incus long process). Some of the amplification provided by the area and lever ratios is used to overcome the stiffness, mass and damping within the TM and ossicular system, so the resultant gain is smaller than expected from calculations based on anatomy and also varies with frequency.3

The middle ear cavity (the air space behind the TM) enables motion of the TM and ossicles by providing a compressible air cushion. When sound in the ear canal strikes the TM, most of the gathered force is used to move the TM, ossicles and the cochlear fluids, but about one-third to one-tenth of the gathered force acts to compress and rarify the air in the enclosed cavity. The result is a sound pressure within the cavity that is 10 to 20 dB lower than the ear canal sound pressure and a trans-membrane difference in sound pressure that is proportional to the drive on the TM and the ossicles.

The increase in sound pressure relative to the oval window is significantly greater than that at the round window.5 Since sound can vary in both its magnitude and relative phase, it is important to understand that the sound-pressure difference at the cochlear windows is affected by differences in the magnitudes and phases of the individual sounds at the windows. One simplification is that differences in magnitude can overwhelm differences in phase. In the normal ear, the difference in magnitude between the sounds acting on the two windows is at least 30 dB. The middle ear gain increases the pressures at the oval window by 20 dB, and sound pressure acting on the round window is the middle ear cavity pressure, which is at least 10 dB smaller than the ear canal sound stimulus. In the normal ear and after successful tymanoplasty, the magnitude of sound pressure at the oval window is significantly greater than that at the round window, and under these circumstances, differences in phase have little effect on determining the window pressure difference.6

It follows from this discussion that the goal of a tymanoplasty should be to restore the difference in sound pressure at the cochlear windows, by (1) reconstructing a TM-ossicular system to amplify the sound pressure at the oval window, and (2) reducing the sound pressure at the round window by placing a reconstructed TM, and an air-filled middle ear space between the ear canal and the round window. In reconstructing the TM-ossicular system, the surgeon should concentrate on restoring the TM-to-stapes area ratio rather than the less important ossicular lever. It is noteworthy that other considerations require that the reconstructed stapes footplate should have an area similar to that of the normal stapes,7 so that minimizing footplate area to maintain a “normal” area ratio is not a viable reconstructive philosophy. It should also be clear that establishing an aerated middle ear cavity that allows motion of the reconstructed TM and reduces the sound pressure acting on the round window is a prerequisite for the success of any tymanoplasty.

PREOPERATIVE CONSIDERATIONS

Tymanoplasty can be considered when there is a conductive hearing loss of 30 dB or greater in an ear with COM that has good cochlear function. It can also be considered for repair of a TM perforation to eliminate the need for water precautions. Tymanoplasty carries a small risk of inducing a sensorineural hearing loss. Therefore, an only hearing ear or much better hearing ear is a contraindication for tymanoplasty.

Surgical decision-making in a patient with COM must be individualized. Several factors should be considered including the hearing levels in the diseased and contralateral ear, the pathology and activity of COM, and the age, general health and medical condition of the patient. These factors must be modified by the experience and talent of the otologic surgeon.

At the outset, it is critical to make an accurate diagnostic assessment of the type and nature of COM in each patient when contemplating tymanoplasty. First, one should distinguish between COM with and without cholesteatoma. Patients with cholesteatoma generally need a mastoidectomy or atticotomy to eradicate the cholesteatoma in addition to tymanoplasty to restore hearing. In such cases, tymanoplasty could be combined with mastoidectomy or be performed at a second stage (see later under staging). Patients who have COM without cholesteatoma may be conveniently divided into three categories: active COM, characterized by a perforated TM with otorrhea, inactive COM, characterized by a dry perforation, and inactive COM with frequent reactivation, characterized by ears that drain intermittently.8 A cleft COM without cholesteatoma should be treated medically to control infection and eliminate otorrhea, thus converting the process to inactive COM. Expectant observation for 4 to 6 months is recommended, and if the ear remains dry, then elective tymanoplasty may be performed. Failure of medical management
in active COM without cholesteatoma generally indicates the presence of irreversible disease in the middle ear and mastoid (typically granulation tissue) and is best treated by combining mastoidectomy with tympanoplasty. Inactive COM with frequent reactivation needs attention to inciting events such as water exposure. If there are no obvious predisposing events, then mastoidectomy is generally recommended in conjunction with tympanoplasty to eliminate infection and granulation in the mastoid tracts, antrum, and epitympanum. Failure to recognize and treat cholesteatoma or potential infection in the middle ear and mastoid is a common cause of failed tympanoplasty.

Children under 5 years of age are not good candidates for tympanoplasty because of risk of subsequent failure from otitis media and poor eustachian tube function. For the elderly and for adults with serious medical problems, one has to determine whether the benefits of surgery outweigh the risks of anesthesia.

Patients with a history of multiple failed tympanoplasty procedures are likely to have insurmountable hurdles, including nonfunctioning eustachian tubes, middle ear fibrosis, and tendency for failure of TM grafts and extrusion of prostheses. In such patients, the goal of chronic ear surgery should be to make the ear safe and dry, and hearing improvement should be achieved by amplification or a bone-anchored hearing aid, rather than additional tympanoplasty surgery.

PREOPERATIVE EVALUATION

The preoperative evaluation should include a complete otologic and medical history, otologic and head and neck examination, and audiometric evaluation. Evaluation using an otomicroscope can provide a wealth of useful information to the trained eye. The size and shape of a perforation should be noted, which in conjunction with the extent of anterior canal wall convexity will help to determine the appropriate surgical approach. A retraction pocket of the pars tensa or pars flaccida with retention of keratin debris signifies a cholesteatoma. Signs of infection may be obvious, such as pooling of pus in the middle ear, or subtle, such as minute granulations at the margins of a perforation. As previously noted, the presence of a cholesteatoma or infection may signify the need to consider an atticotomy or mastoidectomy in addition to the tympanoplasty to eradicate the infection.

Otomicroscopic examination can also help one to assess the integrity of the ossicular chain. Malleus mobility can be evaluated by pneumatic otoscopy if the TM is intact. A perforation may allow for inspection of the continuity of the incus and stapes. Chalky white plaques of tympanosclerosis around the oval window may signify fixation of the footplate, in which case a second-stage stapedotomy may be necessary.

A functioning eustachian tube is critical to the success of tympanoplasty. However, tests of tubal function that can be used preoperatively as a reliable predictor of surgical success do not exist.11,12 Indirect indicators for poor eustachian tube function include bilateral disease, chronic serous otitis media in the contralateral ear, fibrocytic obliteration of the middle ear and mastoid air spaces, uncontrolled rhinosinusitis, cleft palate, and other skull base abnormalities.

Preoperative audiologic evaluation should include a pure tone audiogram with adequate masking and speech discrimination testing. Assessment of the audiometric profile can help the clinician anticipate middle ear pathology which in turn can help in preoperative planning and counseling. Perforations of the TM result in a predominantly low frequency conductive hearing loss that is roughly proportionate to the size of the perforation.13 An air-bone gap that is disproportionately large for a given perforation may indicate ossicular discontinuity or fixation. A piece of cigarette paper or gelfilm coated with ointment may be placed over the perforation with assessment of hearing before and after application of the patch. Lack of hearing improvement after placing the patch indicates ossicular problems such as fixation or discontinuity.

Ossicular discontinuity in the presence of an intact TM results in a relatively flat, 60- to 60-dB air-bone gap on audiometry. Ossicular discontinuity in the presence of a perforation gives a somewhat smaller air-bone gap of about 40 to 50 dB. Resorption of the incudostapedial joint and its replacement by a fibrous band may result in an air-bone gap that is greater at the higher frequencies than at the lower frequencies and may be manifest as fluctuating hearing loss with better hearing thresholds when the ear is autoinflated. Lateral displacement of the TM and incus by autoinflation causes the fibrous band to become taut, improving sound transmission.

An air-bone gap in a patient with an intact, healthy TM and an aerated middle ear usually indicates ossicular fixation. Stapes fixation due to tympanosclerosis or otosclerosis can result in an air-bone gap of up to 50 to 60 dB. In contrast, isolated fixation of the malleus head usually results in an air-bone gap of no more than 20 to 30 dB. Less commonly, lesions of the inner ear (such as superior semicircular canal dehiscence or an enlarged vestibular aqueduct) can present with an air-bone gap mimicking ossicular fixation.12 Distinguishing features of air-bone gaps caused by such inner ear lesions are: (1) bone conduction thresholds below 2,000 Hz may be better than 0 dB (~5 to ~15 dB); hence it is important for the audiologist to determine true bone conduction thresholds in ears with an air-bone gap rather than terminate testing when a threshold of 0 dB is attained; (2) the stapedial (acoustic) reflex is present, as opposed to ears with ossicular lesions where the reflex is abolished; and (3) thresholds for the vestibular evoked myogenic potential (VEMP) test are lower than normal. High-resolution computed tomography (CT) will help confirm a suspected diagnosis of an inner ear lesion such as superior semicircular canal dehiscence or enlarged vestibular aqueduct.

CLASSIFICATION AND SURGICAL TECHNIQUES

We present a modified version of Wullstein’s original classification. Tympanoplasties are classified as types I–V, wherein type I involves reconstruction of only the TM, while types II–V involve reconstruction of the ossicular chain with or without repair of the TM. Table 1 lists the various types of tympanoplasty, which are discussed in more detail below.

Tympanoplasty may be performed under local or general anesthesia, and via a transcanal, endaural, or postauricular incision. The choice of incision depends on several factors including the nature of the anticipated pathology and reconstruction, the desired degree of exposure of the tympanic cavity, the state of the patient’s ear canal and external auditory meatus, whether additional mastoid or atticotomy procedures are contemplated, and preference of the otologic surgeon. Informed consent should also be obtained. A large number of tympanoplasty methods and techniques have been described over the past five decades. This chapter provides an overview of basic techniques.

Type I Tympanoplasty

Type I tympanoplasty refers to repair of the TM without altering the ossicular system. The procedure includes exploration of the middle ear to inspect and ensure normality of the ossicles. Myringoplasty refers to repair of the TM alone, without inspection of the ossicular chain. A large variety of tissue grafts have been described for type I tympanoplasty including temporalis fascia, perichondrium, cartilage, periosteum, ear lobe adipose tissue, etc.13 Furthermore, a large number of techniques have been described for repair of perforations, depending on the size and location of the perforation. Type I tympanoplasty is the most commonly performed tympanoplasty.

For small posterior perforations or small central perforations, a commonly used technique is the medial onlay grafting technique, also called the underlay technique (Figures 1A and 2). The edges of the perforation are freshened with a sharp pick, followed by elevation of a tympanomeatal flap. The medial surface of the TM remnant is inspected under high magnification to identify and remove squamous epithelium that may have migrated through the perforation onto the medial surface of the TM. The ossicles are inspected and their mobility is confirmed. It may be necessary to remove a small amount of bone of the ear canal near the annulus in the posterior-superior quadrant to obtain an adequate view of the incus and stapes. A tissue graft such as that of temporalis fascia is trimmed to approximately double the area of the perforation and then placed medial to the TM. The middle ear is filled with pledgets of gelfoam to support the graft on its undersurface.
If the perforation is in the anterior half of the TM or if the perforation is of a subtotal or total nature, then the medial onlay technique described above may fail because the anterior edge of the graft falls away from and fails to adhere to the anterior remnant of the TM. In such cases of large or anteriorly situated perforations, two techniques that can be utilized are the lateral onlay technique or the technique of total drum replacement (Figure 1B). Both techniques are similar and are described below. While technically demanding, both methods are extremely reliable with graft-take rates in excess of 95%.

The perforation is approached via an endaural or postauricular incision. The skin of the bony ear canal is elevated and either preserved for replacement at the end, or resected if skin grafting is utilized. The bony ear canal is then enlarged (canalplasty) using liberal irrigation to avoid overheating the tympanic bone. Care is taken to avoid trauma to the capsule of the temporomandibular joint and its contents. In the lateral onlay technique (also called overlay tympanoplasty), all epithelium is removed from the surface of the TM remnant, while preserving its fibrous layer. A graft of temporalis fascia is then placed on the lateral surface of the TM remnant but with a slit made in the graft, so that the graft goes deep to the manubrium and can be wrapped around the neck of the malleus. In the total drum replacement technique, the entire remnant of the TM is replaced.

Figure 1 Type I tympanoplasty: repair of a tympanic membrane perforation with a tissue graft in the presence of an intact and mobile ossicular chain. (A) Schematic showing repair of a small perforation of the tympanic membrane with a medial onlay fascial graft (also called an underlay graft). (B) Schematic showing repair of the entire tympanic membrane with temporalis fascia (total drum replacement). (Published with permission, copyright © 2006 S.N. Merchant.)

Figure 2 Type I tympanoplasty by the medial onlay grafting (also called underlay) technique. Schematics depict surgical view of right tympanic membrane. (A) Showing incision made in skin of posterior canal wall. This is followed by elevation of a tympanomeatal flap which is reflected anteriorly. (B) The middle ear is inspected and the ossicles are palpated to confirm integrity of the ossicular chain. If necessary, the bony sulcus tympanicus is removed as depicted by the dotted line to improve visualization of the ossicular chain. (C) A graft of temporalis fascia is placed so that it will be on the medial aspect of the tympanomeatal flap. (D) The tympanomeatal flap is replaced. Gelfoam packing is usually used to fill the tympanic space between the graft and the medial wall of the middle ear, which helps to hold the graft in place against the under surface of the tympanic membrane. (Published with permission, copyright © 2006 S.N. Merchant.)
removed. A graft of temporalis fascia is trimmed to an appropriate size that will bridge the entire tympanic space and reflect approximately 3 mm onto the walls of the bony canal. A slit in the graft enables the graft to be placed medial to the manubrium and be wrapped around the neck of the malleus. The remainder of the procedure is similar in both techniques. The exposed bony canal is covered with canal skin that was saved initially, or with split-thickness skin grafts harvested from the upper arm. In this manner, all raw surfaces of the ear canal are covered with epithelium. This is followed by carefully packing the ear canal to hold the reconstruction in place. The success of the lateral onlay and total drum replacement techniques depends on recreating a sharp anterior tympanomeatal angle so as to prevent blunting, as well as placing the fascia graft medial to the manubrium to prevent lateralization of the graft. Blunting refers to proliferation of fibrous tissue in the anterior tympanomeatal angle, which interferes with mechanics of the TM and the manubrium, resulting in conductive hearing loss. As an alternative to fascia, thin AlloDerm (LifeCell Corporation Branchburg, NJ) can be used.

**Type II Tympanoplasty**

Type II tympanoplasty refers to repair of the TM and ossicular system with restoration of the lever mechanism, which is a normal function of the malleus and incus (Figure 3). The most common indication is osteitic resorption of the distal part of the long process of the incus. Often, the area of the resorption is replaced by a fibrous band. The fibrous band is resected with scissors or a laser. Continuity of the ossicular chain can be restored in one of several ways, including a bone strut, a synthetic prosthesis, or otologic cement. If there is any doubt about the stability or adequacy of the mechanical coupling of the reconstruction, the incus should be removed and continuity restored by a type III procedure (see below).

**Figure 3** Type II tympanoplasty, which implies re-establishing the lever mechanism of the ossicular chain. Schematic shows a small bone strut interposed between the long process of the incus and stapes capitulum. (Published with permission, copyright © 2006 S.N. Merchant.)

**Type III Tympanoplasty**

Type III tympanoplasty restores sound conduction to the oval window by one of the following three types of columellar reconstructions: minor columella, major columella, or stapes columella, each of which is considered separately:

**Tymanoplasty type III, minor columella.** A minor columella procedure consists of placing a graft or prosthesis from the stapes capitulum to the TM or manubrium (Figure 4). A synthetic columella of this type is termed a partial ossicular replacement prosthesis (PORP). A minor columella is suitable for reconstructing an ear with an intact posterior canal wall and a mobile stapes with its superstructure. A minor columella may be the only procedure, as in an elective tympanoplasty, or may be combined with a canal wall up or down mastoidectomy for COM.

A variety of autograft, homograft, and alloplastic prostheses are available for minor columellar reconstructions. A readily available reconstructive material is an autologous ossicle, either the body of the incus or the head of the malleus. The ossicular graft is sculpted to suitable dimensions using the operating microscope and small burs, along with liberal irrigation with saline to avoid thermal injury. A facet is drilled to accommodate the stapes capitulum, and a groove is created on the opposite side to accept the manubrium (Figure 4A). If the manubrium is missing or too far anterior (when compared to the stapes) for a stable assembly, the strut is brought from the stapes capitulum to the TM. It is important to make the ossicle strut small enough so that it is not too close to the bony tympanic sulcus, promontory or facial canal to prevent ankylosis of the strut to these structures. If autologous ossicles are not available, a minor columella can be fashioned from autologous cortical bone. Studies have shown that autogenous ossicular and cortical bone grafts behave in a similar manner and retain their morphologic size, shape, and contour for extended periods of time, at least up to 30 years and probably much longer. They do not incite formation of exuberant new bone nor do they show excessive resorption of bone in the absence of infection.14 They demonstrate varying amounts of replacement of nonviable bone by new bone through a slow process of creeping substitution. A PORP can be used as an alternative to an autograft or homograft ossicle (Figure 4B). A large variety of PORPs have been described, which differ in the material used to make the PORP or in the shape and size of the PORP.15 PORPs made of porous polyethylene, hydroxyapatite or titanium are popular in contemporary otologic practice. A buffer of thin cartilage (0.5 mm or less in thickness) is often interposed between a PORP and the TM to decrease the potential for extrusion.

**Tymanoplasty type III, major columella.** A major columella is a reconstruction interposed between the stapes footplate and TM or manubrium (Figure 5). It is performed in cases where the stapes crurae are missing and the footplate is intact and mobile. A major columella made of synthetic material is termed a total ossicular

**Figure 4** Type III tympanoplasty, minor columella. The reconstruction consists of interposing a sculptured bone strut (A) or a partial ossicular replacement prosthesis (PORP) (B) between the stapes head and manubrium or tympanic membrane. A thin slice of cartilage is generally placed between a PORP and tympanic membrane to act as a buffer and minimize extrusion of the PORP. (Published with permission, copyright © 2006 S.N. Merchant.)

**Figure 5** Type III tympanoplasty, major columella. A major columella is a single reconstructive strut that bridges the space from the footplate to the tympanic membrane or manubrium. Total ossicular replacement prostheses (TORPs) are generally preferable to bone struts which have a tendency to ankylose to the walls of the oval window niche. A thin slice of cartilage is usually placed between the TORP and tympanic membrane to act as a buffer and minimize extrusion of the TORP. (Published with permission, copyright © 2006 S.N. Merchant.)
replacement prosthesis (TORP). A major columnar reconstruction may be the only procedure performed, or it may be combined with a canal wall up or canal wall down mastoidectomy. An ossicular or cortical bone strut fashioned as a major columnella has a risk of delayed ankylosis of the strut to the fallopian canal or to the promontory. It is also difficult to fashion such as a strut with precision. In general, better results are achieved with a TORP. As is the case with minor columnellas, a variety of TORPs are available, and reconstructions can be performed from the footplate to the TM or to the manubrium, if the latter is present. A thin slice of cartilage (0.5 mm or less in thickness) is often placed between the TORP and the TM to decrease the chance for extrusion.

**Tympanoplasty type III, stapes columnella.** A stapes columnar reconstruction involves placing the TM graft directly on the capitulum of the stapes (Figure 6). The procedure is usually done in association with a canal wall down mastoidectomy for active COM. The posterior bony canal wall is removed to the level of the facial nerve. The new tympanic cavity (cavum major) is limited superiorly by the tensor tympani semicanal and tympanic segment of the facial nerve and posteriorly by the mastoid segment of the facial nerve. The mastoid cavity and epitympanum are usually obliterated with pedicled or free muscle-fascial grafts, supplemented with bone pâté. Unepithelialized surfaces are covered by skin grafts. (Published with permission, copyright © 2006 S.N. Merchant.)

**Mastoidectomy**

Mastoidectomy is often combined with tympanoplasty, as described above. A canal wall up mastoidectomy consists of removal of disease from the mastoid, while preserving the posterior wall of the bony external auditory canal. The cells of the mastoid are exenterated by surgical drilling. The limits of surgery are the segmental plate superiorly, the sinodural angle posterosuperiorly, the sigmoid sinus plate posteriorly, the bony canal wall anteriorly, and the bony semicircular canals medially. The epitympanum is opened by enlarging the aditus ad antrum. A posterior tympanotomy is often performed by opening the facial recess, which enables removal of disease. A canal-wall down mastoidectomy consists of removal of the posterior bony canal wall so that the external auditory canal, mastoid, and epitympanum become one common cavity. The bony canal wall is lowered to the level of the facial nerve. Thorough exenteration of cells of the mastoid is necessary for success of the procedure. This includes removal of cells of the mastoid tip, the sinodural angle, and the segmental area. The size of the resulting mastoid bowl is often reduced by obliterating the mastoid cavity. A variety of options are available for obliteration including bone pâté and free or pedicled flaps of soft tissue.

**Type IV Tympanoplasty**

In type IV tympanoplasty, the stapes footplate is allowed to remain directly exposed to incoming sound from the ear canal, and a tissue graft is placed to acoustically shield the round window membrane from sound (Figure 7). The air space that is enclosed between the acoustic shield and the round window is called the cavum minor. The cavum minor is aerated via the eustachian tube. A type IV procedure is suitable when there is a canal wall down mastoidectomy and the TM, malleus, incus, and stapes superstructure are missing but the footplate is mobile. The footplate is usually covered by a thin split-thickness skin graft and the round window is acoustically shielded by a stiff graft, comprised of thick (1 mm) cartilage and temporalis fascia. A stiff graft will help to maximize the sound-pressure difference between the oval and round windows.

**Type V Tympanoplasty**

The type V operation is used to bypass an ankylosed stapes footplate and is performed as a second-stage procedure after eradication of active COM. There are two subtypes: (1) The type Va procedure is the original Wullstein type V and consists of fenestration of the lateral semicircular canal to bypass the ankylosed stapes footplate; and (2) The type Vb is similar to a type IV, except the stapes footplate is removed and the oval window is sealed by a tissue graft, usually made of adipose tissue (Figure 8). Type V a procedures are rarely performed, having been largely supplanted by type Vb operations.

**SPECIAL CONSIDERATIONS: STAGING**

Staging refers to performing the tympanoplasty reconstruction in two operations, usually 6 to 12 months apart. Staging can be considered for three different indications. (1) A two-stage procedure is almost always indicated when the stapes is fixed. The first stage consists of eradication of active disease from the middle ear and mastoid and repair of a TM perforation. The second stage consists of a stapedectomy and is performed provided the ear is dry, aerated, and free of disease. It is unwise to perform a stapedectomy at the first stage, because of the risk of iatrogenic labyrinthitis and meningitis, and subsequent
sensorineural hearing loss. (2) A two-stage procedure is also performed when there is a high risk of residual cholesteatoma at the time of the first procedure. The first stage consists of removal of the cholesteatoma and repair of the TM. The second stage consists of re-exploration of the middle ear and mastoid to look for residual cholesteatoma and is combined with ossiculoplasty. (3) A two-stage operation has also been advocated in patients with extensive mucous membrane destruction of the tympanic cavity due to COM. The first stage consists of elimination of disease, sealing the middle ear with a tissue graft and placing plastic sheeting over the denuded middle ear. The objective of the first stage is to obtain a well-healed ear with a mucosa lined, aerated middle ear cleft so that ossicular reconstruction may be performed later at a second stage under ideal circumstances. Considerable difference of opinion exists among experienced otologists in regard to this third indication for staging.18,19 There are experienced otologists who perform the entire procedure in one stage. Every effort is made to eliminate disease and maximize hearing results at the first operation. Should the hearing results be unsatisfactory and the postoperative status regarding aeration of the middle ear and control of suppurative satisfaction, a revision operation for hearing can be done. In this rationale, revisions are not necessary in many cases; therefore, a second procedure is avoided.

POSTOPERATIVE CARE AND COMPLICATIONS

Surgical packing is placed within the ear canal at the end of the procedure to hold the TM and other grafts in place. A variety of packing materials are in contemporary use including gel foam, antibiotic-corticosteroid ointments, and dressings made of strips of silk or rayon cloth filled with antibiotic-soaked cotton. Prophylactic antibiotic coverage is usually given during surgery and continued for 7 to 10 days postoperatively. The surgical packing is removed 1 to 2 weeks postoperatively. The patient is instructed to avoid nose-blowing and vigorous physical activity for 2 weeks after surgery. Further treatment consists of cleaning and removing debris as well as applying antiseptic or antibiotic drops until complete healing and epithelialization has taken place. Water precautions are advisable until healing is complete. A postoperative audiogram is performed when the ear is fully healed, usually 2 to 4 months after the operation.

The major intraoperative complications are injury to the cochlea, the vestibular system, and the facial nerve. The risk of partial or total sensorineural hearing loss after tympanoplasty ranges from 1 to 5%.18,19 Etiologic factors for sensorineural hearing loss include avulsion or subluxation of the stapes footplate, laceration of the round window membrane, or acoustic trauma due to instrumentation of the ossicles. Injury to the facial nerve occurs most often at the level of the oval window.20 A normal dehiscence of the fallopian canal can be expected in up to 25% of cases with COM in this region. Therefore, avoidance of aggressive manipulations or dissection in the oval window niche area is important. Intraoperative facial nerve electromyography provides useful adjunctive information during the surgical dissection adjacent to a dehiscent facial nerve and therefore can be useful to the surgeon to minimize the risk of facial nerve injury.

Postoperative complications include hemato-ma formation, infection, graft failure with reperforation, stenosis of the external auditory canal or meatus, displacement or extrusion of an ossicular prosthesis, iatrogenic cholesteatoma due to implantation of squamous epithelium, and recurrent COM. Long-term follow-up is advisable to monitor the ear and for early detection of complications or recurrent disease.

RESULTS

Surgery of the middle ear and mastoid is very successful in controlling infection in COM, with success rates in excess of 80 to 90%. On the other hand, improvement in hearing after tympanoplasty is rather modest. Hearing results are determined by the extent of initial damage to the TM and ossicles, and whether or not the tympanic cavity becomes properly aerated after tympanoplasty.21

Restoration of aeration of the tympanic cavity after the operation is the single most important determinant of a successful tympanoplasty. Unfortunately, the otologic surgeon does not have control over whether an ear will become aerated postoperatively or not. Nonaerated ears due to middle ear fibrosis or eustachian tube dysfunction demonstrate large conductive hearing losses of 40 to 60 dB, regardless of the type of tympanoplasty that has been performed. Therefore, the confounding effect of nonaeration must be removed to accurately analyze and compare the results of various types of tympanoplasties.

Patients undergoing type I tympanoplasty have the best outcome, with a greater than 90% probability for successful take of the graft and 80 to 90% probability for a postoperative air-bone gap of 20 dB or less. Hearing results are less satisfactory when the ossicular chain is diseased. When ossiculoplasty is performed, hearing results are better if there is an intact stapes superstructure. Long-term closure of the air-bone gap to less than 20 dB occurs in 40 to 70% of cases in which the stapes is intact, and in only 20 to 55% of cases in which the stapes superstructure is missing.2

One can also consider the effect of a canal wall down mastoidectomy on the hearing result. From an acoustical perspective, a canal wall down mastoidectomy results in a significant reduction of the size of the residual middle ear air space. Experimental studies have shown that this reduction should not create any significant hearing loss as long as the middle ear remains aerated.4 Indeed, clinical studies involving large numbers of patients have revealed no significant differences between canal wall up and canal wall down mastoidectomy for comparable ossicular pathology.22-23

CHALLENGES FOR FUTURE RESEARCH

Tympanoplasty is unique compared with surgery elsewhere in the body because of the constraints imposed by a combination of factors, including the pathology of COM, the unpredictable nature of wound healing, and the need for a functioning tympano-ossicular system. Otologists routinely place TM and ossicular grafts in a recipient middle ear that is hostile as a result of active or arrested inflammatory disease. TM grafts have to be in contact with air over a relatively large portion of their surface areas and must derive nourishment and blood supply from small parts of the graft in contact with the canal wall. Furthermore, ossicular grafts and prostheses must couple well at their ends to bone or soft tissue but must remain suspended in air elsewhere to transmit sound effectively. Therefore, it is not surprising that functional success after tympanoplasty is determined not only by a surgeon’s technical skill and judgment, but also by other factors, such as the mechanics and acoustics of the reconstruction4,24 and the biology and pathology of chronic ear disease.25

COM poses a particular challenge in that postoperative mucosal fibrosis, neo-osteo genesis, and development of negative static pressure in the middle ear with nonaeration of the middle ear can occur over the course of months or years.25 These host responses have a detrimental effect on the hearing result, which is not apparent in the short term. It is instructive to note that the few studies in the literature that assess long-term hearing loss show a progressive and systematic decline in the initial hearing gain, as a function of time. For example, a study of 832 ossiculoplasty procedures found that 77% of ears had an air-bone gap of 20 dB or less at 6 months, but the same measure declined to 42% at 5 years.24 An improved understanding of the biology and pathology of COM would provide fruitful avenues for research to improve upon today’s results after tympanoplasty.

REFERENCES

The term otosclerosis is derived from the Greek words for "hardening of the ear." While first recognized as a pathological entity by Valsalva in the eighteenth century, it was not until the mid-nineteenth century with the observations of authors such as Magnus, von Tröltsch, Politzer, and Toynbee that the clinical presentation of the disease was clearly defined. During the twentieth century, its audiometric features were identified. Today, otosclerosis is recognized as an alteration in bony metabolism that is exclusive to the endochondral bone of the otic capsule. The ongoing process of resorption and redeposition of bone results in fixation of the ossicular chain and a conductive hearing loss.

PREVALENCE

Otosclerosis occurs most commonly among Caucasians with an incidence of 1%, followed by Asians at 0.5%. It is far less common in African-Americans. Guild, in postmortem examinations of temporal bones, found evidence of a higher prevalence rate histologically, with 8.3% of Caucasians and 1% of African-Americans manifesting the disease. Although occurring in all age groups, the usual clinical presentation varies from second to fifth decade of life. There is a female predominance of 2:1, and bilateral disease occurs in 80% of patients. Approximately 20 to 30% develops a progressive sensorineural hearing loss with no reliable preventative measures available.

HISTOPATHOLOGY

Histologically, the otosclerotic process is divided into two phases. Bone resorption and increased vascularity characterize the early phase. As the mature collagen content diminishes, the bone acquires a spongy appearance (otospongiosis). On hematoxylin-eosin staining it assumes a bluish coloration, referred to as the blue mantles of Manasse. In the late phase, the reabsorbed bone is replaced with dense sclerotic bone, thus the name otosclerosis (Figure 1). When involving the stapes, otosclerosis often starts from the fissula ante fenestrum, although focal lesions involving the posterior annular ligament are also seen. In general, the disease progresses from an anterior focal lesion to complete footplate involvement and, in more advanced cases, may fill the oval window niche entirely with new bone (obliterative otosclerosis). In contrast, the round window is less frequently involved, and complete obliteration a rare finding. Involvement of the cochlea can result in sensorineural hearing loss.

ETIOLOGY

Various causes of the disease and evidence for inflammatory or infective relationships have been reported. A genetic component has been long recognized and generally accepted as being dominant in transmission with incomplete penetrance. Current understanding points to the marked heterogeneity of the genetic pattern. Six different loci have been identified as associated with otosclerosis (Table 1). Identified sites are associated with genes involved in the regulation of collagen, cartilage and bone homeostasis, and growth suppression and intracellular communication.

The expression of COL1A1, Type 1 collagen gene has been implicated strongly in osteogenesis imperfecta and osteoporosis, both sharing lesions in the otic capsule and many clinical presentations similar to otosclerosis. While roles for autoimmunity have been suggested, data remains inconclusive.

Recent investigations have evaluated the potential role of infective agents in otosclerosis. The measles virus has been implicated, with viral particles, antigens, and RNA found in active otosclerosis foci. Elevated titers of IgG specific for measles virus antigens have been found in the perilymph of patients with otosclerosis. While the evidence is compelling, the actual role of the measles virus in manifesting or inciting the disease remains to be established.

Bilateral nonsyndromic, not linked to the above, or to COL1A1 or 2
The contributions of the endocrine system to manifestation of otosclerosis is unclear. While clinically implicated anecdotally, the role of estrogen and parathyroid hormone (PTH) has not been proven but warrants further investigation.\(^4^1\)

**CLINICAL PRESENTATION**

The clinical presentation of otosclerosis is that of a progressive conductive hearing loss in an adult, thought to occur in less than 20% of genetically affected individuals. Some note improved speech understanding in noisy environment, known as the paracusis of Willis. Tinnitus is the second most common complaint reported. Vestibular symptoms are uncommon. Sensorineural hearing loss may be associated with the conductive changes in the disease. However, an isolated sensorineural hearing loss due to otosclerosis is rare.

Physical examination shows a normal appearance of the external auditory canal and tympanic membrane. Schwartzte sign, a red hue over the promontory caused by increased in vascularity of the bone immediately under the peristomeum, may be seen in the early stages of the disease but is not present in all cases.

**LABORATORY TESTING**

Depending on the stage of the disease, audiometric studies show typically a mild to moderate conductive hearing loss. The air-bone gap is wider at the lower frequencies. The Carhart notch is characteristic of otosclerosis and this apparent sensorineural hearing loss at 2 kHz is spurious since bone conduction in the mid frequency range is not reliable. Stapes fixation interferes with the bone conduction of the acoustic signal, and the bone conduction thresholds are reduced 10 to 15 dB after stapes surgery. With progression of the conductive loss, the Rinne tuning fork test demonstrates bone conduction to be greater than air conduction, and the Weber test lateralizes to the affected side. The tympanogram is either depressed (A) or normal. The stapedial reflex may be normal in the early stages but cannot be elicited as stapes fixation proceeds. Speech reception threshold and speech discrimination are often normal, except in cases of cochlear involvement. Clinically, other diagnostic studies such as high-resolution computed tomography (CT) and magnetic resonance imaging (MRI) are of little use in evaluation of otosclerosis. With high-resolution CT, however, one may be able to identify the sclerotic lesion.

**MEDICAL MANAGEMENT**

Medical management of otosclerosis remains controversial and is primarily directed at maturing the involved bone and decreasing osteoclastic activity. Shambaugh and Scott\(^4^2\) introduced use of sodium fluoride as treatment, based on its success in osteoporosis. However, this required high doses, and the efficacy has yet to be clearly established. Bisphosphonates that inhibit osteoclastic activity and cytokine antagonists that inhibit bone resorption may offer hope for the future. At present, no medical treatment is recommended on a consistent basis. Hearing aids, however, do offer an effective means of nonsurgical management of hearing loss in otosclerosis.

**SURGICAL MANAGEMENT**

**History**

The history of surgery for otosclerosis dates back to K essel in 1877 with early attempts at mobilization and extraction of the stapes.\(^3^9\) Other otologists subsequently attempted similar procedures, notably M lot in 1930, who described an extensive experience with successful operations and suggested various techniques.\(^4^4\) However, the report by Siebenmann at the beginning of the twentieth century was less encouraging and condemned the surgery, effectively ending these early ventures into stapes surgery.\(^4^5\)

The field of otosclerosis surgery lay dormant until 1938 when Lempert\(^4^6\) described the single-stage fenestration procedure that became popular with otologists of the era, rekindling interest in surgery for stapedial fixation. The focus returned to the stapes with Rosen’s report of stapes mobilization and the restoration of hearing.\(^4^7\) Shea introduced the technique of stapes extraction with tissue coverage of the oval window and polyethylene strut reconstruction of the stapes in the 1950s, ushering in the modern approach to stapes surgery.\(^4^8\) In the intervening years since the reintroduction of this procedure, techniques have changed slightly and new materials for reconstruction have been introduced; however, the principles remain basically the same.

The surgical goal in otosclerosis is restoration of the sound transmission mechanism from the tympanic membrane, going through the ossicular chain to the oval window membrane, bypassing the resistance of the fixed stapes footplate. Today, a variety of techniques are used to correct for stapes footplate fixation. Generally, the stapes arch is removed, and either a perforation or a partial to complete removal of the footplate is performed. A prosthetic implant is employed to connect the incus to the oval window.

**Patient Selection**

Surgical selection of patients is based on audiologic findings and physical examination. Preferred are patients with normal middle ear aeration, free of any infection or tympanic membrane perforation and with a Rinne test that demonstrates bone conduction to be greater than air conduction. When bilateral disease presents, the worse hearing ear is treated first, followed by the other ear, typically at least 6 months later. The performance of stapes surgery on an only hearing ear should be done with great trepidation.

**Informed Consent**

Preoperative consent is obtained, informing the patient of the risks of hearing loss, vertigo, injury to the facial nerve, loss or alteration of taste, tympanic membrane perforation, prosthesis extrusion or displacement, and residual conductive hearing loss. Singers and musicians are informed of possible change in quality of sound perception that may affect their professional performance. Individuals who are exposed or plan to be involved in activities associated with rapid and/or considerable change in pressure, such as SCUBA diving and piloting a nonpressurized airplane, are advised that their risk for postoperative hearing loss during these activities may be greater following stapedectomy.

**Preoperative Treatment**

Surgery may be performed under either general or local anesthesia. With improvements in anesthesia in recent decades, more otologists are now using general. Use of any anticoagulants during the 2 weeks prior to the surgery should be avoided, including antiinflammatory agents. Muscle relaxants in conjunction with anesthetic agents are not recommended, because of their effect on the facial nerve activity. Perioperative antibiotics are at the surgeon’s discretion, but antiemetic agents are recommended should nausea and vomiting occur.

Whether a general or local anesthesia is employed, injections of local anesthetics should be administered in such a manner as to avoid unintentional involvement of the facial nerve medial to the mastoid tip. Sterility of the operative field is of paramount importance, since a direct connection to the labyrinth is established during parts of the operation. Routinely, surgical site preparation includes installation of preparation solution into the external auditory canal. Facial nerve activity is monitored by direct vision of the face through a transparent occlusive drape, or an electromyographic monitor, should stapedectomy be performed using general anesthesia.

**Surgical Technique**

Stapes surgery may be performed via an endaural or anterior incisural incision. The endaural incision requires use of a speculum held stationary, either manually or with a speculum holder assembly. In contrast, the anterior incisural incision is held open using one or two self-retaining retractors, eliminating the need to operate through a speculum. The cosmetic result is good as the incision is rarely noticeable. The latter also provides direct access to the tragal cartilage, should a perichondral graft be desired.

Regardless of the approach, a tympanomeatal flap is raised; the annulus identified, and hemostasis established, prior to entering the middle-ear space. A 1% lidocaine with 1:100,000 epinephrine or a 1:1,000 epinephrine soaked piece of Gelfoam or small cotton ball is used in this step. The tympanomeatal flap is elevated anteriorly, and the chorda tympani nerve is dissected free toward
the malleus. A portion of the scutum should be curetted to expose the incus and the incudostapedial joint. Fixation of the stapes is determined by palpation of the malleus, while viewing the superstructure and footplate of the stapes.

Prior to any footplate work, the distance between the mid-shaft of the long process of the incus and the footplate is measured (Figure 2). The incudostapedial joint is separated, and the stapedial tendon is severed. The stapes superstructure is fractured inferiorly and removed from the middle ear (see Figure 2).49

Establishing contact with the perilymphatic space may be done in several ways. The trend within the last two decades has moved to smaller fenestra to protect the inner ear as much as possible. Typically, either a small fenestra is created, or the footplate is partially removed. When the surgeon removes the entire footplate, a stapedectomy is performed. Depending on the training and preference of the otologist, the posterior half or the entire footplate is removed (Figure 3). In the partial stapedectomy technique demonstrated, the footplate is fractured in half, with the posterior portion being removed. A perichondrial graft from the tragus or a vein graft is placed over the defect, and the prosthesis is positioned over it and secured to the incus.

In the stapedotomy technique, a perforation in the footplate is made, just large enough to allow passage of the prosthesis (Figure 4). In the technique popularized by Fisch, a perforation is gradually enlarged with a hand-held drill to 0.6 mm in diameter. The stapes replacement prosthesis of choice is placed in the perforation and attached to the incus. The length of the prosthesis used is slightly longer (0.25 mm) than the measured length between the incus and footplate to ensure contact with the perilymph space and prevent displacement during the healing process. The addition of fresh clotted blood to the area also helps reduce the risk of a perilymphatic fistula.

Many otologists have advocated use of laser in performing a stapedotomy. The advantage of the laser is decreased mechanical manipulation of the superstructure and the footplate. The thermal effect is negligible.50 The disadvantage is the additional time, expense, and instrumentation needed. Perkins and Curto popularized a combination laser stapedotomy with tissue coverage of the perforation (Figure 5). A vein graft is placed over a drilled hole in a Teflon block. A prosthesis is placed in the hole, and the vein graft allowed to dry and become adherent to the prosthesis. Rosettes of charred bone are created by the laser and gently removed with a pick. The prosthesis with adherent graft is positioned over the fenestra with the tip projecting into the vestibule and then positioned under the incus.

Postoperative Management

Postoperatively, the patient is sent home to bed and requested to remain on light activity for several days to allow initial healing. Pain management requires mild oral medication, and antibiotics are not necessary. Postoperative vertigo or nausea is managed with antiemetics and sedation as needed. Stool softeners help reduce straining, decreasing the chance of forming a perilymph fistula. Patients are cautioned against nose blowing and sneezing with mouth closed. Postoperative follow-up is scheduled at 1 week to remove any suture or packing and to assess the integrity of the tympanic membrane. Repeat hearing testing is performed at 4 to 8 weeks following the operation.

Pitfalls

Pitfalls of stapes surgery include inadequate exposure and anatomical variations. The endaural incision and speculum produces a narrower opening when compared to the anterior incisural approach. The scutum can cover the long process of the incus and the posterior half of the stapes. Adequate removal of the scutum ensures proper visualization of the footplate in the crucial stage of footplate perforation and prosthesis placement. Greater exposure is obtained if the superior limit of the tympanomeatal flap is carried forward to the area of the short process of the malleus. Reflecting the tympanic membrane forward with visualization of the malleus handle adds greatly to the ease of performance of the procedure. An aberrant location of the facial nerve may prohibit a stapedotomy, and relocation of the nerve, which carries a risk of facial weakness and paralysis, is not recommended. With a dehiscent facial canal, the nerve has a higher chance of being injured. Surgical judgment dictates when a stapes operation should be aborted.

A advanced otosclerosis with obliteration of the oval window requires drilling of the footplate and significant experience with temporal bone anatomy. Sclerotic obstruction of the round window is of less importance since only a small opening over the round window is necessary to allow proper cochlear function. Drilling out the round window often results in a severe hearing loss and is avoided.

If the footplate should be displaced into the vestibule, attempts should be made to remove it. However, this should be done, only if one can easily grasp the edge and gently remove it. Never go “fishing” for a bony fragment that has descended into the vestibule away from the annular rim.

During the stapedectomy, the protective function of the stapedial muscle is destroyed. A new technique in which the stapedial muscle is left in place and the posterior crus of the down-fractured superstructure is shaped and used as autologous footplate replacement graft has been proposed and used. The efficacy of this technique in preserving the acoustic reflex is controversial.

Results

Otosclerosis surgery has withstood the test of time since its reinstitution in the early 1950s. Shea in his review of 40 years of stapes surgery reported closure to within 10 dB of the preoperative bone conduction level in over 95% of patients. This changed little over the next several years. Glasscock and colleagues reported over 91% closure to within 5 dB. Both groups reported significantly less success in revision surgery. Persson and colleagues contrasted stapedectomy and stapedotomy in the review of their series. They demonstrated that partial and total stapedectomy had better results at all frequencies with the exception of 4 kHz. However, the hearing results in this group tended to deteriorate more quickly than the stapedotomy patients. Others have reported similar preservation of high frequencies with stapedotomy. Results in the training situation demonstrate significantly less success. A definite learning curve in stapes surgery occurs after training. The overall accepted rate of anacusis following stapes surgery is in the range of 1 to 2%.

Complications

Complications of stapedectomy surgery are both immediate and delayed in nature. Immediate complications are those occurring during the operation, for example, facial nerve injury, vertigo and/or hearing loss, or persistent postoperative perilymphatic leakage from the oval window. Bed rest and light activities are recommended for vertiginous patients, and most recover shortly after surgery. Changes in or loss of taste may result from excessive manipulation or injury to chorda tympani nerve. Labyrinthitis, though possible, occurs rarely under sterile conditions.

Delayed postoperative complications, including fistula formation, granuloma, and prosthesis dislocation have been reported. Immediate treatment with antibiotics and rest is recommended. Re-exploration should be entertained to correct the fistula, should vertigo persist. Granuloma
formation can occur for unknown reasons and in the best of settings. Keeping all foreign material, such as glove powder and bone dust, away from the footplate area may decrease the chances of development of a granuloma. A dislocated prosthesis requires re-exploration and revision.

Trauma to the Middle Ear, Inner Ear and Temporal Bone

D. Bradley Welling, MD, PhD
Mark D. Packer, MD

Trauma to the ear is a natural consequence of the innate sense of protection of the eyes and face. We instinctively turn away from approaching insult exposing one ear or the other to projectiles, blows, blasts, etc. The pinna and temporal bone encase and deflect injury from deeper middle and inner ear structures and contribute to the scalp and skull that protect the central hearing and balance pathways. The fragile middle ear is readily damaged when affronted by foreign objects introduced through the outer ear, as well as by the larger forces that are required to disrupt the inner ear. In a world where technology produces exposure to new heights, depths, speeds, and pressures that increase the risk of damage to ear structures, new technology may also allow preventative measures to avert damage and novel treatment options when such has occurred. The objective of this chapter is to provide information that will aid in diagnosis and treatment, and will guide future endeavors that may be necessary when the technology of protection does not exceed the forces of destruction.

More than a space of anatomical structures, the outer and middle ear is a system that captures ambient sound pressure waves that are transduced into the inner ear. This normally efficient transfer of information is dependent on an intact, taut tympanic membrane (TM) and an intact, mobile ossicular chain that traverses an air-filled medium. Trauma disrupts this system in several different ways. The end result of trauma to the TM and middle ear structures is a compromise in the efficient handling of sound information and potential breach of the sealed inner ear structures.

The middle ear is secondarily affected by trauma to the nose, mid-face, and paranasal sinuses. Congestion, blood, edema, and fracture of those regions surrounding the nasopharynx can inhibit eustachian tube function that is responsible for maintaining middle ear pressure and aeration. Resultant negative pressure from a disrupted eustachian tube can induce secretion that manifests as a middle ear effusion and conductive hearing loss. Blunt force applied to the mandible can be transmitted through the glenoid fossa fracturing the tympanic bone and rupturing the TM or disrupting the ossicles.

Trauma to the middle ear, inner ear, and temporal bone, as well as the central pathways of hearing, balance, and facial function are dealt with systematically in a lateral to medial approach. Sources, instruments, and mechanisms of trauma vary, and the understanding of each is central to management decisions and determining prognostic outcome information. Whether a product of blunt trauma, penetrating trauma or barotrauma, the magnitude of force applied to the ear differs widely, as does the outcome.

Foreign bodies within the external auditory canal (EAC) can pose a threat to the middle ear as well. They obscure visualization and may penetrate the TM, disrupt the ossicular chain, and create fistulae of the oval or round window membranes. Small batteries deserve particular attention as liquifactive necrosis can cause burns that affect surrounding bone and can extend into the middle ear and mastoid. They damage tissue by pressure necrosis, low-voltage burns, and alkaline corrosion. Corticosteroid drops that enhance burns if applied prior to battery extraction, facilitate reepithelialization of ulcers once the battery is removed.¹

MIDDLE EAR TRAUMA

Penetrating objects vary from the misguided cotton tip applicator, hairpin, key, or pencil, to the more directed injury from picks and knives. Injury is usually localized and often has a predictable path. Pain, conductive and/or sensory hearing loss, disequilibrium, tinnitus, and rarely dysgeusia or facial nerve paresis may occur. Delayed infection, otorrhea, and subsequent cholesteroloma formation may result.

Visualization of the extent of damage is necessary. Otomicroscopic removal of debris and blood gives an optimal assessment. If evidence of inner ear penetration, for example, vertigo, nystagmus, or sensorineural hearing loss (SNHL) is present, an examination under anesthesia may be necessary. Up to 88% of traumatic perforations of the TM heal spontaneously within 3 to 10 months.² ³ ⁴

The rate of spontaneous healing is inversely related to the size of the perforation. Sensorineural, mixed, or conductive hearing loss may complicate perforations. The latter may be due to the perforation alone or may be associated with ossicular chain disruption in 4 to 33% of cases. Ossicular chain disruption without perforation may result in losses up to 50 dB. In a prospective study of 62 perforations, Mehta and colleagues examined the effect of perforation on hearing.² They found that the location of perforation did not significantly affect hearing, while the size of the perforation was directly proportional to the amount of conductive loss. Their findings argue against the “phase cancellation effect” of a posterior perforation overlying the round window as location-specific differential losses were not apparent. Hearing loss was frequency specific with larger losses in the lower frequencies.

Evidence of inner ear injury includes vertigo, hearing loss, or ongoing tinnitus. Nystagmus and sensorineural loss may be associated with perilymphatic fistula (PLF), although fistula may be difficult to differentiate from labyrinthine concussion. Weber and Rinne testing following debridement and documentation of symptoms are important to help guide further audiometric testing and to determine the necessity or urgency of middle ear exploration.

In most conditions, early management of acute perforations is directed toward facilitating spontaneous closure. This may require debridement of the canal with unfurling of medialized squamous cell epithelium associated with flaps or tears. The placement of a paper patch on the TM provides a scaffold for healing and helps splint mobile flaps from falling medially. Ongoing research shows potential application of a multitude of techniques from laser welding to growth factor solutions to promote TM closure, for example, fibrin gel, cyanoacrylates, calcium alginate patches, transforming growth factor beta-1 (TGF ß-1), epidermal growth factor (EGF) releasing film, and keratinocyte/basic fibroblast/platelet-derived growth factors. Topical nonototoxic antibiotic drops may be used to treat associated infection and inflammation. Whether or not the addition of corticosteroids to the solution promotes or inhibits healing is not clearly defined.

Perforations that do not heal spontaneously within 3 to 10 months may require tympanoplasty to reduce the risk of chronic infection or cholesteroloma. Additionally, if conductive hearing loss persists, exploration may be warranted. In Kronenberg and colleagues’ series of 147 perforations, the risk of postinjury cholesteroloma was limited to patients whose perforations did not heal within 10 months.⁵ A postinjury audiogram is necessary to delineate and document associated SNHL prior to any recommended surgical repair. Tympanoplasty and ossicular chain reconstruction are discussed in Chapter 19, “Reconstruction of the Middle Ear.”
INNER EAR TRAUMA

Traumatic penetration of the TM may be complicated by fistulae of the oval or round window. A PLF can result from direct blast or penetrating forces that may also dislocate or fracture the ossicles, or by barotrauma or blunt forces exerting their energy indirectly through the ossicular chain. Pressure exerted on an intact TM transmitted along an intact ossicular chain strain the round or oval window coverings as TM perforations have been shown to be protective against fistula formation in animal studies.

Barotrauma

Barotrauma occurs due to pressure differentials between the atmosphere and the middle ear. Pressure differentials develop when diving, during air travel, in hypo- and hyperbaric chambers, and to a lesser extent along mountain paths, and in fast moving elevators. The pressure volume relationship of a gas is defined by Boyle gas law. Pressure (P) times volume (V) equals a constant (k) which varies with the mass and temperature of a gas, PV = k. This applies to trapped gases as can occur in the middle ear due to a dysfunctional eustachian tube, or the EAC when completely occluded by cerumen or foreign bodies. As pressure increases, volume decreases maintaining the constant.

As ambient pressure drops in ascent, air trapped in the EAC by a foreign body expands causing pressure against the lateral surface of the TM. Air expansion in the middle ear space egresses via the eustachian tube. The middle ear pressure decreases in relation to the gas trapped by canal occlusion creating a pressure gradient across the TM. The TM bows medially which causes pain, and possible rupture relieves pressure if the differential becomes great enough. Alternatively, as ambient pressures increase with descent, pressure differentials develop when diving, during air travel, in hypo- and hyperbaric chambers, and to a lesser extent along mountain paths, and in fast moving elevators. The pressure volume relationship of a gas is defined by Boyle gas law. Pressure (P) times volume (V) equals a constant (k) which varies with the mass and temperature of a gas, PV = k. This applies to trapped gases as can occur in the middle ear due to a dysfunctional eustachian tube, or the EAC when completely occluded by cerumen or foreign bodies. As pressure increases, volume decreases maintaining the constant.

The reverse situation occurs in an open canal when air is trapped in the middle ear by a tympanic membrane obstruction or dysfunction. The air volume trapped within the middle ear expands unopposed by the decreased ambient pressure in the ear canal at altitude. The TM bows outward, the round window membrane bows medially, and the stapes footplate lateralizes in suit. Pain from the displaced TM can be relieved by actively opening the eustachian tube with an insufflation maneuver, or by swallowing, or yawning to contract the tensor veli palatini muscle. Too forceful an opening of the eustachian tube exacerbates the situation and can outwardly tear the TM or oval window ligament or implode the round window membrane. Similar maneuvers if ineffective in overcoming eustachian tube closure can elevate intracranial pressure. This pressure transmitted through the internal auditory canal (IAC) or a patent cochlear aqueduct can release pressure differentials which may be necessary to allow continued CPAP treatment.

When compared with middle ear pressure fluctuations that occur during CPAP treatment and commercial flight, barotrauma using self-contained underwater breathing apparatus (SCUBA), during unpressurized flight, or occurring with exposure to blast overpressures are due to greater sustained pressure differentials and larger peak intensity levels. The result is a much higher propensity to cause damage to ear structures. The symptoms are more severe, and the otoscopic examination more revealing. Perforations of the TM are managed expectantly as with penetrating perforations. Close observation over 6 to 12 months is warranted to monitor closure, rule out cholesteatoma formation, and to ensure hearing and balance function revert to normal.

Middle ear barotrauma associated with SCUBA diving generally occurs with exposure to increasing water pressure, upon descent. Most injuries occur in shallow water where the pressure differentials are greatest. Water volume does not compress and does not follow Boyle’s gas law, but the air within the middle ear does. The increasing water pressure in the ear canal pushes the TM medially and is not equalized by the compressing volume of air behind the eardrum. Otalgia can develop in as little as 3 ft of water, and the eustachian tube can become entirely dysfunctional and locked at 4 ft. If the pressure differential is not relieved, TM rupture

Figure 1 Schematic depiction perilymphatic fluid leak through the annular ligament, at the oval window, or through a ruptured round window membrane.
can occur within 5 ft of the surface. Cortes and colleagues reported a dive-related temporal lobe injury manifesting as acute otalgia and persistent headache. CT findings of hemorrhage and pneumocephalus in the epidural space and adjacent temporal lobe where documented. Forceful autoinsufflation could theoretically rupture thin bone of the tegmen tympani. A reported rate of 52% dehiscence of the tegmen tympani in 100 temporal bones of 50 routine autopsies could explain the transmittal of air into the epidural spaces with Politzerization or baropressure and clarify the route of intracranial communication even without rupture of the tegmen.

Inner ear decompression sickness (DCS) is a separate entity that generally manifests during or within 24 hours of SCUBA or unpressurized aircraft ascent. This occurs as nitrogen gas, which is normally compressed into solution in serum at atmospheric pressure, bubbles out of solution with decreasing ambient pressures. Neurologic symptoms of tinnitus, pain, hearing loss, and vertigo may occur related to occlusion of the labyrinthine microcirculation. Severe neurologic or respiratory symptoms of cerebral or pulmonary edema may complex the situation. The otoscopic examination is usually normal. Diagnosis is presumed based on temporal association with a recent ascent, and treatment for dive-related DCS is immediate recompression in a hyperbaric chamber to three times the depth at which symptoms occurred with a more gradual ascent. If prophylaxis for high-altitude DCS with a carbonic anhydrase inhibitor fails, patients are treated with 100% oxygen and immediate descent to sea level.

Perilymphatic Fistula

PLF must be considered when a documented pressure exposure, head trauma, or posterosuperior quadrant TM perforation is complicated by symptoms of SNHL, vertigo, tinnitus, and headache. PLF was first described to explain similar symptoms in patients after stapedectomy; however, trauma is the most common cause followed by iatrogenic exposure of the vestibule or membranous labyrinth. A ditionally, events that raise intracranial pressure such as straining, nose blowing, coughing, or sneezing may have been linked to PLF formation. Minor head trauma without loss of consciousness was seen in 36% of 350 patients with purported PLF, and whiplash injury loss of consciousness was seen in 36% of 350.

When the history and symptom complex leave the diagnosis in question the diagnosis may be suspected based on physical examination findings. Nystagmus brought on with pneumatic otoscopy is considered a positive fistula test. Audiometry may also confirm the side of pathology if hearing loss is present, although it is unable to distinguish a fistula from the more commonly seen labyrinthine concussion. It can be helpful distinguishing round window fistulae from superior semicircular canal dehiscence as the latter may result in a pattern of conductive hyperacusis. Videonystagmography (VNG) may show dysfunction even with a normal audiogram. Findings may be side specific, but not necessarily pathology specific. Electrocochleography has been reported to show an elevation of the summing potential to the action potential (SP/AP ratio) in an active PLF. This finding is quite nonspecific and would be anticipated in active or posttraumatic endolymphatic hydrops as well.

High-resolution (<1 mm cuts) computed tomography (HRCT) may show fistulae. Veillon and colleagues studied 800 temporal bone fractures. They were readily able to identify trauma to the oval and round windows and discuss findings suggestive of PLF. The more common oval window trauma may be diagnosed by following fracture lines, identifying stapedial fracture, and/or displacement of the footplate. Even subtle displacement is picked up when the plane of the footplate falls out of parallel with the tympanic segment of the facial nerve canal. A footplate within the vestibule, or air bubbles within the vestibule or cochlea are less subtle signs of PLF.

Round window fracture was only seen in 2.5% of all 600 fractures, but in 20% of the translabyrinthine fractures. The round window niche is normally an air space, and hence black on CT. When one-third or more of the recess is grayed by fluid, PLF was diagnosed and surgically confirmed in 14 of 16 patients with only one false-positive, and one false-negative result. One hundred temporal bone CT examinations from patients with chronic otitis media were reviewed to assess the prevalence of round window recess secretions. The round window niche rarely had fluid when the middle ear was normally aerated and other recesses were dry. A cute findings following blunt trauma might expect to be confounded by blood, inflammation, and effusion depending on the timing of the examination. Imaging of temporal bones associated with barotrauma overlaying serous otitis media would be expected to be an unusual situation. Imaging the round window could be repeated after 3 months when effusions should be resolved if no fracture was seen at the outset and if symptoms of PLF persist. Other authors have a less encouraging opinion regarding the utility of CT in the diagnosis of PLF and view imaging evidence of PLF as unreliable and expensive. Further evidence is necessary to validate or refute its utility.

Magnetic resonance imaging (MRI) is rarely of value or utility in acute trauma; but, for persistent symptoms, it may reveal contusion of the labyrinth as seen by diffusion of gadolinium within the labyrinth on T1 sequencing and a usual normal loss of signal on T2 sequencing. MR does have other applications in defining dural defects, meningonecephaloceles, and examining the course of the facial nerve and other IAC and retrococcal structures.

PLF management remains controversial possibly due to the historical difficulty in specifically identifying the pathology. Other diagnostic means, such as fluorescence endoscopy and beta-2 transferrin analysis of suspect fluid, among others are described in the otologic literature, but exploratory tympanotomy based on a high suspicion of fistula remains the current standard of both diagnosis and treatment. Identification of perilymph-specific proteins will likely be of great value in definitive diagnosis. Conservative initial management is advocated with bed rest, avoidance of provocative maneuvers, for example, cough, sneeze, strain, and observation for 24 to 72 hours. Exploratory tympanotomy with closure of the fistula site is warranted for severe persistent symptoms, positive findings on HRCT, or complications such as meningitis. Weber and colleagues reported the outcome of fistula exploration and repair in 137 children that had not shown improvement with conservative management. Hearing was stabilized in 83%, improved in 10%, worsened in 3%, and 4% were lost to follow up. All vestibular complaints stopped within 24 hours of surgery.

Surgical treatment of PLF is accomplished by exploration of the round window membranes after elevation of a tympanomeatal flap. The ossicular chain is surveyed and palpated for integrity. Fractures, dislocations, and disarticulations are accounted but left undisturbed. Meticulous hemostasis, and topical adrenaline are helpful to ensure that any fluid welling up within the oval or round windows is not dripping in from above. The window regions should be observed for at least 5 minutes looking for accumulation of clear fluid consistent with perilymph. Fat, fascia, perichondrium, or vein may be used to close off both windows. A associated ossicular abnormalities may then be addressed using standard tympanoplasty methods as discussed in Chapter 19, “Reconstruction of the Middle Ear.” Newer ionomeric and other cements and bone mimicking pastes (hydroxyapatite, Bone Bource, and Mimix) may prove useful in reconstructing fractured and dislocated ossicles (Figure 2). PLFs are discussed in Chapter 25, “Perilymphatic Fistulae.”

TEMPORAL BONE TRAUMA

Trauma to the inner ear, other than that sustained by transmission through middle ear structures as with pressure and blast trauma, requires greater forces, and generally manifests both clinically and radiographically as identifiable temporal bone fractures. These high-energy impact injuries...
fractures occurred predominantly in men (71 to 81%), as a result of blunt trauma (87 to 90%), and were unilateral (85 to 90%). The mechanism of injury in 45 to 47% was motor vehicle related (one-third of these were motorcycle crashes), followed by falls/accidents in 31 to 33%, and assault in 11 to 12%. Six to 10% were related to gunshot wounds. Fractures were also associated with intracranial injuries in 56% of one large study that lists a 16% neurosurgical procedure rate. Death from related injuries was as high as 18.7% in patients with temporal bone fractures.

Initial hospital-based evaluation and management of patients with temporal bone fractures generally happens in the emergency department by emergency physician, or a general/trauma surgeon or team. Trauma patients are assessed according to advanced trauma life support protocol. A long with cervical spine imaging, standard CT trauma protocols for head injury usually are carried out at 5 mm intervals. Consultation is requested for neurosurgical and other more urgent intracranial, vascular, thoracic, abdominal, and open orthopedic injuries. Treatment and stabilization of these injuries often happen prior to requesting evaluation by an otolaryngologist as temporal bone fracture itself is not often life threatening, and otologic symptoms may be masked or not expressed due to obtundation. The otolaryngologist is consulted based on the temporal location of the known or suspect fracture for complications related to the injury, or to evaluate other areas of the head and neck. The initial assessment should include a thorough head and neck examination. Inspection of the EAC, TM, and middle ear may require debridement.

**Temporal Bone Fracture**

Temporal bone fractures occur along lines of limited resistance between foramina that weaken its mechanical strength. These fracture lines may disrupt the intervening structures causing edema, hematoma, bleeding, conductive or SNHL, dizziness, CSF leak, and facial paralysis. A access to previously closed spaces can result in infection including meningitis and CSF abscess. Disruption of the carotid artery can manifest as exsanguination by bleeding from the nose or ear or cerebrovascular compromise. Hemotympanum and or blood in the EAC was associated with temporal bone trauma in up to 90% of patients. Twenty-six of 113 suspected fractures had a combination of audiometric SNHL, vertigo or nystagmus. This combination was associated with fracture in 100% of cases. The initial head CT showed the fracture 67 to 79% of the time, Blood behind the TM or within the EAC had a positive predictive value (PPV) for fracture of 86%, and when combined with a positive head CT the PPV was 99%. HRCT confirmed suspected fractures in 79% and ruled out fracture in 11 to 21%.

Normal extrinsic sutures and intrinsic fissures and channels of the complicated temporal bone anatomy may be misinterpreted as fractures on trauma imaging (Figure 3). “Pseudofractures” extrinsically separate the temporal bone from adjacent bones at the parieto-occipital, the temporo-occipital, and the occipito-mastoid sutures. Intrinsic fissures along the tympanosquamous, tympanomastoid, and petrotympanic junctions may be similarly misleading. Several structures transit through channels of the temporal bone that may be misread as fracture including: the cochlear aqueduct, glossopharyngeal sulcus, vestibular aqueduct, petromastoid canal of the subarcuate artery, singular canal, mastoid canalculus transmitting Arnold branch of the tenth cranial nerve from the jugular foramen, and the inferior tympanic canalculus that houses Jacobson nerve. Awareness of the course of these normal structures, and comparison to the contralateral temporal bone, provides for astute and accurate diagnoses.

Whether or not HRCT is necessary or useful is debated. In an interesting study, Ishman and Friedland showed the referral rate of patients with temporal bone fractures to the otolaryngology services was only 43%. The audiology service was contacted in 58% of cases. When consulted, two-thirds of otolaryngologists surveyed always or almost always evaluated the temporal bone further with HRCT. One-third based imaging requests on clinical symptoms for surgical planning. Otolaryngologists and neuroradiologists alike consider HRCT of the temporal bone as the most appropriate radiology study in temporal bone trauma, and many feel that it is a necessary part of the evaluation of a patient with a temporal bone fracture, particularly for patient counseling or surgical planning.

Traditionally temporal bone fractures were categorized by their orientation with relation to the long axis of the petrous ridge based on postmortem examinations and animal studies. This classification scheme, as based on developing imaging technology was leaving fracture distinction largely up to clinical judgment. With widespread access to HRCT, temporal bone fracture patterns are more fully appreciated. The following discussion revolves around the
accuracy of the longitudinal and transverse typing of fractures.

Longitudinal fractures run parallel to the long axis of the petrous ridge. These were extensions of fractures from the temporal skull that were initiated by lateral or temporo-parietal blows and run through the foramen lacerum parallel to the eustachian tube and IAC (Figure 4). They comprised 70 to 90% of all temporal bone fractures and were seen with facial nerve injury 10 to 25% of the time. Lacerations of the EAC extending into tears of the TM were seen, and hearing loss was generally due to perforation of the TM or ossicular discontinuity. Anterior fractures were associated with a low incidence of middle meningeal artery laceration causing epidural hematoma formation.

Transverse fractures are thought to originate at the vestibular aqueduct and run perpendicular across the petrous pyramid (Figure 5). Traditionally these accounted for 10 to 30% of fractures and were caused by occipito-frontal blows. They were associated with signs and symptoms of hemotympanum, SNHL, vertigo, nystagmus; and facial nerve paresis in 38 to 50% of the patients. Subtypes of medial and lateral helped explain SNHL. Medial fractures traversed the fundus of the IAC and resulted in complete and permanent SNHL. Lateral subtypes fractured the cochlea or vestibule, and SNHL was incomplete and fluctuant related to PLF.

Retrospective temporal bone series have shown that fractures do not often fit into the classical scheme. Fractures that did not fit the generalized class have been referred to as mixed, and recent review place 35 to 75% of fractures in this category, while 38 to 64% could be described as longitudinal and 0 to 23% as transverse. Fractures do not often fit into the classical scheme. Fractures that did not fit the generalized class have been referred to as mixed, and recent review place 35 to 75% of fractures in this category, while 38 to 64% could be described as longitudinal and 0 to 23% as transverse.

Several authors feel that fracture nomenclature should better reflect important inner ear anatomical structures and predict potential risk of complications by their involvement. To this end authors have attempted to classify fractures as otic capsule sparing versus otic capsule violating, petrous versus nonpetrous, or labyrinthine versus non-labyrinthine. Fractures involving the otic capsule, ie, cochlea, vestibule, or semicircular canals, are reported in only 0.7 to 6.7% of patients. When the otic capsule is violated, the risk of facial nerve paralysis is more than two times greater than when the otic capsule is spared, the risk of CSF leak is four times greater, and the risk of SNHL is seven times greater. Conductive hearing loss in otic capsule sparing fractures is as high as 56% whereas the rate in otic capsule violating fractures was 20% but dropped to 5% when reexamined after 7 weeks.

Fractures are best seen on axial imaging, which is often the only direct examination available in the trauma setting. With thin collimation axial imaging (0.5 to 0.75 mm), it is possible to reconstruct multiplanar and 3-D images that approximate direct coronal and sagittal examinations. These provide excellent identification of fracture involvement of the labyrinth, IAC, facial nerve, and ossicles. Schuknecht and Graetz felt that 3-D imaging would make a useful contribution in up to 29% of fracture patients. Symptom and outcome correlation, as well as the cost, benefit, and utility of HRCT diagnostics impacting management, are subjects of debate. Fractures can be defined with great precision, but the question is whether that knowledge affects the patient’s outcome or provides crucial management information. Retrospective review of trauma data bases comparing initial head CT with follow up HRCT further correlating these with complications and interventions has been used to evaluate the indications for HRCT.

Kahn and colleagues estimated that HRCT was clinically warranted in approximately 10% of cases of temporal bone fracture. The clinical picture of blood in the EAC or behind the TM along with a positive head CT, was an excellent indicator of fracture. A definitive CT diagnosis of fracture did not alter the clinical management. HRCT did not play a role in the management of 30 out of 39 patients with facial nerve paresis in a series of 105 fractures. It did provide complimentary localizing information in those patients who were surgical candidates by timing and degree of weakness. Of 11 patients with carotid canal fractures on HRCT, 1 was symptomatic, 6 had angiography, and only the single symptomatic patient was shown to have carotid injury. Resnick and colleagues reviewed 230 skull base fractures, 55 of which involved the carotid canal. Thirty-three underwent an angiongram, and only the 6 symptomatic patients were shown to have injury. HRCT for hearing loss was not helpful unless the loss persisted more than 7 to 8 weeks, was fluctuant, mixed or associated with otorrhea. Kahn and colleagues proposed that HRCT is a useful expenditure when the clinical examination is unreliable, for the unusual clinical course, or for surgical planning. If the clinical examination is reliable, initial head CT is helpful, and the patient follows an expected course, HRCT may not add practical information (Figure 6).

The majority of blunt temporal bone fractures are managed expectantly. Complications which may require surgery include facial nerve
The incidence of facial palsy is 1,000 to 1,250 per 5 million per year, and 1 per 5 million per year for bilateral facial nerve paresis. Facial nerve injury is noted in 7 to 40% of patients with temporal bone fractures. Historically the injury occurs along the labyrinthine segment in 80% of medial transverse fractures, and in the perigeniculate region of laterally based transverse fractures. The perigeniculate region is involved up to 94% of the time in longitudinal fractures. Eighty-seven percent of gunshot fractures affect the nerve along the descending mastoid segment. Intracranial injury coincides with 22% of temporal bone fractures, higher when bilateral or gunshot related.

Early evaluation of facial function is the most telling sign of the extent of nerve damage. Patients with complete paralysis, immediate or delayed, within 14 days have a poor prognosis for satisfactory recovery. The mechanism of immediate paralysis is thought to be due to crush, traction or bony fragment laceration or confusion of the nerve at the fracture site. Delayed paralysis is seen less often, but attributed to edema, arterial spasm, thrombosis, intraneural hematoma, or external compression. Delayed injuries manifest approximately 4 to 5 days after injury and recover adequately in 94%. As noted above, the otolaryngologist is not always involved in initial triage and treatment and often must rely on the examination of the trauma responders who may be focused on more pressing injuries. Referrals also lag the injury because evaluation of facial function in the first few days can be confounded by the patient’s level of consciousness, facial edema and dressings that can give the illusion of retained facial function and residual muscle tone. Bilateral facial nerve injury may also be overlooked because of symmetry. Coexisting symptoms of hearing loss and vertigo are easily overlooked for similar reasons. The first neurologic examination averages 3 to 5 days postinjury.

If facial weakness does not progress to paralysis [House-Brackmann (HB) grade II to V], prognosis is good; and care is supportive focused on ensuring adequate eye protection to avoid corneal abrasion and ulceration. The injury is neurapraxia, a conduction block with myelin damage that spares the axon, or axonotmesis where the axon is transected with retention of the perineurium and epineurium. Wallerian degeneration occurs in axonometric injuries in the distal nerve segment in 3 to 10 days (Figure 7). Regeneration of the distal nerve ensues at 1 to 2 mm/d, and return of full function is seen in up to 94%. Immediate facial nerve paralysis is likely due to neurotmesis and surgical intervention is warranted. When facial function is observed to diminish completely within 6 days, prognosis is less sure and consideration of decompression is debated.

### Facial Nerve Paralysis

Trauma causes 3 to 5% of all facial weakness. The incidence of facial palsy is 1,000 to 1,250 per 5 million per year, and 1 per 5 million per year for bilateral facial nerve paresis. The onset of facial nerve paralysis is often delayed, varying from 1 to 14 days postinjury. Facial nerve injury is noted in 7 to 40% of patients with temporal bone fractures. Historically the injury occurs along the labyrinthine segment in 80% of medial transverse fractures, and in the perigeniculate region of laterally based transverse fractures. Eighty-seven percent of gunshot fractures affect the nerve along the descending mastoid segment. Intracranial injury coincides with 22% of temporal bone fractures, higher when bilateral or gunshot related.

Immediate paralysis is thought to be due to crush, traction or bony fragment laceration or confusion of the nerve at the fracture site. Delayed paralysis is seen less often, but attributed to edema, arterial spasm, thrombosis, intraneural hematoma, or external compression. Delayed injuries manifest approximately 4 to 5 days after injury and recover adequately in 94%.

### Penetrating Trauma

A discussion of penetrating trauma to the temporal bone requires a certain understanding of ballistics keeping in mind a general dictum of emergency medical management to “treat the injury, not the weapon.” The degree of tissue damage is determined by the velocity and design of the projectile, and the physical properties of the tissue that it disrupts. Weapons are considered low velocity if they project a missile at less than 1,000 feet per second (f/s), mid velocity between 1,000 and 2,000 f/s, and high velocity if they exceed 2,000 f/s. Handguns, and shotguns are generally low-velocity weapons unless fired at close range. Rifles usually project high-velocity missiles. Skin is penetrated by a projectile at about 163 f/s, while bone requires 213 f/s to fracture. Acceleration of fractured bone or fragmentation of the missile in contact with bone can produce numerous secondary missiles.

Tissue damage is caused by laceration, crush, cavitation, and shock waves. Low-velocity injuries cause damage by lacerating and/or crushing tissues. Cavitation follows mid- to high-velocity missiles traveling at greater than 1,000 f/s. A permanent cavity is formed by the bullet path, and a temporary cavity is created by the acceleration of the tissue in the wake of the missile. Shock waves that can reach 200 atmospheres of pressure are formed by tissue compression before and to the sides of the projectile. Tissue damage is dependent on the density and elastic properties of the tissue. More damage occurs in tissues with greater specific gravities, and less damage in those with higher elasticity.

A cute management of ballistic injury is similar to management of other open wounds and fractures requiring initial basic life support assessment with control of airway and life-threatening bleeding, cervical spine evaluation and control, copious irrigation, debridement of devitalized tissue, and sterile dressing. Predictors of infection are delay in treatment, gross contamination of the wound, significant tissue devitalization, open fractures, and larger or multiple wounds. Antibiotic prophylaxis is recommended for high-velocity, shotgun, and intraarticular gunshot fractures.
Electrophysiological Testing. Further information about the extent and location of the injury can be obtained through electrophysiological and imaging studies. Neurofunction testing of the damaged distal segment of the nerve should be normal in neuropraxic injuries but may also give false-negative results if performed prior to Wallerian degeneration with more severe damage. Nerve excitability testing (NET) is a bedside test whereby nerve conduction is evaluated with a Hilger monitor, and the minimal stimulation intensity of the damaged side is compared to that of the normal side. Greater than 3.5 mA difference is considered clinically significant and leads to more objective testing. If tested within 3 to 21 days, electroneurography (ENoG) is a reliable test.

This is also a comparison study that requires a functional contralateral nerve. The amplitude of nerve conduction velocity stimulated at the stylomastoid foramen and detected with surface electrodes at the nasolabial fold correlates with denervation, severe injury, and poor prognosis if >95% reduction in amplitude occurs on the affected side.

ENoG information is extrapolated from data pulled from Bell palsy research for which there is good untreated natural history record correlating timing of viral injury with electrophysiological and functional results.23,26-28 Some cases of blunt temporal bone trauma may be expected to follow a similar pathophysiologic course, but one would expect to see the possibility of more diverse and devastating injury patterns following traumatic facial nerve injury. As yet, there are no published reports showing the untreated functional results of facial nerve injury due to injuries in any substantial number of patients with >95% degeneration of the facial nerve by ENoG. Prognosis has been presumed to follow the observations of patients with Bell palsy, as ENoG is a measurement of functional conduction along the damaged distal nerve. The proportional difference in electrical output from side to side theoretically correlates with the percent of damaged neural motor units; but, until the natural history is studied prospectively, the correlation of ENoG findings with functional recovery will remain undetermined.

Spontaneous and volitional electromyography (EMG) provides useful information regarding nerve status. EMG is of greatest prognostic value in patients with delayed paralysis and can be used for cases with bilateral paralysis.23,26-28 They require more sophisticated equipment, technical support, and training to read. Voluntary potentials equate to neural integrity, ie, no transaction, and an intact motor endplate. Reassuring polyphasic regeneration potentials may be seen on spontaneous EMG after 21 days from injury and can be seen 8 to 12 weeks prior to clinical movement. Positive waves and fibrillation potentials are more ominous. EMG can be used to rule out fibrosis of the nerve-muscle interface that precludes nerve repair benefit in long-standing paralysis.

Continued slight motion, 95% ENoG degeneration, or voluntary potentials should prompt further observation as partial nerve damage spontaneously healed offers better outcome than nerve grafting. When nerve recovery is in question, corticosteroid therapy offers theoretical benefit if not medically contraindicated. Corticosteroid treatment within 3 days of paresis for Bell palsy offered a higher and faster rate of recovery of facial function and increased the likelihood of complete facial recovery. High-dose methylprednisolone was shown to be detrimental to wound healing compared to the usual dosage.21 EMG testing after 6 months allows sufficient time for distal nerve healing to manifest clinically or may show electrical signs of healing that will determine further planning.

Imaging. Imaging to localize injury for surgical planning is important. This information is extremely useful for patients with gunshot wounds and bilateral paralysis or unilateral fractures with immediate facial paralysis.15,21,28 Paralysis in gunshot injuries may be seen without CT evidence of disruption due to ballistic heat or shock properties, or the bone may be comminuted to the point that the location of the injury cannot be found. HRCT with the contribution of ENoG and clinical judgment has the greatest impact on decision-making in patients seen late in the course of their injuries.21 Imaging in the axial and direct coronal planes should be obtained when possible. Dehiscence of the middle third of the tympanic segment of the fallopian canal occurs in 41 to 74% and leaves the nerve vulnerable to heat injury, fragments, or spicules.22 The labyrinthine segment is the narrowest division averaging 1.2 mm in diameter and has been shown to be involved in up to 96% of some paralysis series.

Surgical indications, timing, and approach have been controversial subjects. CT imaging showing fracture, diastasis, or bony spicules along the course of the nerve with >95% degeneration within 14 days by ENoG together are indications for exploration with decompression or nerve repair.29 We advocate for intervention as soon as the patient’s status permits. Ongoing denervation of >95% of the facial nerve and regeneration potential instead of regeneration patterns on EMG portend a poor prognosis. Site of injury information correlated with audiometric findings will help plan the surgical approach.

MRI may be useful to follow the course of the facial nerve to identify injury in patients with late referral or who show no improvement primarily, and to exclude other unsuspected pathology such as a facial nerve schwannoma or tumor invasion. Some caution should be exercised however as enhancement in the geniculate and proximal tympanic segment of the facial nerve due to a rich perineural venous plexus has been documented in patients without facial nerve dysfunction.22 A brownish thickening of the nerve may be seen in conjunction with strong gadolinium enhancement on T1-weighted sequences at sites of injury. Posttraumatic labyrinthine enhancement is due to facial nerve prolapse. Facial nerve enhancement can be seen up to 2 years postinjury but does not directly correlate with electrophysiological findings. Most series concur that the perigeniculate region is the area most often injured.22,26-29 Retrograde injury was seen by intrameatal enhancement on T1-weighted sequences in 92% of 22 traumatic palsies.23 Fisch found perigeniculate involvement in 94% of longitudinal fractures that he decompressed through a middle cranial fossa (MCF) approach.22 Dural enhancement along the anterior border of the pyramid without facial nerve enhancement may indicate trauma leading to facial nerve injury even without other imaging signs of nerve damage.22

Timing of Management. Review of management patterns shows a consensus that facial nerve repair is beneficial for immediate posttraumatic facial paralysis when surgically addressed within the first 2 weeks of injury, although other philosophies exist.26-28,29 Fisch has advocated immediate exploration only for those with delayed paralysis that reach >90% degeneration within 6 days of injury.23,22 He proposed that this pattern is due to the development of an intraneural hematoma that would benefit from decompression. The same argument might be made for the upper face. Delayed exploration of immediate palsies by 3 to 4 weeks, as they were often associated with other injury. Waiting allowed the patient to stabilize and tolerate a procedure better and cleared the anatomy improving surgical visibility. Most controversy has revolved around what to do with facial paralysis outside of the 14-day window. With patient access delayed for various reasons, patients that show evidence of nerve injury on HRCT by bony impingement or obvious fracture disruption and displacement of the nerve may still benefit from surgical repair.26 Patients without apparent disruption or impingement and those without immediate paralysis or with unknown timing of progression to >95% degeneration fall into a gray zone.

Short of complete transaction, the type of nerve injury has no clear effect on facial outcomes. Integrity of the partially injured nerve yields a better outcome than cable grafting, and interposition results are similar if performed prior to significant muscle atrophy and fibrosis of the motor endplates, which takes place within 12 to 18 months of the injury. Awaiting a functional recovery is an option. Prolonged delays can increase the risk of traumatic neuroma formation, ear infection, scarring, and fibrosis around the nerve that may affect the functional outcome. Late exploration and decompression of those with severe head trauma, or without recovery seen late for other reasons have been reportedly successful and may be managed based on HRCT and EMG findings.26-28 As a nerve regeneration rates average 1 to 2 mm/d, if no clinical evidence of recovery is supported by a lack of volitional EMG responses at 9 months with passive fibrillation rather than regeneration potentials, exploration with nerve repair is warranted. If the function of the motor endplate is uncertain, EMG stimulation is useful to demonstrate muscular contraction proving...
residual function at the distal nerve muscle interface prior to grafting.

Quaranta and colleagues retrospectively studied 13 patients who underwent surgical decompression 27 to 90 days post injury.23 All fractures resulted in immediate paralysis from lateral impact motor vehicle accidents. All showed >90% denervation within 6 days and >95% at the time of surgery. The fracture location in all cases was the perigeniculate region from five transverse, three longitudinal, and five mixed fractures. Interpretation of audiometric testing revealed conductive hearing loss in 69%, SNHL in 8%, and mixed loss in 23%. All patients were decompressed through a transmastoid extralabyrinthine approach. Exploration showed additional labyrinthine injury in 15% and mastoid pathology in 23%. Pathology encountered was edema in 62%, hematoma in 23%, and a bony spicule in 38%. Facial function in the 9 patients followed over 1 year showed HB grades I or II in 7 of 9 patients, and III in the other 2.

Ulug and Ulubil prospectively looked at 10 patients with 11 facial nerve paralyses operated on 14 to 75 days after trauma.24 Surgery on 9 patients was delayed more than 21 days. The timing of the first neurologic examination was 5 to 50 days obviating utility of ENoG in all but 1 patient. Surgery was based on HRCT and EMG findings. Sixty-three percent of fractures were longitudinal and were decompressed through the MCF, 37% were mixed and underwent combined middle fossa and transmastoid decompression. No postoperative hearing deterioration ensued. Pathology encountered showed fibrosis in the region of the geniculate ganglion in five, bony spicule impingement at the geniculate ganglion in two, disruption and laceration at the greater superficial petrosal nerve in two, and edema around the geniculate ganglion in two. Facial outcome in 9 of 10 patients was HB grade I or II, and was HB III in 1.

Surgical Approach. Approaches to the traumatized facial nerve are individualized by surgeons, as no universal guidelines have been adopted. Most advocate surgical approach based on fracture location and hearing status, others on type of nerve injury or repair expected, others on fracture orientation, and some others attempt to decompress all nerve injuries through the same approach. Most agree that decompression or nerve repair on the side of profound hearing loss warrants a translabyrinthine approach. This allows exposure of the nerve along its entire length with access to reroute and graft as necessary. The caveat being that with expanding indications for cochlear implantation, the slightest amount of cochlear reserve justifies great care to preserve the eighth cranial nerve.

Controversy lies in the extent of decompression necessary and whether or not an "adequate" decompression can be accomplished via the chosen route. Findings show involvement of the perigeniculate region in the majority of cases. The geniculate ganglion is not bony covered 16 to 18% of the time, which is important in MCF exposure of the nerve.22 For patients with serviceable hearing, a combined transmastoid and MCF operation can also expose the length of the nerve for decompression and allow access for cable grafting as necessary.

Some authors advocate a "less invasive" approach and feel that adequate exposure for decompression can be frequently accomplished through the transmastoid extra-labyrinthine operation.19,28,29 This entails a complete canal wall up mastoidectomy with isolation of the facial nerve from the stylomastoid foramen to the labyrinthine segment. After opening of the aditus ad antrum and identifying the short process of the incus, the incus is disarticulated and removed. The head of the malleus is removed through a posterior tympanotomy. The epitympanicum and canal are drilled, thinning the tegmen tympani, which offers exposure of the labyrinthine segment of the facial nerve and geniculate ganglion. Proponents of this approach feel that it offers sufficient decompression of the intratympanic segment of the facial nerve to the geniculate ganglion without a craniotomy and cite review series supporting adequate outcomes.

The disadvantages of this approach are that it is insufficient access for repair of a transected nerve proximal to the first genu of the facial nerve, and the surgeon may be unable to expose the fundus in up to 40% of cases, the labyrinthine segment of nerve is hidden behind and poses risk of injury to the tympanic segment, and the incus is necessarily disarticulated for exposure potentially compounding facial nerve injury with hearing loss.23,26–29 Fisch argues that the extent of decompression of a perigeniculate injury should be from the meatal foramen to the stylomastoid foramen. This is based on animal studies, imaging data, and surgical experience showing that intraneural edema and demyelination extend proximal from the site of injury. The retrograde effect is suspected to be due to a damming effect on axoplasmatic flow at the level of the narrow lumen of the labyrinthine segment. The facial nerve occupies greater than 80% of the cross-sectional area of the surrounding facial canal between the meatal foramen and geniculate fossa, and less than 75% of the facial canal lumen in the more distal segments of the canal. This offers a slight buffering effect that may reduce the risk of extensive axonal injury. The medial extent of decompression should include the meatal segment to help avoid progressive fibrosis of the traumatized nerve and ossification of the fallopian canal, and offers the best chance for good restoration of facial function.21,26,27

Twenty to 50% of gunshot wounds to the head involve the temporal bone and are associated with a higher rate of vascular and CNS injury than blunt trauma.26 Penetrating trauma resultant in facial nerve paralysis is most often immediate, and exploration shows that most are total or near-total facial nerve transections. Damage is mostly seen in the descending mastoid segment. Wounds have a high incidence of infection. In a review of 98 patients whose facial nerves were injured by gunshot wounds, Bento and de Brito showed that physiologic testing was only indicated in two patients.26 Eighty-one required cable grafting, 14 underwent hypoglossal to facial reanimation, 2 were repaired with an end-to-end Anastomosis, and 1 had decompression only. Sixty-five percent had HB grade III or IV, and 35% had V or VI function. Only 1 patient was conducive to decompression and had a grade 1 outcome (1%). The treatment of choice was an open mastoidectomy with metaplasty in 63 of 98. MCF exposure was added in four to facilitate grafting. Thirty-five patients were treated with canal-wall down mastoidectomy, fat obliteration of the cavity, and closure of the EAC to protect the sural nerve graft if all foreign bodies were removed and the pinna was not damaged. Thirty-five percent of these were revised for infection. They found that an open mastoid with metaplasty had a lower incidence of infection (10%) and subsequent cholesteatoma formation.

Opening of the nerve sheath is also controversial.24,28 Recommendations have been made for a bony decompression without opening the nerve sheath based on a review that showed lower recovery in the sheath opening arm compared with a bony decompression arm and an observation arm. It was proposed that opening the nerve sheath might further damage axonal elements and compound injury. The study had low numbers and was retrospective and nonrandomized. Also, decompression stopped at the geniculate area in a transmastoid procedure; and therefore the labyrinthine segment was not decompressed.

If less than 50% of the nerve is found to be disrupted, at the time of exploration, decompression of the nerve proximal and distal to the site of injury is warranted. If the extent of nerve injury is greater than 50%, repair with end-to-end anastomosis or cable grafting is advocated although any remaining axonal connections should not be disrupted to minimize synkinesis (Figure 8). Eighty-two percent result in HB grade III or IV function.26 Retrouting the tympanic segment of the facial nerve can offer 1 cm of latitude to accomplish an end-to-end anastomosis. The easy access and good approximate size match of the greater auricular nerve makes it an ideal source for grafting. If unavailable, the sural nerve is an alternative donor cable graft. If no return of function is noted within 12 months of nerve grafting, consideration of a partial hypoglossal to facial nerve reinnervation may be considered. More detailed discussion of facial paralysis, facial nerve repair and rehabilitation of facial nerve dysfunction is found in Chapter 34, "Facial Paralysis."

Cerebrosplinal Fluid Leak

The enchondral bone of the inner ear is mature at birth. The low metabolic activity of the otic capsule accounts for its lack of bony healing with trauma. Micro- and macro-fractures heal by fibrous repair rather than neo-osteogenesis with callus formation. Bony exchange in the peri-lymphatic
Imaging; however, intrathecal administration of contrast material prior to HRCT can be useful. MR may be useful to delineate dural defects with soft tissue herniation and is indicated if CT does not explain cranial nerve injury to rule out hematoma. The common sites of leakage are along the tegmen, through or around the labyrinth, or along the posterior fossa plate. The site of CSF leakage depends on fracture orientation, the surgical route if iatrogenic, and presence of inner-ear malformations when spontaneous.

Most traumatic CSF leaks heal spontaneously. In a study by Savva and colleagues, 24 of 29 head injury patients with CSF leaks were managed successfully with observation and measures to prevent CSF pressure spikes such as bed rest with head of bed elevation, avoidance of cough and sneezing, diuretics, and stool softeners. Brodie and Thompson showed 78% of 122 traumatic leaks healed with conservative management.7 Seven to 12% required a lumbar drain or serial lumbar taps to decrease intracranial pressure. CSF drained too rapidly can cause tension pneumocephalus. Intracranial inflammation from meningitis, trauma, blood, or surgery can impair CSF resorption elevating intracranial pressure. Surgical intervention should be considered for the 6 to 10% of traumatic CSF leaks that do not seal spontaneously within 7 to 10 days.

Prospective double-blind studies from the neurosurgical literature maintain that prophylactic antibiotic treatment of traumatic skull base CSF leak does not prevent the onset of meningitis. Brodie performed a meta-analysis of six retrospective reviews that individually found prophylactic antibiotic treatment of traumatic CSF fistula ineffective.22 Collectively they showed that the combined numbers correlated a significant decrease in cases of meningitis with prophylactic treatment of traumatic CSF leaks. Meningitis ensued in untreated controls at a rate of 8 to 10%, and 2.5% in those receiving prophylaxis. The risk of meningitis increased in patients with leaks that did not seal within 7 days and in patients who had concurrent infections. In a more recent retrospective review of 122 traumatic leaks, Brodie and colleagues again showed an elevated risk of meningitis in patients whose leak persisted beyond 7 days and in those with concurrent infections. No cases of meningitis were seen in patients without a concurrent infection who were treated with an adequate antibiotic. The authors advocate prophylactic antibiotics for patients with fracture-related CSF leaks.

Iatrogenic CSF leaks more commonly necessitate surgical repair.30 Only one spontaneous closure was seen in a series of 53 iatrogenic leaks. Surgical intervention was recommended if spontaneous closure did not occur within 3 to 4 days. Seventy-nine percent were controlled through a transmastoid re-exploration. Repair is again dictated by site of injury and hearing status.30,31 Historically, many methods have been used to repair CSF fistulae. A desiccant, such as isobutyl-2-cyanoacrylate and fibrin glue with dural patching or trans tympanic glue combined with lumbar drain for isolated leaks have been described. Muscle, fascia, perichondrium, and fat as well as several regional flaps have been utilized to prevent or stop leaks. Persistent leaks since Hilselberger described the use of fat strips have been rare. Multilayer closure supported with autologous grafts, for example, fat, fascia, muscle, showed an 81% 2-year success rate that was increased to 100% when artificial material, for example, bone wax, Oxy cell cotton, gel foam, was added to the closure in 16 of 16 repairs. Bone wax has been associated with osteomyelitis in other surgical fields, but its use in the temporal bone has not caused this complication. Bone wax mixed with Oxy cell cotton provides a sturdy yet conforming sealant for open mastoid air cells and to plug the eustachian tube. Dural defects may be plugged with soft tissue and supported by fascia. If the dural opening is greater than 1 cm in diameter, support with cartilage or bone is suggested along with filling the mastoid with fat and covering the mastoid with fascia. For multiple tegmen defects, or those greater than 2 cm, MCF exposure should be considered.

When conservative measures fail, re-exploration and fat repacking and they have serviceable hearing, Glasscock and colleagues have recommended the middle fossa approach to expose and pack the eustachian tube.21 Air cells that track below the IAC toward the hypotympanum and eustachian tube have been identified and are impossible to identify through a transmastoid approach.32 For those with nonserviceable hearing, the transcoclear approach to obliterate these cell tracts is effective. Blind sac closure of the lateral EAC in conjunction with obliteration of the middle ear and eustachian tube may be necessary. This requires full eversion of the sac and complete removal of all squamous cell epithelium from the EAC and TM.

**Hearing Loss**

Hearing loss is documented in 24 to 66% of patients suffering temporal bone fracture and may occur by different mechanisms.24,16,19,29 In a study of 820 temporal fracture patients, hearing loss was conductive in 21%, mixed in 22%, and sensorineural in 57%. Only 3% had profound loss, and 1 patient had bilateral profound SNHL. Most regions gradually increases in a centrifugal pattern to the periphery of the labyrinth where bone turnover approximated normal healing patterns. Inhibition of bony healing is greater around the cochlea and vestibule than around the semicircular canals. This healing pattern may explain the 15 to 20% traumatic CSF leak rate found in otic capsule violating fractures. Poorly sealed microfractures may also explain cases of latent meningitis seen years after trauma.

CSF leaks in general are categorized as traumatic or nontraumatic. The majority are traumatic related to head injury and surgery.30,31 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.30 In a retrospective series of 92 leaks, 32% were related to head injury, 58% were iatrogenic, 8% were spontaneous, and 2% related to osteolytic erosion from chronic otomastoiditis.30 Otorhinorrhea was a presenting sign in 94%. Meningitis occurred in 16.3% with 11 of 15 related to iatrogenic trauma.
Conductive hearing loss as discussed is explained by damage to or obstruction of the outer- or middle ear structures. Many resolve over time. Patients who sustain conductive losses attributed to acquired canal stenosis, perforation of the TM, tympanosclerosis causing ossicular adhesions, ossicular fracture and dislocations, and posttraumatic cholesteatoma, may benefit from surgical repair or reconstruction (Figure 9).

Direct trauma to the auditory pathway causing SNHL may be obvious, such as fractures through the otic capsule or the eighth cranial nerve or central damage along cortical auditory pathways. Indirect damage may result from secondary hemorrhage/hematoma, edema, ischemia, hypoxia, and infection that damage hair cells. Direct damage may cause permanent injury while other injuries may show greater resiliency. Damage may be transient as with labyrinthine concussion, show fluctuating symptoms related to PLF and posttraumatic endolymphatic hydrops, or trend to progression with fibrosis related to healing.

Enlarged vestibular aqueduct (EVA) syndrome may predispose to transient, fluctuating or persistent SNHL with even minor trauma. This syndrome is the most common congenital ear abnormality seen on CT affecting up to 14% of children with SNHL. There is an average gap of 22 months from the diagnosis of hearing loss to the specific identification of the anomaly with CT. This gap without the protective information for vigilant avoidance of minor trauma leaves children vulnerable to hearing loss from minor insult. Progressive hearing loss was seen in 22%, and fluctuating loss in 39% of 77 patients with EVA. Progressive deficits in pure tone average were less than 20 dB in 92%. In this study group, 4% had vestibular symptoms, 4% gave a history of antecedent head trauma, and 4% were explored for PLF and all were found to be negative. The authors felt that the low incidence of trauma related hearing loss was due to counseling efforts and reflects a falsely low incidence of trauma-associated hearing loss, but also possibly the protective effect of avoidance of trauma.

A another theory for progressive loss is traumatic autoimmune damage through activation of preexisting conditions or exposure of previously naïve proteins to the immune system. Corticosteroid responsive hearing loss mimicking rapidly progressive autoimmune losses have been anecdotally reported. These reports were in patients with Meniere disease undergoing endolymphatic sac procedures, which confounds the issue given Meniere disease may have possible autoimmune cause in some patients. Further elucidation of this theory is necessary to draw direct conclusions.

Posttraumatic SNHL may be due to the synergistic effects of acoustic trauma, physical trauma, systemic physiologic abnormalities, and ototoxic medicines. Some SNHL persists beyond the 6-month time frame expected for resolution of concussion. Segal and colleagues reviewed audiograms and medical records from 1,741 ears in patients with hearing loss. They imposed a highly selective process that excluded patients with skull or temporal bone fracture, or those with closed head injury. Their strictly defined inclusion criteria minimized the influence of other diseases or age-related hearing loss. The investigators completed a 4-year posttrauma study of the group with a goal of identifying the time course and pattern of trauma induced hearing degeneration. Any change in the severity of the initial 655 mild losses, 701 moderate losses, and 385 severe losses took place in the first year after trauma. The minor changes that did occur showed an increase in the proportion of mild loss, and a decrease in the proportion of severe loss. No significant changes happened after the first year. Bergemalm followed a smaller group to look at long-term hearing outcomes. The subjects included more severe trauma including fracture and CNS injury. They followed 43 patients for 2 to 13 years.

Significantly poorer thresholds with a higher risk of progression occurred as compared to an atraumatic age-matched control group. Hearing loss in 74% of the study group progressed. When stratified, significant progression in hearing loss was only noted in the patients diagnosed with skull fractures. Patients whose hearing loss was attributed to contusion did not progress. The progression with fracture victims was not limited to 1 year and was noted across all frequencies.

The violent nature of modern head injury can affect hearing anywhere along peripheral or central pathways. With anatomical evaluation by otoscopy and imaging one can explain how injury may predispose to hearing and balance dysfunction, and it may help prompt testing but cannot determine the severity of hearing loss. Evaluation of inner ear and central function is difficult at the bedside. Otoscopic examination along with whisper, Weber and Rinne tuning fork, and ototraumatic emissions testing may be correlated to offer simple gross determination of sensorineural injury, although acute testing is often confounded with mixed conductive loss and SNHL. Formal audiometric analysis as well as tuning fork testing requires a certain cognitive level of functioning and mobility. Often traumatic brain injury leaves patients unable to participate in traditional behavioral audiometric testing even past the acute phase of their injuries. Coexisting impairment may make it difficult for the patient or the caregiver to recognize the silent handicap of hearing loss. A utidary brainstem response (ABR) testing can be accomplished in these difficult patients and lead to hearing rehabilitation that will facilitate directed therapy and overall recovery.

Sensory function can be evaluated by electrocochleography if the EAC and middle ear are free from obstruction. ABR electrophysiologically tests the neural hearing, displaying five waves that fall along the hearing pathway. Evoked stimuli travel between the eighth cranial nerve, cochlear nucleus, superior olivary complex, lateral lemniscus, and the inferior colliculus on their way to the auditory cortex. Potentials are recorded representing ipsilateral as well as contralateral synapses. Prolonged latencies or poor waveform morphology can identify neural injury. In a patient that cannot participate in behavioral audiometry, the entire hearing pathway can still be evaluated by otoscopy, tympanometry, otocoustic emissions as long as the middle ear is aerated, ABR, and may be correlated with CT and MR imaging to combine anatomical and physiologic testing to determine hearing status.

Although there are patients who experience bilateral profound hearing loss after head trauma, it is rare. When this occurs, however, successful rehabilitation through cochlear implantation can be achieved, provided that the cochlear nerve remains intact. The US Food and Drug Administration (FDA) warns of an increased risk of meningitis in cochlear implants placed in patients with temporal bone fracture, but the risk is reduced by preoperative administration of the pneumococcal vaccine, for example, Pneumovax 23. HRCT
imaging is important to rule out IAC fracture and labyrinthitis ossificans. High-resolution T2-weighted MRI may even be more sensitive to determine patency of the cochlea. Promontory stimulation helps determine cochlear nerve integrity, and if negative bilaterally, suspicion of disrupted cochlear nerves should prompt consideration of an auditory brainstem implant. Cochlear and brainstem implants are discussed in Chapter 32, “Cochlear and Brainstem Implantation.”

Facial nerve stimulation has been reported to be a greater problem in patients with cochlear implant with temporal bone fractures than in patients deaf from other causes, although otosclerosis may also predispose to facial nerve stimulation. Overt or even microfractures of the otic capsule allowing leak of current affecting the facial nerve may explain this occurrence.

POSTTRAUMATIC VESTIBULOPATHY

Traumatic disequilibrium is a common and usually self-limited entity following head injury. Postconcussive syndrome is reported in 40 to 60% of head injured patients. Interestingly, it seems to be unrelated to the severity of the injury. Symptoms are often vague. Those related to the vestibulocochlear system include dizziness, vertigo, hearing loss, tinnitus, and noise sensitivity. Spontaneous resolution of symptoms occurs within 3 to 9 months in the majority of patients but may persist past 1 year in 8 to 15%. Elderly patients may especially show lingering symptoms of chronic disequilibrium due to either increased susceptibility to shaking axial injury or to coexistent sensory deficit. When symptoms are suspect or motivated by secondary gain, dynamic posturography is useful in identifying cases of malingering. Vestibular rehabilitation is useful for those with profound or protracted symptoms.

Ernst and colleagues looked at posttraumatic vestibular symptoms. They categorized primary and secondary disorders in a prospective study of posttraumatic vertigo in patients with mild head injury. Primary disorders stratified as labyrinthine concussion in 29%, PLF in 10%, and cervicogenic vertigo in 19% of patients. The secondary disorders included otologic disturbances in 8%, delayed endolymphatic hydrops in 19%, and canalolithiasis in 14%. Most patients, 74%, were successfully treated by directed habitation training and or medical or surgical interventions for more discrete symptoms.

Hoffer and colleagues categorized patients with dizziness following mild head trauma into three groups: posttraumatic vestibular migraine, 41%, positional vertigo, 28%, and spatial disorientation, 19%. 12% of the total group could not be categorized. They prospectively treated 58 patients with vertigo following mild traumatic brain injury with 6 to 8 weeks of vestibular rehabilitation. Those with symptoms of positional vertigo and vestibular migraine responded well to therapy and returned to work within 1 to 8 weeks, respectively. A normal static posture and dynamic posturography findings were signs of spatial disorientation that were not seen in the positional vertigo and migraine-associated diziness groups. Those in the spatial disorientation category followed a more protracted course averaging 39 weeks to resolution of symptoms with 4% remaining symptomatic past 1 year.

Electronystagmographic testing is typically normal in postconcussive disequilibrium. Symptoms are self-limited but can be distressing. Supportive treatment with reassurance is generally adequate with vestibulospessant medications reserved for intractable nausea and vomiting, and then withdrawing these drugs as soon as possible to allow for central compensation for the balance disability. Vestibular rehabilitation stressing vestibulo-ocular and vestibulo-spinal exercises have also been shown to accelerate recovery. A associated audiometric threshold shifts are often temporary but must be monitored with follow-up testing.

Concussive injury to the membranous labyrinth or brain may exacerbate preexisting Meniere disease or vestibular migraine, or may produce syndromes that mimic these processes and cause vertigo. When vertigo more discrete falls into classical diagnostic schemes, medical and surgical treatment can be applied to those symptom complexes. Posttraumatic benign positional vertigo evoked by specific head positioning with observation of fatiguable geotropic nystagmus on the Dix–Hallpike maneuver is treated with canalith repositioning maneuvers. Fluctuating or persistent audiovestibular symptoms of posttraumatic endolymphatic hydrops may respond to dietary salt restriction and diuretic therapy. Posttraumatic migraine syndrome may benefit from an occipital nerve block for cervicogenic pain. Sciatic nerve or trigeminal nerves by hypnosis for prophylaxis of idiopathic migraine, propranolol, or amitriptyline. As previously discussed, surgical exploration should be considered for management when overt signs and symptoms of a PLF are present.

Noise-Induced Hearing Loss

Sharon G. Kujawa, PhD

Noise-induced hearing loss (NIHL) is common, its consequences currently not amenable to medical treatment, and its impact on communication and quality of life, significant. Theoretically, NIHL is entirely preventable; in practice, exposure to high-level sound is one of the most common causes of permanent, sensorineural hearing loss and inner ear damage. NIHL usually accumulates gradually with repeated exposure to high-level sound, although a single traumatic exposure can have immediate and permanent outcomes. NIHL is influenced by many factors, both related to the exposure itself and to characteristics of the individual that shape vulnerability to NIHL. In spite of numerous attempts to regulate exposure and to educate, there is mounting concern that NIHL prevalence is increasing, and reaching younger ears. Given the aging of our society, the co-existence of noise-induced and age-related hearing losses (AHLs) in the same ears will impact an increasingly larger proportion of the population and the societal burden will grow.

NIHL is thus of significant epidemiological concern. The National Institutes of Health, the Centers for Disease Control and Prevention, the World Health Organization (WHO), the European Commission, and many organizations with more focused missions all identify NIHL as a strategic target area for their efforts.

This chapter will review effects of high-level sound (for simplicity, noise) on the ear. In its description of structural and functional consequences of noise exposure, and of the variables that shape outcomes, it will rely heavily on animal models, as they provide the opportunity for strict experimental control and provide access to the underlying histopathology. The chapter will describe methods and outcomes of surveillance programs for NIHL in the human. Finally, it will address current management and treatments on the horizon that may prevent or reduce NIHL and inner ear damage.

PREVALENCE OF NIHL

Opportunities for noise exposure are commonplace in work and recreational activities. The WHO describes exposure to excessive noise as “the major avoidable cause of permanent hearing impairment worldwide.”1 In the United States, estimates cited by the National Institute on Deafness and Other Communication Disorders suggest that 10 million individuals already have permanent NIHL and that 30 million more are exposed daily to potentially damaging sound.2 Occupational sources of exposure are problematic worldwide.3 In the United States, NIHL is among the most common reasons workers seek medical attention for workplace injury and among the most common reasons they seek compensation.4 Auditory-related disabilities were the second most common type claimed by veterans of U.S. military service who initiated compensation in 2003.5 On an annualized basis, monthly compensation payments to veterans with hearing loss as their major disability were ~$660 million and payments for tinnitus were ~$190 million in 2004.

NOISE-INDUCED PATHOPHYSIOLOGY AND HISTOPATHOLOGY

It should not be surprising that a system optimized to respond to exquisitely small displacements would suffer compromise, for example, sensitivity loss and structural damage, when exposed to displacements orders of magnitude greater. Although NIHL is common in the human, characterization of physiologic and histologic outcomes is limited by incomplete and often retrospective assessment of cumulative noise dose, numerous confounding influences that cannot be readily controlled and may not be apparent, and of course, limited access to tissue. Thus, much of what we know about the effects of noise on the ear has been characterized in animal models, and most of this work has concentrated on noise-induced loss of threshold sensitivity and histopathologic correlates of that loss.

Pathophysiology: Temporary and Permanent Threshold Shifts

Noise exposure can produce temporary and permanent effects on function. Noise-induced sensitivity alterations that resolve on a timescale of hours to a few days after exposure are termed temporary threshold shifts (TTS). Such shifts tend to recover exponentially with postexposure time and reach a steady state, such that “final” permanent threshold shifts (PTS) are attained with a time course similar to that shown in Figure 1.6 Details of the magnitude and frequency extent of the functional compromise and the recovery time course are related to the frequency composition, level, temporal characteristics, and duration of the exposure and are shaped by the vulnerabilities of the individual as discussed later in this chapter.

Typically, threshold shifts secondary to shorter, lower-level exposures (those producing threshold shifts of about 40 dB or less when assayed at short postexposure times), resolve in this timeframe. The long-term impact of such apparently reversible insult is currently unresolved. As exposure becomes more significant, initial shifts increase, time to recovery is prolonged and, of course, shifts may become permanent.

Sensitivity losses apparent at longer postexposure times are termed PTS. As an example, Figure 2 displays temporary and permanent ABR threshold shifts in the same ears of young CBA/CJ mice 24 hours and 2 weeks following octave-band noise exposure. Here, lower levels of exposure (94, 97 dB) produced milder degrees of TTS which have largely recovered by 2 weeks, except for a small residual shift apparent at high frequencies after 97 dB exposure. Noise exposures at 100 and 103 dB SPL resulted in progressively larger TTSs that spread across an increasingly greater extent of the frequency range tested. In such ears, a significant, but more frequency restricted PTS remained 2 weeks after exposure. PTS grows rapidly with exposure level in most mammalian species. In the example provided here, this rapid growth is evident: a 3 dB increase in the level of a single, 2-hour exposure (97 to 100 dB), yielded a nominally 40 dB difference in measured PTS.

Noise-induced threshold shifts are often observed to be greatest not at the frequency of exposure but rather, approximately one-half octave above it, particularly for narrow band (including pure tone) and higher-level exposures. Such an upward shift of functional compromise is apparent in Figure 2. The “half-octave shift” in measured thresholds that occur after high-level noise exposure are apparent in Figure 2.
originates in the nonlinear mechanical response of the basilar membrane to high-level sound. Evidence of this upward shift of sensitivity loss can be seen in the basilar membrane response\(^8\) and in electrophysiological\(^9,10\) and behavioral\(^10,11\) responses to sound, and histopathology can be documented in correspondingly shifted cochlear places\(^12,13\). In addition to this tonotopically “appropriate” injury, the literature provides clear examples of threshold shifts and cochlear lesions which are tonotopically “inappropriate” with respect to the frequency content of the exposure.\(^14\) Most often, these lesions are observed in the extreme base or “hook” region of the cochlea, which demonstrates greater vulnerability to insult. As exposure bandwidth increases, maximum injury can be greatest in basal cochlear regions.

Although the threshold shifts shown in Figure 2 for a murine model reveal little variability among identically exposed, age- and strain-matched animals within groups, it is important to note that vulnerability to noise-induced TTS, PTS, and cochlear structural injury demonstrates dramatic variability among animals heterogeneous for genetic background, exposure age, gender, and certain other variables. It is reasonable to suspect that such factors contribute materially to apparent noise vulnerability differences observed in humans. Such individual differences will be addressed later in this chapter.

**Histopathology: Temporary and Permanent Injury**

Assessment of noise-induced histopathology reveals that many cell types in the cochlea can be affected. Various diagrams and images illustrate the common sites of temporary and permanent noise-induced histopathology. These include stereocilia disarray, hair cell damage/loss, strial edema, neuronal loss, fibrocyte loss, excitotoxicity: vacuolization and swelling, and supporting cell collapse. These changes are assessed by light microscopy in serial plastic-embedded sections of the cochlea.

**Figure 2** Noise-induced threshold shifts assayed by auditory brainstem response (ABR) 24-hour and 2-week postexposure (8 to 16 kHz octave noise band, 94 to 103 dB SPL, 2 hours) in CBA/Ca\(\text{J}\) mice (\(n = 8\) to \(>100\)) exposed at 4 to 6 weeks of age. At highest exposure level, ABR metric saturates at some frequencies; points at which >50% of responses were absent are noted by up arrows. Data are expressed as mean shifts ± SE relative to strain- and age-matched, unexposed controls. (Kujawa, unpublished data.)

**Figure 3** Common sites of temporary and permanent noise-induced histopathology. Noise-induced histopathology assessed by light microscopy in serial plastic-embedded sections reveals compromise to numerous cell types within the cochlear duct. Images taken from CBA/Ca\(\text{J}\) mice noise exposed at various levels and held for various post-exposure times (see text and references 16 and 33 for details). compromised by sound overexposure (Figure 3). Hair cell stereocilia damage, evidence of swelling and vacuolization in the inner hair cell (IHC) area, hair cell loss, collapse of supporting cells, strial compromise, fibrocyte loss, and neuronal loss all have been identified in noise-exposed ears.\textsuperscript{15,16,18} Although there is overlap in the histologic underpinnings of TTS and PTS, the mechanisms underlying a large but reversible threshold shift, eg, 40 dB at 12 hours post exposure, and a comparable permanent threshold shift, eg, 40 dB at 2 weeks post exposure, are widely regarded to be fundamentally different, and attempts to predict the latter from the former have been largely disappointing.\textsuperscript{17} In the sections that follow, the focus is on recurring themes of damage and loss, apparent in many species and for a range of exposures.

At short post-exposure times, histologic examination frequently reveals alterations to hair cell stereocilia.\textsuperscript{16–20} Stereocilia deflection changes tip-link tension, opening mechanically gated transduction channels. High-level sound can cause disarray of the stereocilia bundle, fusion of its elements, and break tip links as shown in Figure 4A. Stereocilia damage or loss has been correlated both in its distribution and degree with the frequency extent and degree of functional compromise, assayed by threshold shift metrics.\textsuperscript{16,21}

The afferent synapase between IHCs and peripheral terminals of spiral ganglion cells (Figure 4B) is glutamatergic, and a type of glutamate excitotoxicity appears to be a ubiquitous aspect of the cochlea’s acute response to noise. Sound overexposure resulting in massive transmitter release can tax postsynaptic receptors and glutamate clearance mechanisms leading to classic signs of glutamate excitotoxicity.\textsuperscript{22} If an ear is fixed 0–12 h after an acoustic overexposure, there is often evidence of vacuole formation and swelling of afferent dendrites under the IHCs and swelling of spiral ganglion cells and/or their satellite cell sheaths in Rosenthal canal (Figure 3).

Histologic evidence for excitotoxicity is visible whether the exposure produces a temporary threshold shift (TTS) only, or has both temporary and permanent components, and can be present even if no hair cell loss will eventually ensue.\textsuperscript{16} Excitotoxic injury seen acutely may have long-term consequences. Puel and colleagues\textsuperscript{23} have suggested that such changes may underlie the neuronal degeneration seen in a subset of human ears with presbycusis.

Swelling of the stria vascularis (Figure 3) is an acute consequence of noise exposure with as yet unclear functional consequences.\textsuperscript{16,24} The stria vascularis, as the name implies, is a highly vascular tissue located at the cochlear lateral wall. It plays an important role in maintaining the ionic environment and the endocochlear potential (EP) which are, in turn, crucial for the normal transduction processes of the hair cells. Such fundamental

\begin{figure}

\caption{Acute and chronic consequences of noise-induced hair cell compromise. Panel A. Noise-induced damage to hair cell stereocilia can include disarray, fusion or loss of individual stereocilia or entire bundles, and breakage of the fine tip links that connect the individual stereocilia. Such changes can occur without other obvious ultrastructural changes being visible and can contribute materially to noise-induced threshold shifts. Panel B. Synaptic transmission between IHCs and dendrites of type 1 SGCs takes place at ribbon synapses, where released glutamate activates AMPA receptors on the postsynaptic membrane. Mechanisms for glutamate clearance and receptor regulation maintain optimum responsiveness; however, with acoustic overstimulation, release of neurotransmitter may exceed such regulatory processes and induce dendritic damage, presumably through glutamate excitotoxicity. Panel C. Organ of Corti schematics and idealized threshold tuning curves are shown for 3 cochlear conditions: top panel—the normal condition, in which there is a full complement of outer and inner hair cells and a sensitive and sharply tuned response; middle panel with noise-induced OHC loss, and associated loss of the physiologically-assisted amplification of low-level sounds resulting in a less sensitive and more broadly tuned response; bottom panel now adding IHC loss which prevents communication with neural elements, resulting in no acoustic responses from this cochlear region. (Organ of Corti schematics courtesy of M C Liberman).}
\end{figure}
contributions to normal cochlear function suggest that noise-induced compromise to the stria should have functional consequences.25,26 Although the EP recovers quickly from the effects of noise, degeneration of strial marginal and interdental cells may contribute to threshold shifts in the steady state.27

Supporting cell collapse can also be evident in the acute post-exposure period, and reversible components of such structural alteration have been associated with reversible effects on cochlear potentials in guinea pigs29 and in chinchillas.30 Reversible changes to supporting cell architecture (at least to highest levels of exposure) were also seen in ears with TTS in a recent survey of noise effects in mice (Figure 3).16

Histopathology evident weeks to months after exposure can be quite different from that seen in the acute post-exposure period. Cells damaged by noise can degenerate rather quickly. Hair cells damaged during exposure, for example, may degenerate, being replaced by nonsensory (supporting) cells which form a phalangeal “scar” on the surface of the cochlear sensory epithelium.29

There is wide agreement that the hair cells, especially the outer hair cells (OHCs), are particularly vulnerable to noise-induced injury and that their compromise is a primary contributor to post-exposure changes in function.21,25,30,31 OHCs amplify motion patterns, enhancing the cochlear mechanical response to low-level sound. IHCs serve as traditional sensory receptors. Noise-induced OHC loss elevates thresholds and broadens tuning (Figure 4C). Noise-induced IHC loss eliminates cochlear communication with afferent neurons altogether, resulting in unresponsive regions, as Figure 4C.

Noise-induced histopathology often originates with focal OHC damage and loss, and for more significant exposures, IHC, and supporting cell compromise. Degeneration of myelinated afferent neurons and spiral ganglion cells can follow as a secondary consequence to IHC loss,22 although it also can occur in ears without such loss (Figure 3).31 It is nevertheless clear that frank hair cell loss is not obligatory, even in ears with PTS on the order of 40 to 50 dB. Threshold shifts of this magnitude can be explained entirely by stereocilia damage.19 In mice, stereocilia damage seen in acute ears often persisted and was the most functionally important structural change underlying PTS.16

The functional significance of certain cellular changes and details of their postexposure appearance in different species remains under active investigation in many laboratories. Fibrocyte loss in the spiral ligament (Figure 3), for example, is seen commonly in noise-exposed ears of mice.29,31 Loss of these cells has currently unknown effects on auditory sensitivity; ears with large fibrocyte losses may demonstrate minimal threshold shifts and vice versa. It has been suggested that fibrocytes of the lateral wall may be involved in an endolymph K+ recycling pathway that is particularly crucial during acoustic overstimulation. In this role, K+ ions entering and leaving the OHCs are subsequently shuttled through the fibrocytes and finally back to the stria vascularis.34

**FACTORS INFLUENCING NIHL RISK**

The appearance, nature, and degree of noise-induced functional and structural compromise depend on various characteristics of the exposure, the individual, and interactions between the two. In the sections that follow, such variables will be briefly reviewed.

**Variables Related to Noise Exposure**

Efforts to establish risk of NIHL in individuals and in populations rely heavily on characterization of the exposures themselves. Although straightforward in laboratory studies, obtaining reliable work and/or recreational exposure estimates for individuals and groups is a comparatively daunting task. In quantifying exposures to human ears in occupational settings, exposure assessments often focus on sound level and duration. Sound-level measurements, including those acquired by wearable noise “dosimeters” usually are made using the “A” frequency weighting scale, to approximate the frequency response of the human ear. The resulting sound level is designated in dBA. A metric of particular interest is the “noise dose,” in which the overall level is integrated over the entire time of exposure. Because such information is most frequently captured in relation to work-related noise monitoring, noise dose is commonly specified relative to a full-shift (8 hour) time-weighted average (TWA).

Exposure variables related to frequency composition, level, temporal pattern, and duration of the exposure, however, all can influence the risk of NIHL and cochlear histopathology. In brief, the mechanical properties and tonotopic arrangement of the cochlear sensory epithelium and the frequency content of the exposure combine to determine the base-to-apex places of overstimulation and the frequency range of hearing loss produced by the exposure. As the level of the noise increases, risk of temporary and permanent hearing loss and inner ear damage also increase. As seen previously in Figure 2, exposure level also influences the frequency range of the noise-induced insult, as higher-level exposures (over)-stimulate a broader extent of the cochlear epithelium. Risk of noise-induced compromise increases with exposure duration. A time-for-intensity trading relationship exists for many exposures, such that the higher the level, the shorter the time before insult. Such generalities are influenced, however, by temporal characteristics of exposure, including whether exposures are intermittent or continuous.

For exposures equal in total energy, those delivered in interrupted fashion are associated with less PTS than continuous exposures. The periods of quiet appear to afford some protection against the noise-induced insult, as long as the noise off time is of sufficient duration. In contrast, impulsive noise is more hazardous to hearing than continuous noise of the same spectrum and intensity. A non important variable appears to be the degree of amplitude kurtosis in the noise exposure stimulus.35 Detailed treatments of exposure parameter influences on NIHL and cochlear histopathology can be found elsewhere.5,36,37

**Acoustic Trauma**

To this point, the focus has been on consequences of more or less continuous exposure. NIHL can result, however, from short duration, even single exposure to a particularly damaging sound, for example, explosion, gunshot or firecracker, commonly termed an acoustic trauma. Here, the mechanical insult may produce different patterns of structural damage, frequency patterns of functional involvement may shift, and recovery patterns may be altered from those seen after chronic exposure with longer duration, less intense sound. Structural compromise may include tympanic membrane rupture and injury to middle-ear structures as well as damage to the inner ear. Significant and permanent hearing loss is a common result.

**Exposure History and NIHL**

Bridging the transition between variables related to the exposure and those intrinsic to the individual is the observation that risk of NIHL may be shaped by an individual’s history of particular kinds of exposure. Substantial reduction of threshold shifts (protection) has been seen for a variety of chronic noise-exposure protocols, collectively referred to as “conditioning” or “toughening” of the ear. These protective effects of sound-exposure history have been studied with a number of different paradigms; however, the protocols fall into 2 main classes. In 1 case, animals are conditioned by daily exposure to a moderately intense sound, which, by itself, causes little or no permanent damage. Then, after a variable rest period, they are given a traumatic exposure of shorter duration; usually, 1 with the same spectrum as the conditioning stimulus but applied at a higher sound pressure.38,39 The protection observed is that animals sound conditioned before frank overexposure show less PTS (and/or cochlear damage) than those overexposed without conditioning pretreatment. In a second type of experiment, here is 1 type of exposure stimulus, usually a mildly traumatic one, which is delivered in daily doses (eg, 6 hours on, 18 hours off).40 The “toughening” observed in this paradigm is that thresholds measured each day, immediately postexposure, improve as the number of daily doses increases. However, in most such studies, thresholds measured immediately before each exposure progressively deteriorate, and the animals demonstrate PTS (and/or permanent cochlear damage) weeks after the daily exposures are terminated.41 Thus the toughening consists of an observed decrease in a compound threshold shift (CTS) consisting of a small, increasing PTS and a larger, decreasing TTS component.
Coexposures. Risk of developing an NIHL may be increased for noise-exposed individuals who receive certain therapeutic drugs like aminoglycosides and cisplatin, and for individuals working in certain industrial and military settings that likely expose them to certain chemical agents, e.g., solvents, chemical asphyxiants, heavy metals. Such agents can interact with noise and add to or even potentiate NIHL. Some produce hearing loss on their own and, when delivered to a noise-exposed individual, contribute in an additive fashion to NIHL. Other agents potentiate the effects of the noise on hearing and histopathology, in some cases doing so with little or no effect on hearing of their own; Such co-exposure synergies are well described in the toxicology literature and perhaps easier to identify and quantify, as the effects of 2 chemicals with the same target organs or sharing the same metabolic pathway may be more easily predicted and prevented.42

Variables Related to the Individual

Hearing losses recorded in noise-exposed ears are highly variable in human populations. This variability may arise from differences in noise exposure as described above, as well as other intrinsic and environmental variables that produce hearing loss on their own or alter susceptibility to NIHL. Many variables have been considered over the years.43 Aiding these efforts, low-variance murine models have been used to characterize genetic influences on NIHL susceptibility; and, with genetic variability minimized, effects of other individual variables on NIHL outcomes may be isolated as well, as discussed below. Such work promises to translate to the human, as genetic influences on NIHL and other susceptibilities are clarified.

Genetic Influences on Noise Susceptibility. Many investigators have turned to animal models to characterize effects of noise on the ear without certain of the confounding variables inherent when studying NIHL in humans. Although the additional experimental control possible with such approaches can reduce variability, for example, by careful specification and control of exposure parameters, variability among identically exposed, outbred animals can remain high.44 Noise-induced sensitivity loss and cochlear histopathology within inbred strains of mice, in contrast, show comparatively small variability, suggesting that genetic differences contribute to interindividual NIHL vulnerability differences.

Within-strain NIHL phenotype homogeneity has facilitated characterization of between-strain NIHL susceptibility differences. At some ages and with certain levels of noise exposure, mice from some inbred strains, for example, 129/SvEvTac and MOLF/Ei, demonstrate remarkable resistance to NIHL, whereas mice from other strains (B6, BALB/c) can show dramatic vulnerability.46 Since animals of a given strain are genetically identical, these phenotype differences may provide important clues to mechanisms contributing to such vulnerability differences. Moreover, given the similarities between mouse and human auditory systems and mouse and human genomes, such findings may provide important clues to human NIHL susceptibility.47

Age-at-Exposure. There has long been general agreement that a period of heightened sensitivity to insult from noise or ototoxic drugs exists during and even beyond the period of obvious structural and functional maturation of the cochlea.48 Elimination of genetic variation, however, uncovers dramatic effects of age-at-exposure on vulnerability to noise; effects that do not asymptote until young adulthood.43,49 This vulnerability cannot be explained by differences in baseline sensitivity, nor can they be accounted for by differences in transfer through the middle ear.50 Additional work will be required to identify mechanisms contributing to these NIHL vulnerability shifts with age.

Efferent Influences. The olivocochlear (OC) system of neurons comprises a descending system that originates in the brainstem superior olivary complex and projects to the cochlea through which the noise has passed.51 Additional influences on this efferent-mediated protection may contribute to NIHL vulnerability. Investigators have shown, using a DPOAE-based assay of efferent response strength, that reflex strength in noise-exposed guinea pigs was inversely correlated with the degree of hearing loss following subsequent noise exposure.52 These data suggest that the well-known distinction between "tough" and "tender" ears may arise, at least in part, from differences in OC reflex strength. Since OC reflexes can be assayed noninvasively using otoacoustic emissions (OAEs), a screen for NIHL vulnerability may be possible for human application.

EVALUATION AND MANAGEMENT OF NIHL IN HUMANS

Behavioral thresholds for pure tones are the most commonly employed metric for assessing the effects of noise on hearing in clinical and occupational settings. Pure-tone threshold audiometry has served as the standard assay of hearing sensitivity in humans for many decades. Measurement protocols are standardized and validated. Such measurements form the basis of population sensitivity norms against which individual sensitivity can be assessed. Moreover, NIHL risk models, upon which every existing noise exposure standard is based, utilize audiometric data.

The Audiometric "Noise Notch"

Probably the most clearly recognizable audiometric pattern of permanent hearing loss is that commonly seen in human ears with a history of noise exposure. The pattern takes the form of a notched reduction in sensitivity which reaches a maximum between 3,000 and 6,000 Hz. Hearing may be quite normal at lower test frequencies and often demonstrates substantial recovery at 8 kHz44 (Figure 5). There can be substantial variation in the specifics of this configuration; in a given ear, it is influenced by the many variables already discussed, as well as any other pathology that might be present.

Several explanations have been offered for the noise-notch hearing loss configuration. Noises to which human ears are often exposed are broadband signals. These signals are shaped (some frequencies amplified, others filtered out) by passage through the external and middle ears.55 Vulnerabilities of cochlear regions stimulated by these signals, and even frequency-dependent attenuation of those noises that may activate the acoustic reflex, also have been cited as contributing to the observed hearing loss pattern in human ears. Reports of different frequency foci for noise-induced threshold shifts usually can be traced to differences in the frequency composition of the exposure or differences in the system through which the noise has passed.

No universally accepted metric for NIHL exists; however, the 3 to 6 kHz notch is so often seen in noise-exposed ears that it has been taken as a proxy measure for noise-exposure history.56,57 Specifics of its use in this manner are controversial and are problematic for those tasked with assigning cause and determining compensation for individual cases of NIHL. The general observation, particularly if accompanied by a reported noise-exposure history in work and/or recreational activities, nevertheless has broad clinical utility in the differential diagnosis of NIHL from other causes, for example those with genetic, ototoxic, and age-related underpinnings. Several methods have been proposed to aid identification and quantification of these so-called noise notches.56,58

Are OAEs a More Sensitive Indicator?

To increase sensitivity to subtle changes in function, particularly those occurring early for a given individual exposed to noise, some investigators and clinicians have turned to OAEs. OAEs are sensitive and objective measures of cochlear function, and their sensitivity to noise-induced OHC compromise, in particular, makes them a
potentially good candidate for monitoring early effects of noise exposure of OHCs. Indeed, several investigations have presented evidence that OAEs may demonstrate noise-induced shifts earlier than conventional pure tone thresholds. The potential for OAEs to provide early warning of cochlear insult suggests that these noninvasively recorded responses may be of value in hearing conservation efforts.

Delayed Consequences of Noise Exposure

Once an ear has been compromised by noise, a question with significant clinical and public health importance is whether the insult influences future changes in hearing; for example, those that accrue with age. In the human, NIHL and AHL often coexist in the same ear, and current clinical and medical–legal evaluations often require allocation of noise-induced versus age-related components of such aggregate hearing losses. Methods commonly used to aid such allocations treat these components as though they add independently (allowing some compression for large shifts) in their contribution to the aggregate hearing loss. Work by Miller and colleagues appears to support this notion, showing asymptote of threshold shifts between several weeks and several months postexposure (see Figure 1). If original noise-induced shifts remain stable, age-related changes would be expected to add to the preexisting hearing loss. Few animal studies, however, have followed the NIHL for extended postexposure times, that is, spanning time windows over which AHL sets in.

Two recent studies in aging humans challenge the view that NIHL and AHL are independent, suggesting, rather, that prior NIHL exacerbates subsequent AHL. In the Gates study, males with audiometric configurations suggesting prior noise exposure (stereotypic 3 to 6 kHz noise notch) showed ongoing, 15-year threshold shifts with age that were smaller in the region of the original noise notch (presumably related to large preexisting hearing loss and cochlear damage) but were greater in frequency regions below the notch than males without notches. This finding was confirmed in an analysis of the annual decline of pure-tone thresholds in aging men with, versus without, reported histories of occupational noise exposure. In contrast, a recent longitudinal study, threshold shifts over 3- to 11.5-year time spans were not significantly different for individuals with and without reported histories of noise exposure. Thus, although there is general agreement that AHL often includes a component that can be attributed to noise exposure, characterizing NIHL–AHL relationships in humans has proven difficult.

Recent work in a low-variance mouse model has tested the issue directly and provided support for the notion that there can be significant, delayed effects of noise exposure. In these studies, prior exposure set in motion a slow cascade of events leading to an exaggerated AHL and dramatic primary neuronal degeneration when followed to old age. Such findings may have significance in the consideration of noise risk assessment for human populations.

Beyond Sensitivity Loss

Depending on the magnitude of the hearing loss, its distribution in the frequency domain, and the degree and nature of the underlying histopathology, effects on auditory performance can range from subtle to profound. Audiometric threshold changes that have been the focus of discussion here clearly have downstream consequences that can impair performance on supra-threshold listening tasks like listening to speech. Pure-tone audiograms are imperfect reflections of these performance limits. Comprehensive management of the individual with significant NIHL thus should include a more comprehensive assessment of the functional consequences of their sensitivity loss to provide appropriate treatment recommendations.

OCCUPATIONAL NOISE EXPOSURE

A major source of noise exposure for many individuals is in connection with work-related activities, and substantial effort has gone into development and implementation of regulations designed to protect workers from exposure to hazardous levels of noise.

Permissible Exposure Limits

Models relating exposure level and duration to risk of NIHL have been in place for many years, and have been incorporated into existing models developed to predict NIHL. The current 8-hour steady-state noise exposure standard used in many industrial settings uses a value of 90 dBA, measured at the location of the unprotected ear of the exposed individual. Some agencies, however, have adopted a more stringent 85 dBA, 8-hour TWA. How do such maximum allowable exposures relate to those of different durations or levels? Commonly, exchange rates (5 dB [OSHA], 3 dB [NIOSH]) are employed to describe trading relationships between exposure level and time predicted to yield equivalent noise dose and hazard. Thus, using OSHA’s 5-dB exchange rate, a 90-dBA exposure is allowed for 8 hours; for 95 dBA, exposure time must be reduced to 4 hours, with continued halving of duration such that a 115-dBA exposure is allowed for only 15 minutes. A recent review of findings in humans reports that safety data support the use of the more stringent 85 dBA 8-hour exposure limit and 3 dB exchange rate, concluding that chronic exposure (8 h/d, 40-hour work week, for years) to noises exceeding this 85 dBA TWA pose significant risk to human hearing, with risk of NIHL increasing as the TWA increases beyond this value.

Exposure Estimation

Noise exposures traditionally have been assessed using a full-shift TWA assigned to a particular
job title or work group. This approach can reasonably be used in steady-state, continuous noise environments for stable groups of workers but is not particularly useful for intermittent and variable noise exposures and nonconstant work tasks and workers. Thus, task-based exposure assessment strategies have been employed in certain industries, for example, construction. Task-based methods have distinct advantages over full-shift methods in that they can target measurements on those tasks with the greatest exposure level or variability and allow for exposure level estimation for a whole range of task combinations and exposure durations. Error using such task-based estimates is largely due to high variability in noise levels between individuals doing the same task or between tasks conducted in different circumstances by the same individual.71

Exposure estimation can be particularly challenging among groups in which the use and attenuation of hearing protection devices (HPDs) is variable. Among 44 construction workers utilizing foam insert earplugs, the mean attenuation was 20 + 10 dB, demonstrating a wide range of HPD effectiveness as applied by these individuals. Furthermore, among 557 construction work shifts assessed for noise exposure and simultaneous HPD use, the mean percent of time HPDs were used during exposures above 85 dBA was only 17.1% (range, 0 to 100%; SD of 34.9%), again demonstrating large variability in use time among construction workers. The variability in personal HPD attenuation and time of use contributes substantially to error in assigning individual exposures52 and, of course, to protective benefit received from such devices, as will be discussed later.

Recreational Sources of Exposures

There is little disagreement that the potential exists for nonoccupational exposures to cause NIHL. Some have argued that a growing prevalence of such exposures may contribute to the apparent overall NIHL prevalence stability and even growth in the face of significant regulation of exposure on the job.73 NIHL has been reported in a significant proportion of young children not receiving occupational exposures.53 Such concerns have been heightened in recent years as personal stereo systems have become more or less permanently attached to the ears of their wearers. Putting such concerns in perspective, however, Rabinowitz and colleagues found no evidence for increased hearing loss prevalence in a large group of young adults over a two-decade period.74

Nevertheless, there are many potentially dangerous sources of exposure for individuals of all ages.75 Other work has investigated whether such nonoccupational exposures add materially to risk of NIHL for occupationally noise-exposed workers.76,77 In general, reports suggest that nonoccupational sources represent high noise levels for some individuals, but they often account for little total exposure time. Such findings were recently supported by studies of Neitzel and coworkers for noise-exposed workers in various construction trades.72,78 They concluded that, for most workers, little additional risk is incurred from nonoccupational exposures, as these constitute a small proportion of the noise exposures they receive.

HEARING CONSERVATION AND EDUCATION

Prudent safety practices, bolstered by government regulations in some settings, have fostered the implementation of hearing conservation programs to protect the hearing of workers at risk for NIHL. Such programs include provisions for noise-level surveys, engineering and administrative controls to reduce high-level sound at its sources (equipment) and to limit exposure time of individuals to high-level sound, training and use of personal HPDs, and hearing monitoring through serial audiometry. Currently, OSHA regulations require the establishment of such hearing conservation programs in settings where noise levels exceed 85 dBA. In most settings, efforts have concentrated on regular audiometric screening and on use of HPDs.

Education on dangers and sources of hazardous noise should be an integral part of any hearing conservation program and should be widely available to the general public. Signs and symptoms of overexposure should be described, the usually gradually progressive and insidious nature of the accompanying hearing loss emphasized, and the permanent and significant consequences of noise damage made clear. Although use of HPDs would significantly reduce NIHL risk both on and off the job, it is clear that, in practice, there are many barriers that limit their effectiveness. Training in effective and consistent use of HPDs should be an integral part of any hearing conservation effort. Noise reduction ratings can be employed to help guide choices; ultimately, however, the most effective HPDs are those that will be consistently and correctly worn.

Efforts to make such messages widely available have been aided in recent years by electronic (web-based) information, sponsored by various governmental, professional, and concerned private entities. Such media also provide a means to assay the public’s knowledge and concern regarding NIHL. Unfortunately, recent work suggests that awareness of the hazard by some who may be at significant risk is low.79 Responses to a web-based survey of attitudes and knowledge regarding NIHL from exposure to loud music revealed that, while a majority of those responding had experienced tinnitus and hearing loss following exposure to loud music, most expressed little concern. Most also indicated that education on the risks of NIHL from loud music could motivate them to protect their ears. Web-based educational tools may be an effective avenue for transmitting such information.

TREATMENTS ON THE HORIZON

Currently, hearing aids are the most common form of treatment used in the management of the permanent sensorineural hearing loss that arises secondary to noise exposure. Many individuals can realize significant benefit from such devices. There are others, however, for whom benefit from hearing aids is limited. Moreover, such treatment cannot address hearing loss prevention or minimize hearing loss progression. Even with optimal device fitting, they cannot increase a damaged ear’s basic capacity.

Recent advances in the pharmacology and molecular biology of hearing are paving the way for new and powerful possibilities for preventing or minimizing hearing loss. In the future, drug treatments arising from these discoveries may be used to minimize damage to cellular constituents from postexposure processes that lead to their demise, or they may be used to promote the regrowth or replacement of cells lost to compromise from any number of inner ear insults, including noise exposure.

Work in animal models is progressing. Compounds have been identified that target several cellular processes associated with noise-induced damage, and certain of these compounds have demonstrated promise in protecting against the threshold shifts and cochlear damage that can result from exposure.

REFERENCES

Ototoxicity can be broadly defined as damage of the inner ear by a toxin. The damage can occur in the cochlea, vestibular apparatus, and/or auditory nerve, and the toxin can be any number of substances. The most commonly used ototoxic substances are drugs administered to treat potentially life-threatening conditions where other treatment options have failed or are unavailable. Some of these ototoxic substances do not become ototoxic unless other conditions are present at time of administration, which predisposes the patient to the ototoxicity. Risk factors associated with potentially ototoxic substances have been identified and will be discussed in this chapter, along with monitoring practices designed to minimize the ototoxic effect during drug administration and improve patient outcome once ototoxicity has been detected. This chapter will cover effects of systemically and topically applied drugs that have been shown to induce ototoxicity.

SYSTEMICALLY INDUCED OTOTOXICITY

Both auditory and vestibular symptoms can occur in ototoxicity. The symptoms of cochlear ototoxicity from systemic administration typically include bilateral hearing loss and tinnitus (the sensation of sound when none is present). Vestibular ototoxicity causes a loss of the sense of balance, dizziness, lightheadedness, faintness, unsteadiness, and/or nystagmus. The symptoms can be temporary, subsiding after the ototoxic substance has been cleared from the body, or they can be permanent.

When hearing loss from ototoxicity becomes permanent, the first detectable symptom is increased auditory thresholds for high frequency sounds. This change is often unnoticed by the patient until lower frequencies become involved. Although not always the case, the outer hair cells of the organ of Corti are commonly the first cells that exhibit signs of intoxication. Early outer hair cell loss can be demonstrated morphologically in both human tissue and animal models. Injury ranges from damaged stereocilia on the surface of the hair cell to complete loss of the hair cell with only supporting cells remaining (Figure 1). Severe damage includes inner hair cell loss with associated loss of spiral ganglion cells (Figures 2 and 3). In electrophysiological studies, damage first manifests as a reduction in evoked otoacoustic emissions (OAEs), compound action potentials (CAPs), and/or auditory brainstem responses (ABR). The reduction is typically first seen in high frequency responses. Although not typical, in some cases of cochlear ototoxicity, such as that occurring after carboplatin administration, degeneration begins within the inner hair cells. Carboplatin adversely affects the central and peripheral nervous systems and may...
injure the auditory nerve. In such cases, OAEs may be normal, but abnormalities will be detected in the CAP or ABR. This type of deficit is known as auditory neuropathy.

Ototoxic changes in the cochlear nerve or the auditory brainstem resemble cochlear ototoxicity, i.e., hearing loss first seen in the high frequencies, but speech discrimination is typically worse than what would be expected for the level of hearing loss. The ABR testing can demonstrate damage to the auditory nerve or brainstem by increased latencies of later peaks, as these peaks are generated by the auditory nerve or brainstem nuclei. The body can only compensate for the mildest forms of hearing loss, in which only a small region of the organ of Corti is affected. More severe forms of hearing loss require hearing aids or cochlear implants to help compensate for the loss of function.

Vestibular manifestations of systemic ototoxicity are typically bilateral and can be detected with caloric testing, electronystagmography (ENG), or via rotational chair testing, all of which assess the integrity of the vestibulo-ocular reflex (VOR). Often, compensation for loss of some vestibular function occurs over time, even if the damage to the tissue is permanent. Vestibular compensation can be enhanced through professionally directed rehabilitation programs.

**Temporary Ototoxicity**

Many ototoxic drugs typically cause only temporary hearing loss, known as “temporary threshold shift” (TTS). Other temporary effects can include tinnitus or vertigo. These effects may occur as a direct consequence of the drug’s effects on the sensory organ or on other components of the inner ear that are required for organ function. For instance, loop-inhibiting diuretics have been shown to cause temporary cochlear dysfunction. In this type of ototoxicity either the “stiffness” of outer hair cells is affected, directly affecting the organ of Corti; or the stria vascularis is affected, resulting in strial edema, loss of endolymphatic potassium and a corresponding reduction in endocochlear potential. The reduction in endolymphatic potassium concentrations and the endocochlear potential leads to a loss of transduction in the organ of Corti. Whether the effect occurs at the outer hair cell or the stria vascularis, the result is an elevation of auditory thresholds. Under normal circumstances, once the loop-inhibiting diuretic clears the blood stream, normal thresholds are restored.

Substances that cause temporary ototoxicity are often used to treat serious disease. Therefore they are administered to fairly ill patients with multiple medical problems in whom an otherwise temporary ototoxic effect may become permanent. For example, loop-inhibiting diuretics are administered to patients with renal insufficiency. This leads to an increase in the blood levels of the drug beyond the threshold for permanent ototoxicity.

Combining administration of multiple drugs, which when administered individually and at low concentrations are nontoxic, can also result in permanent ototoxicity. For example, when low doses of aminoglycoside antibiotics are administered to a patient who is also receiving loop-inhibiting diuretics, the ototoxic effects are synergistic. Patient age can also be a risk factor for increased ototoxicity.

**TOPICAL OTOTOXICITY**

Severe inner ear damage encompassing large areas of sensory cell loss, obvious neural degeneration, and significantly reduced auditory function has been repeatedly demonstrated in animals following middle ear application of commercially available otic drops. Therefore, ototoxicity should be considered a possible side effect of topical drug applications to the human ear. Since these affects are local, ototoxicity due to topical agents is limited to the side of application. The symptoms of cochlear topical ototoxicity (hearing loss) are similar to those seen in systemic cochlear ototoxicity but are limited to the treated ear. Unilateral hearing loss has less severe consequences than bilateral hearing loss because only one ear is needed for adequate function in most hearing conditions. Conversely, manifestations of vestibular ototoxicity may be more severe after unilateral topical application because the injury to the vestibular system is asymmetric. Normal vestibular function relies on symmetrical input from both ears. A cute asymmetric vestibular loss is associated with significant discomfort for several days following the insult. Severe rotary vertigo, uncommon following systemic ototoxicity (which is usually a symmetrical loss), is not unusual after unilateral injury from topical aminoglycoside treatment of the middle ear.

**MONITORING FOR OTOTOXICITY**

Audiologic monitoring for ototoxicity can detect changes early during administration of potentially ototoxic drugs to allow for altered treatment plans and help prevent permanent losses. The standard test battery for audiologic monitoring include a baseline pure tone audiogram, speech discrimination testing, and OAEs. Follow-up can usually be limited to pure tone air-conduction thresholds, unless there is a change in hearing threshold. In which case, repeating the test battery is recommended.

Tests for OAEs measure an involuntary response created by outer hair cell activity in the cochlea. The tests are relatively inexpensive, quick and do not rely on patient response, making them especially useful in monitoring ototoxicity in patients that are unable to provide reliable behavioral responses. Monitoring OAEs can detect alterations in outer hair cell activity before the lesion is sufficiently large for detection by a standard audiogram. There are several types of OAEs, but transient evoked otoacoustic emissions (TOAEs) and distortion product otoacoustic emissions (DPOAEs) are most commonly used to monitor ototoxicity. TOAEs are occasionally used when DPOAEs cannot be obtained.

Severe inner ear damage encompassing large areas of sensory cell loss, obvious neural degeneration, and significantly reduced auditory function has been repeatedly demonstrated in animals following middle ear application of commercially available otic drops. Therefore, ototoxicity should be considered a possible side effect of topical drug applications to the human ear. Since these affects are local, ototoxicity due to topical agents is limited to the side of application. The symptoms of cochlear topical ototoxicity (hearing loss) are similar to those seen in systemic cochlear ototoxicity but are limited to the treated ear. Unilateral hearing loss has less severe consequences than bilateral hearing loss because only one ear is needed for adequate function in most hearing conditions. Conversely, manifestations of vestibular ototoxicity may be more severe after unilateral topical application because the injury to the vestibular system is asymmetric. Normal vestibular function relies on symmetrical input from both ears. A cute asymmetric vestibular loss is associated with significant discomfort for several days following the insult. Severe rotary vertigo, uncommon following systemic ototoxicity (which is usually a symmetrical loss), is not unusual after unilateral injury from topical aminoglycoside treatment of the middle ear.

Audiologic monitoring for ototoxicity can detect changes early during administration of potentially ototoxic drugs to allow for altered treatment plans and help prevent permanent losses. The standard test battery for audiologic monitoring include a baseline pure tone audiogram, speech discrimination testing, and OAEs. Follow-up can usually be limited to pure tone air-conduction thresholds, unless there is a change in hearing threshold. In which case, repeating the test battery is recommended. Tests for OAEs measure an involuntary response created by outer hair cell activity in the cochlea. The tests are relatively inexpensive, quick and do not rely on patient response, making them especially useful in monitoring ototoxicity in patients that are unable to provide reliable behavioral responses. Monitoring OAEs can detect alterations in outer hair cell activity before the lesion is sufficiently large for detection by a standard audiogram. There are several types of OAEs, but transient evoked otoacoustic emissions (TOAEs) and distortion product otoacoustic emissions (DPOAEs) are most commonly used to monitor ototoxicity. TOAEs are occasionally used when DPOAEs cannot be obtained. TOAEs have broader spectra, less frequency-specific responses than DPOAEs and, therefore, are less sensitive to small lesions along the organ of Corti. DPOAEs can often be recorded in subjects with a higher degree of hearing loss and can detect lesions at higher frequencies.

In addition to monitoring for hearing loss, vestibular monitoring should also be performed when administering potentially ototoxic medications to detect vestibulotoxicity early and allow for intervention prior to the development of irreversible injury. There are no widely accepted protocols to test for vestibulotoxicity. However, there are a number of both qualitative and quantitative tests that are commonly used to assess vestibular function. The integrity of the VOR is commonly used to detect changes in the vestibular end-organ and some central nervous system pathways. There are two neural pathways involved in the VOR, the pathway from the eighth nerve to position-vestibular-pause cells (PVP) to oculomotor nuclei and the pathway from the eighth nerve to floccular target neurons (FTN) to oculomotor nuclei, with additional input to the FTN from the cerebellum. In practice, the VOR is elicited either by calorific testing or by use of a rotational chair. For calorific testing, warm and cool liquids or air are placed into the external ear canal to cause unequal heating/cooling of the inner ear, which results in bulk fluid movement within the vestibular system, triggering the VOR. Rotational chair testing uses a more “natural” stimulus with a range of quantifiable stimuli (rotational speed) that results in a quantifiable result. The VOR response can be elicited at several different physiological rotational frequencies. The response for each rotational frequency can be quantified.

The ENG is a widely used test battery that includes measurement of spontaneous nystagmus, calornic testing, testing for benign positional vertigo, the ability to suppress nystagmus by visual fixation, an optokinetic test, a gaze test, a sinusoidal tracking test, and the saccade test (which tests the ability of the eye to rapidly fix and refix.
OTOTOXIC DRUGS

A variety of drugs have been shown to be ototoxic (Table 1). Their mode of action and ototoxic effects differ. Below are classes of ototoxic drugs and the characteristics of specific drugs in their classification.

Salicylates

A cetylsalicylic acid (aspirin) can cause reversible ototoxicity, usually manifesting as a mild to moderate hearing loss and tinnitus. A salicylate-associated hearing loss is due to reversible enzyme inhibition, and symptoms typically clear 24 to 72 hours after cessation of the drug. Permanent damage to the organ of Corti in humans is rare, but administration of 5 to 10 g/d can cause a permanent hearing loss and abolish spontaneous OAEs in animals.

Nonsteroidal Antiinflammatory Agents (NSAIDs)

NSAIDs have ototoxic side effects that are similar to aspirin. Examples of commonly used NSAIDs are ibuprofen, naproxen, and indomethacin.

Quinine

As is true of aspirin, hearing loss is generally temporary with quinine ototoxicity but cases of permanent hearing loss have been reported. In addition to producing hearing loss and tinnitus, quinine intoxication can result in temporary vertigo. Hearing loss from quinine administration is bilateral, initially affecting the higher frequencies, with a characteristic notch at 4 kHz. Permanent effects of quinine administration have been reported in patients receiving prolonged daily doses of 200 to 300 mg. Quinine administration is used as an initial treatment of severe Plasmodium falciparum malaria.

Heavy Metals

Chronic lead and mercury toxicity cause little histopathologic change in the inner ear, but nonetheless produce subclinical changes in hearing, observed by slight, but significant lengthening of ABR peak latencies. This indicates these substances have a more dramatic effect on neural processing than on the organ of Corti. Mercury is the most frequently implicated heavy metal and has been associated with occupational hearing loss.

Cisplatin ototoxicity, like the aminoglycoside antibiotics, typically causes high frequency sensorineural hearing loss in a dose-dependent manner. However, unlike the aminoglycosides, cisplatin administration rarely causes vestibular dysfunction. The most susceptible cell type within the inner ear for most platinum compounds is the outer hair cell. The principal mode of action is an alteration of DNA transcription, leading to cell death through a combination of necrosis and apoptosis.

Carboplatin administration can cause inner hair cell damage, leading to abnormal synaptic activity or complete inner hair cell loss, resulting in changes known as auditory neuropathy.

Vinca alkaloids are antineoplastic drugs that are often administered in combination with drugs like cisplatin. Vinca alkaloids include several drugs derived from the periwinkle plant, vincristine, vinblastine, and the semisynthetic vinorelbine. The chief mode of action for these drugs is interference with outer hair cell metabolism.

Iron chelators, such as deferoxamine, are used to alleviate the affects of acute iron intoxication or chronic iron overload due to repeated transfusions. Iron chelators can cause mild to moderate high frequency sensorineural hearing loss, which is more commonly seen in younger patients and patients receiving higher dosages. In some instances, this loss has been shown to be reversible upon cessation of drug administration.

Aminoglycoside Antibiotics

Earlier studies suggest an incidence of ototoxicity from aminoglycosides of up to 41% of subjects treated, but more recent studies indicate an incidence of 5 to 7%. This discrepancy may reflect a change in treatment protocols and a reduction in the use of the more ototoxic aminoglycosides, such as streptomycin.

There are a number of aminoglycoside antibiotics in clinical use; examples include streptomycin, dicyclohexylstrepptomycin, neomycin, tobramycin, kanamycin, gentamicin, neomycin, and amikacin. All share common characteristics in their chemical structure and biological activity but differ in their ototoxic potential. Hair cells are the cellular target for aminoglycoside antibiotics in the ear. Outer hair cells seem to be the most vulnerable to attack, but inner hair cells...
can be affected with higher doses or with a longer period of drug treatment. Typically, these drugs affect the high frequencies first. The drugs selectively concentrate in hair cells when present in the perilymphatic space. These drugs can be found within the inner ear after systemic application, and they can remain in inner ear fluids for months after treatment.

Apoposis appears to be the most likely pathway for cell death in aminoglycoside antibiotic ototoxicity. The antibacterial action of aminoglycoside antibiotics relies on their ability to disrupt protein synthesis within bacterial cells through binding to the cellular ribosomes (mRNA). The disruption of protein synthesis affects protein turnover and leads to cell death. In the mammalian hair cell, the most likely mode of cell death after aminoglycoside intoxication is via interference in cell metabolism, creating reactive oxygen species (ROS) free radicals that cause oxidative damage to the cell leading to apoptotic death.

**Maternally Inherited Aminoglycoside-Induced Deafness.** A high incidence of aminoglycoside antibiotic-induced hearing loss is especially likely in individuals with an inherited defect in their mitochondrial rRNA. Unlike eukaryotic cell DNA, which is a product of both parent’s DNA, mitochondrial DNA is passed directly from mother to child. Therefore, mitochondrial defects are maternally inherited. One mitochondrial mutation shown to increase aminoglycoside ototoxicity is the 1555 A → G (A1555G) mutation in the 12S rRNA gene. This mutation has been most commonly reported in families of Asian descent; however, it has also been detected in a large family of Arab-Israeli descent. This mutation has not been found in the American or Swiss populations. In addition to an increased sensitivity to aminoglycoside antibiotic ototoxicity, individuals carrying the A1555G mutation are also more likely to develop hearing loss over time, without exposure to aminoglycoside antibiotics. This finding indicates the mutation compromises the hair cell to a greater extent than just rendering it more vulnerable to aminoglycoside antibiotic intoxication.

**Macrolide Antibiotics**

Aminoglycoside antibiotics have been reported to cause temporary

</table>
hearing loss, which is not accompanied by tinnitus or vestibular symptoms. There is some indication that erythromycin can have either central or peripheral neural effects on the auditory system. While there is clinical evidence of temporary ototoxic effects after systemic administration, the strongest evidence for an ototoxic effect to involve the inner ear comes from animal studies. Cochlear hair cell loss has been demonstrated after topical (middle ear) application, and a temporary reduction in endocochlear potentials in guinea pigs was seen after systemic delivery of the drug. Patients with renal failure, hepatic impairment, and patients who have undergone renal transplantation are most susceptible to macrolide antibiotic ototoxicity. In transplant patients, there is a clear correlation between dosage and effect. The higher and/or longer dosage regimens have been shown to affect hearing.

A zithromycin and clarithromycin are newer-generation macrolide antibiotics that have shown some temporary ototoxic effects in patients compromised by HIV or age. Ototoxicity appears after prolonged administration of doses between 500 to 600 mg/d. Most often the hearing improved after reducing the dose to 300 mg/d.

Like chloramphenicol, polymyxins are highly ototoxic when administered topically. However, no ototoxicity has been reported with systemic administration of these drugs.

**Vancomycin and Vancomycin Analogs**

Vancomycin is a glycopeptide whose antibiotic actions were first used clinically in the late 1950s. Its potential ototoxicity limited its use until the 1980s when it was shown to be beneficial in the treatment of resistant Staphylococcus aureus infections.

Reports of vancomycin ototoxicity are varied. Usually patients experiencing ototoxic effects during vancomycin treatment have resolution once the treatment is stopped. Permanent effects occur when the patients have other conditions that contribute to the ototoxic outcome, or when other potentially ototoxic drugs were given during treatment.

Animal studies of the effects of vancomycin administration on inner ear functions have shown little evidence of ototoxicity when the drug is administered alone. But, when combined with aminoglycosides or tobramycin, vancomycin administration can result in a significant ototoxic effect.

Several analogs of vancomycin have been developed: teichoplanin, daptomycin, and normycocin. To date, ototoxicity has not been demonstrated, but since these drugs resemble vancomycin chemically, they should be considered potentially ototoxic.

**Antifungal Medications**

Otomycosis has been defined as a fungal infection of the external auditory canal, the middle ear, or open mastoid cavities. Although this condition is not as common as bacteria-associated external otitis and otitis media, it is a significant problem in cultures where swimming in natural bodies of water is a common practice (swimmer’s ear) or in areas with tropical and subtropical climates. Patients who have increased susceptibility to fungal infections, such as HIV or chemotherapy patients are at higher risk for otomycosis. The choice of antifungal medications used for treatment in the past has been varied and not based on scientific data. There is no US Food and Drug Administration approved otic preparation specifically for otomycosis, and only a few animal studies have assessed potential toxicity of antifungal agents applied topically to the external or middle ear.

Tom and colleagues reported no discernible evidence of ototoxicity in guinea pigs when he examined several antifungal agents: the azoles, clotrimazole, miconazole; the polyene nystatin; or tolnaftate. However, middle ear and inner ear toxicity has been demonstrated in guinea pig studies designed to assess toxic effects of several other types of medications used to treat otomycosis, ie, the antiseptics gentian violet and Cresyl blue and preparations containing the solvent propylene glycol.

**Disinfectants and Antiseptics**

Disinfectants and antiseptics used to help sterilize the skin preoperatively have been shown to be ototoxic if they enter the middle ear. Preoperative use of chlorohexidine has been implicated in several cases of severe sensorineural hearing loss after otologic surgery. Since then, permanent ototoxic effects have been shown after middle ear application of chlorohexidine in several different animals, using several different means to determine the effects including morphological changes and cochlear and vestibular electrophysiology. Alcohols and some iodine-containing skin preparations have also been shown to be ototoxic when applied to the middle ear in animals.

Benzalkonium chloride, a quaternary ammonium compound, is a substance shown to cause irritation to corneal and middle ear tissues at the typical concentrations used. In addition, Aursnes demonstrated inner ear ototoxicity in middle ear applications of 0.1% concentrations of benzalkonium chloride with or without a 70% ethanol base.

**DEFINITION, CLINICAL PRESENTATION, AND PROGNOSIS**

Idiopathic sudden sensorineural hearing loss (ISSNHL) is a term that requires little elaboration. Most patients describe waking up with hearing loss that was not present the night before, or they can identify the time of day when hearing loss began. Nevertheless, the literature reflects a consensus to consider onset over a period of less than 3 days as “sudden.”

Hearing loss, whether sudden or more gradual in onset, can obviously range from barely detectable to profound, but, once again, a convention has evolved: ISSNHL is generally defined as demonstrating a threshold change for the worse of at least 30 dB in at least three contiguous audiometric frequencies. Occasionally, this change can be assessed by comparing current to prior audiograms. More often, the affected ear is compared with the unaffected ear, assuming that the two ears were equal before. Fortunately, ISSNHL is almost always unilateral.

According to Byl, ISSNHL affects about 1 person per 10,000 per year; this would correspond to over 25,000 cases per year in the United States. In contrast, Hughes and colleagues estimate only 4,000 cases per year in the United States.

All ages and both sexes are affected; the peak ages are 30 to 60 years. Tinnitus is usually present (>90%), and vertigo is frequent, either spontaneous (as in acute vestibular neuritis) or as isolated positional vertigo. Sixty-five percent of patients recover completely with or without treatment, most within 2 weeks. Low-frequency losses have a better prognosis than high-frequency losses; of course, this is true of all types of rapidly progressive or fluctuating sensorineural hearing loss (SNHL), not just ISSNHL.

**ETIOLOGY**

Since ISSNHL is, by definition, idiopathic, the cause of any individual case is not known. Nevertheless, there has been considerable speculation about viral and vascular causes, with rather more evidence for the former than the latter.

**Viral**

Many otologists believe that viral infection (or reactivation of latent viruses) is the most important cause of ISSNHL. The circumstantial evidence for that belief can be summarized as follows:

1. Many viral diseases, for example, mumps, can cause congenital or sudden SNHL.
2. Cochlear histopathology after these diseases resembles that seen after ISSNHL.
3. Patients with ISSNHL often demonstrate immunologic evidence for viral infection.
4. Viruses such as herpes simplex may lie dormant in neural tissue for years and have been identified in human spiral ganglia.

Intrauterine viral infection may damage many organ systems. The rubella (German measles) virus caused thousands of cases of congenital deafness during a 1964 to 1965 epidemic; most were associated with a syndrome that included eye, heart, and brain abnormalities. Since the introduction of the mumps–measles–rubella (MMR) vaccine, the congenital rubella syndrome has virtually disappeared in the United States.

Byl has shown an infection rate (virus cultured from urine) of 1.3%: 10% of these cases had either congenital or progressive hearing loss. Most of the babies who had (or developed) hearing loss were otherwise healthy and would have been missed by conventional high-risk criteria for congenital hearing loss. No vaccine is yet available to reduce or eliminate hearing loss from CMV.

Neonatal herpes simplex virus (HSV) infection is associated with hearing loss in about 30% of cases. Mumps (viral parotitis) is the prototypical example of sudden unilateral hearing loss in childhood. Rare since the widespread use of the MMR vaccine, mumps deafness occurred in about 5 of every 10,000 mumps cases and was usually unilateral. Like CMV, the mumps virus has been cultured from the inner ear and causes cochlear lesions in experimental animals.

**Vascular**

Vascular causes can be divided into primary (causing hearing loss in isolation) and secondary (causing hearing loss in association with other vascular diseases). A few primary vascular causes were identified initially: congenital deafness is cytomegalovirus (CMV) infection; (2) Congenital CMV syndrome includes deafness and lesions of the eye, brain, liver, and spleen. It is important to note, however, that most CMV-infected neonates do not demonstrate the full-blown CMV syndrome. Indeed, “asymptomatic” CMV infection causes more hearing loss than “symptomatic” (syndromic) CMV infection. Neonatal CMV screening has shown an infection rate (virus cultured from urine) of 1.3%: 10% of these cases had either congenital or progressive hearing loss.

Schuknecht and Donovan first showed that ears from patients who had suffered ISSNHL demonstrated atrophy of the organ of Corti and tectorial membrane and spiral ganglion losses; these findings were similar to those seen in cases (mumps, measles) known to be caused by viral infections and different from the cochlear pathology (fibrous and osseous proliferation) seen after ischemic disease. However, more recent temporal bone histopathologic studies by Merchand and colleagues from 15 ears with ISSNHL from the same laboratory showed similar findings, and the authors suggested that there was no direct evidence of viral cochleitis, such as viral particles by electron microscopy. They support a separate etiologic factor for ISSNHL, pathologic activation of cellular stress pathways involving nuclear factor-kappaB within the cochlea.

**Genetic**

Although the identification of DNA from HSV in human spiral ganglion and the development of an animal model
for HSV neurulabyrinthitis\textsuperscript{26,27} that responds to antiviral drug treatment, have added to suspicion that this virus may be an important cause of ISSNHL. Pikaranta and colleagues noted that there are many negative serologic studies, failing to implicate HSV or other viruses, but also noted that long-dormant neurotropic viruses can reactivate and cause localized disease without triggering changes in systemic immunoglobulin levels.\textsuperscript{28} This is true for herpetic cold sores, for example, and may also be true for diseases such as ISSNHL, Bell palsy, and vestibular neuritis. Unfortunately, the difficulty of inner ear culture or biopsy makes proving this hypothesis in individual cases impossible.

\textbf{Vascular}

Diseases of blood vessels affect many organ systems and constitute some of the most important causes of death and disability in developed countries. Risk factors for vascular disease include diabetes, hypertension, obesity, and hyperlipidemia; controlling these risk factors can reduce the incidence of heart attacks, strokes, blindness, kidney failure, and premature death. Equally important, but uncontrollable, risk factors include age, sex, and family history. Since no organ can survive without adequate blood supply and since vascular disease affects so many different organ systems, it is natural that investigators have looked for evidence that SNHL is linked to vascular disease or to its risk factors. Despite the intensity of their efforts, the evidence is extremely weak.

In other organ systems, vascular disease may cause either gradual or sudden/stepwise deterioration of function. Congestive heart failure may develop insidiously in some patients, whereas others have sudden-onset myocardial infarctions. Even when the disease process, for example, atherosclerotic narrowing of arterial lumen, is gradual, the symptoms and signs of dysfunction are often sudden, when a critical point is reached or a new event such as thrombosis or embolism totally shuts off blood flow. If vascular disease is important for a particular organ, for example, the cochlea, one should expect it to cause both sudden and gradual changes in function.

Unfortunately, otologists cannot yet measure cochlear blood flow in clinical practice, so whether a person (or an ear) has cochlear ischemia cannot be determined. Reliance must be placed on correlations between hearing loss and vascular disease risk factors (or established vascular disease elsewhere in the body) and to a lesser extent on histopathologic evidence.

Consideration can begin with age-related hearing loss (ARHL). Age is not really a cause of SNHL but rather an association; still, after excluding common causes of SNHL (noise, head injury, etc), the hearing loss of the vast majority of people with adult-onset SNHL cannot be labeled any more precisely than to call it age-related. If vascular disease was an important component of ARHL, it might be expected that patients, and longitudinal studies of ARHL, would describe stepwise progression with substantial asymmetry as one ear suffers ischemic events whereas the other escapes, at least for a while. The rarity of such reports in ARHL should already cast doubt on the vascular hypothesis, but those doubts can momentarily be put aside and one might ask whether vascular disease and its risk factors are correlated with ARHL. For example, do diabetics have more hearing loss than nondiabetics of the same age and sex? The extensive literature addressing this issue has been reviewed and can best be described as inconclusive.\textsuperscript{29} If vascular disease is responsible for some proportion of ARHL, its contribution is small.

Focusing on patients presenting with ISSNHL, are some of these cases attributable to “vascular accidents” such as thrombosis, embolism, or hemorrhage affecting the cochlea? If vascular disease caused a substantial fraction of ISSNHL, the incidence of ISSNHL would be expected to be much higher in men than in women and to rise sharply with age; however, neither is true. Frequent recurrences and, over time, bilaterality would also be expected, yet most people who suffer ISSNHL have only one event, affecting only one ear. Studies of vascular disease and risk factors have shown only that diabetics with ISSNHL have a poorer prognosis.\textsuperscript{30,31} Not that any of these factors predict the likelihood of suffering ISSNHL.

None of this proves that vascular disease is totally irrelevant to ISSNHL. Inner ear hemorrhages with sudden deafness do occur rarely in patients with leukemia, sickle cell disease, and thalassemia.\textsuperscript{32-34} Although the temporal bone histopathologic findings after hemorrhage or ischemia are very different from those seen in patients who have suffered ISSNHL, as previously discussed. Sudden SNHL may\textsuperscript{35} or may not\textsuperscript{36} be an occasional complication of cardiopulmonary bypass surgery presumably owing to emboli. Patients with sudden hearing loss have significantly more blood loss.\textsuperscript{37} The THFR (methylentetrahydrofolatereductase) gene polymorphisms and factor V Leiden mutations that control in patients, these deficiencies being risk factors for thrombovascular disease.\textsuperscript{37,38} Until otologists are able to assess cochlear blood flow reliably and noninvasively in their patients, we will not know much about the role of vascular disease in ISSNHL (or SNHL in general); at this point in time, it appears to be somewhere between small and negligible.

\textbf{Otoxic}

Simmons postulated that double inner ear membrane breaks could be responsible for some cases of ISSNHL,\textsuperscript{39} and it is hard to prove that he was wrong, but there is little evidence that he was right either. The only temporal bone evidence of cochlear membrane ruptures has been associated with barotrauma.\textsuperscript{40} Because Simmons hypothesized that one of these membrane breaks would involve the oval or round window, producing a perilymphatic fistula (PLF), there was a wave of enthusiasm in the 1980s for middle ear exploration, looking for PLF, in patients with ISSNHL. Today, most otologists believe that PLFs do occur, causing SNHL and dizziness, but almost exclusively in the context of identifiable barotraumas: after scuba diving, violent nose blowing, or extreme exertion during breath holding, for example, weight lifting with improper technique. In the absence of such a history, few otologists would diagnose membrane breaks and/or PLF in sudden SNHL or recommend therapy appropriate to such a diagnosis including bed rest and/or middle ear exploration.

\textbf{DIFFERENTIAL DIAGNOSIS}

As shown in Table 1, there are dozens of otologic and systemic disorders have been associated with sudden SNHL. Many of these disorders, for example, M eniere disease or autoimmune inner ear disease, typically cause rapidly progressive or fluctuating hearing loss rather than truly sudden loss. The more important identifiable causes of sudden SNHL (by definition, these are not “idiopathic”) are clinically easy to diagnose, for example, meningitis, acoustic trauma, head injury. Others, such as multiple sclerosis, are usually missed when sudden SNHL is the first manifestation. In areas where Lyme disease is endemic, it is probably wise to ask patients with sudden SNHL about recent rash or arthralgia.

\textbf{INVESTIGATIONS}

Patients presenting with sudden unilateral hearing loss without obvious antecedent cause should...
receive a careful otologic history and examination, as well as an audiologic assessment (including the Stenger test to detect functional hearing loss). Otoacoustic emissions (OAEs) are sometimes present (implying sparing of outer hair cells) in ISSNHL, but it is unclear whether OAE testing is clinically useful, that is, whether the results can assist in selecting therapy.

Routine blood testing in ISSNHL is of dubious value. Children with ISSNHL, although rare, should receive a complete blood count as a screening test for leukemia. If there are clinical cues pointing toward Lyme disease, confirmatory testing is indicated. Patients with symptoms of systemic disease should probably be referred to an internist rather than receive blood tests selected by an otolaryngologist. If corticosteroid therapy is being considered in a patient who has not been tested for diabetes recently, a blood glucose test is probably in order.

About 1% of patients presenting with sudden SNHL have vestibular schwannomas, and even complete recovery of hearing loss does not completely rule out this diagnosis. When hearing in the affected ear is poorer than the opposite ear, magnetic resonance imaging (MRI) with gadolinium contrast injection is the most appropriate study to detect or rule out a tumor. The poorer ear is commonly defined as having asymmetry in two or more pure-tone thresholds of 15 dB or more or asymmetry in speech discrimination scores of 15%. For patients who cannot have an MRI, alternative strategies include serial audiometry, auditory brainstem response testing, or computed tomographic testing, which could detect larger tumors.

The increasingly frequent use of MRI in cases of sudden SNHL has shed additional light on the etiology. Precontrast films can document inner ear hemorrhage in the rare cases associated with hematologic disorders. Soon after the onset of hearing loss, gadolinium enhancement of the cochlea is seen in typical cases of ISSNHL, probably owing to a transiently leaky blood-brain barrier. Six months or more after onset, no fibrotic or osseous proliferation (such as would be expected after ischemic damage) could be identified.

**INTERVENTIONS**

**Corticosteroids**

Wilson and colleagues showed, in a randomized clinical trial, that patients receiving oral corticosteroids achieved substantial recovery, defined as clinical trial, that patients receiving oral corticosteroids as the control group for comparison to alternative treatment.

Subsequent studies have validated the efficacy of oral corticosteroid treatment for ISSNHL. A nonrandomized study by Moshkowitz and colleagues showed benefits similar to those seen in the Wilson and colleagues’ study (89% recovery with corticosteroids, 44% recovery without treatment). Most otologists offer oral corticosteroids to patients with ISSNHL who have no contraindications, for example, diabetes, active duodenal ulcer, tuberculosis. Higher-dose prednisone, 60 mg/d for 9 days, followed by a 5-day taper, and treatment within 2 weeks of the onset are associated with clinically significant hearing recovery as compared to lower doses and later treatment.

Recently, corticosteroids injected into the middle ear space have been used as a salvage treatment for patients with ISSNHL failing oral corticosteroid treatment. Most of these studies have been uncontrolled but hint that a minority of patients could benefit from this treatment. Xenellis and colleagues published the only randomized clinical trial comparing intratympanic corticosteroid injections to no treatment in patients who were initially treated with 10 days of intravenous corticosteroid but did not benefit. They found that patients treated with four intratympanic injections of methylprednisolone over 2 weeks had improvement in the pure-tone average (14.9 dB), which was statistically better than the control group, which did not improve. Clinical trials employing intratympanic corticosteroid injection as first-line treatment for ISSNHL are in progress.

**Antiviral Drugs**

Useful oral antiviral drugs have been available in recent years but have yet to be found helpful for patients with ISSNHL. Two prospective, randomized, double-blind clinical trials exist in which acyclovir combined with oral prednisolone or valacyclovir combined with prednisone was compared to placebo combined with corticosteroid. Neither study could demonstrate that the addition of the antiviral agent improved outcome in hearing levels.

**Other Treatments**

The vascular hypothesis is extremely popular in Europe, where treatments such as oral pentoxifylline and intravenous dextran (intended to reduce blood viscosity), apheresis (intended to remove low-density lipoprotein cholesterol from the blood), and carbenicillin (a mixture of 10% carbon dioxide and 90% oxygen) and papaverine (intended to dilate blood vessels) are often used. None of these has been shown to be superior to placebo.

Other medications having antioxidant properties have been studied, such as magnesium, ginkgo biloba, and vitamin E. These randomized trials typically combine antioxidant treatment/placebo with carbogen inhalation and corticosteroid and conclude that the addition of antioxidant improves hearing outcomes.

When a cause for sudden SNHL is found (see Table 1), treatment is not idiopathic, and the treatment should depend on the diagnosis. The management of persistent tinnitus and hearing loss, when recovery is incomplete, is nonspecific. Some patients choose to try hearing aids, but, for most, sympathetic counseling is the best approach.

Perilymphatic Fistulae

David R. Friedland, MD, PhD

Perilymphatic fistulae (PLFs) are abnormal connections between the middle ear space and perilymphatic compartment of the inner ear. Such connections may be congenital, traumatic, spontaneous, postsurgical, or the result of otologic disease such as cholesteatoma. Clinical presentation may include sudden or fluctuating hearing loss, disequilibrium, episodic vertigo, tinnitus, and aural fullness. This chapter will review the various forms of PLFs, their diagnosis and management, with particular attention being paid to the controversial entity of spontaneous PLF.

HISTORY AND BACKGROUND

The first widespread use of the term “perilymph fistula” began in the 1960s shortly after the introduction of stapedectomy surgery. Steffen and colleagues reported on delayed postoperative symptoms consisting of hearing loss, tinnitus, and vertigo. In a significant number of these patients leakage of perilymph from the oval window was observed on middle ear exploration. Additional reports of poststapedectomy fistula associated with the constellation of symptoms of hearing loss and/or vertigo followed. Shortly thereafter, perhaps due to the awareness of the signs and symptoms of fistulae postsurgically, reports of nonsurgically related PLFs appeared. Manuscripts detailed evidence of congenital PLFs with leakage at the stapes footplate. In 1966, Fee reported on 3 patients with posttraumatic signs of fistulae who demonstrated perilymph leak from the oval window on exploration. Two years later, Stroud and Calcatera reported on 1 pediatric and 3 adult cases of spontaneous PLFs apparently caused by episodes of increased intracranial pressure. The noise- and pressure-induced symptoms of some of their patients invoke consideration of superior semicircular canal dehiscence as a potential alternative explanation. Even at that time the difficulty in distinguishing PLF from other ear diseases such as Meniere disease was acknowledged.

Case reports of spontaneous PLFs continued until enough experience had been achieved to evaluate large series of explorations and treatments. Two classic studies by Shelton and Simmons and later Rider and House found negative exploration rates for spontaneous PLFs of 50 to 60%. All patients underwent patching around the oval window and improvement was noted in 64 to 68% of those with PLFs in 29 to 44% of those with negative explorations. High negative exploration rates raised questions as to the validity and existence of spontaneous PLFs, and contentious manuscripts appeared decrying their existence. Others began to look more critically at difficulties with diagnosis and the role of surgery in evaluation and treatment.

Investigators of spontaneous PLFs performed anatomic studies of the temporal bone for natural conduits for the potential egress of perilymph. Kohut and colleagues described the histology of the fissa ante fenestrum, a region of the otic capsule just anterior to the oval window. They found this region to contain a loose fibrous matrix in 5 patients with PLFs and postulated it could allow for the passage of perilymph. Kohut and colleagues later reported on a surgically confirmed and treated case of PLF whose temporal bone upon bequeathal demonstrated an unobstructed fissa ante fenestrum with an intact “patch” on the middle ear side. In control temporal bones, in contrast, they reported that the fissa ante fenestrum is closed by bone or cartilage. A radiographically definable “cochlear clef” has subsequently been reported in approximately 34% of temporal bones and was postulated to represent the fissa ante fenestrum. Visualization of this region decreased with age suggesting a developmental reduction in the prominence of the fissa ante fenestrum. Correlation of this radiographic finding with the incidence of clinically suspected PLF has not been performed.

Other investigators revisited an early twentieth century concept of otic capsule microfissures as being potential conduits for perilymph leakage. Harada and colleagues in 1981 and later Sato and associates in 1993, found round window and oval window microfissures in a significant percentage of temporal bone specimens. They found these fissures to increase in length and number with age and proposed that they could represent weak points in the bony labyrinth. Ellis and Linthicum in 1991, in contrast, felt microfissures were common occurrences and had no clinical significance. Correlation of microfissures with PLFs was indirectly addressed by Kamerer and colleagues, and this concept remains one potential route of communication between the middle and inner ear. An alternative anatomical argument for the development of PLFs has focused on the cochlear aqueduct as a potential conduit for transmitting cerebrospinal fluid (CSF) pressure to the inner ear. This would lead to the “explosive” form of PLF as postulated by Goodhill. Kerth and Allen in 1963 and later Beentjes in 1972 showed in animal models that CSF pressure changes are transmitted through the cochlear aqueduct to the perilymphatic space. In 1991 Weider and colleagues reported a patient with PLF noted to have an unusually large cochlear aqueduct both radiographically and on exploration. Also in 1991, Jackler and Hwang contested the concept of an enlarged cochlear aqueduct and found the lateral component to be fairly consistent and small.

At present there is little overall consensus regarding the anatomical basis for spontaneous PLFs. The fissa ante fenestrum is considered the most likely source of perilymph leakage, but many surgeons will patch the region of the round window as well. It is not clear whether explosive forces transmitted from the CSF or implosive forces through the middle ear exploit postulated otic capsule weakness.

PATIENT PRESENTATION

Individuals with PLFs may have a myriad of symptoms that often overlap the complaints of patients with other ear disorders. The most common presentation is the triad of hearing loss, vertigo, and tinnitus (Table 1). Given these symptoms, it is easy to see how a PLF can be confused with Meniere disease, labyrinthitis, and even vestibular migraine. A detailed history regarding the patient’s aural symptoms is thus critical to determining the potential for a PLF and the need for further evaluation or exploration.

Hearing loss is one of the most common symptoms in reported series of PLF patients. Looking at confirmed leaks based on surgical exploration, Selzer and McCabe found over

Table 1. Presenting Symptoms of Perilymphatic Fistula
80% of individuals to have some form of hearing loss. Their most common finding was fluctuations in speech discrimination. Shelton and Simmons found hearing loss in just over 50% of patients but no diagnostic pattern on the audiogram. Rizer and House also found hearing loss in approximately 50% of patients with the majority of these occurring suddenly. A large series reported by Fitzgerald and colleagues found hearing loss or fluctuation in 35% of patients. vestibular complaints are the most common reason for seeking medical attention among PLF patients. Shelton and Simmons found approximately 75% of their patients with vestibular dysfunction, and 90% of Fitzgerald’s patients also complained of vestibular problems. Black and colleagues found vestibular symptoms to be the most common complaint with a sense of disequilibrium predominating. Seltzer and McCabe noted vestibular symptoms consisting of chronic disequilibrium punctuated by attacks of vertigo. In the House Ear Clinic series, dizziness was found in 46% of the patients, roughly the same incidence as those with hearing loss. The duration of vestibular symptoms and the number of physicians seen for evaluation are typically higher in PLF patients than in other ear conditions. The mean duration of symptoms until diagnosis with PLF is about 3 to 4 years.

Tinnitus has been commonly reported as an associated symptom in PLF but is not considered to be associated with PLF if it occurs in isolation. In fact, any single ear symptom in the absence of other findings or complaints is uncommon in PLF. The vast majority of patients have all components of the triad, namely, hearing loss, vestibular symptoms, and tinnitus. An association of this triad with aural fullness is also commonly reported in PLF patients. This makes it difficult to distinguish PLF from Meniere disease. In both disorders, symptoms appear suddenly, are episodic, and with time, can be progressive or fluctuating. PLF, however, is more commonly associated with inciting events such as head trauma, sneezing, barotrauma from airplanes or SCUBA diving, and straining. Yet, in most series at least half of the patients do not recall or note a precipitating event. In clinical practice, the author focuses on establishing a diagnosis of Meniere disease (see Chapter 28, “Meniere Disease, Vestibular Neuritis, Benign Paroxysmal Positional Vertigo, Superior Semicircular Canal Dehiscence, and Vestibular Migraine”); and, if the patient does not fall into a category of definite or probable Meniere disease, consideration is given to a PLF as a possible alternative cause.

### Table 2 Diagnostic Methods Used for Evaluation of Perilymphatic Fistula

<table>
<thead>
<tr>
<th>Test</th>
<th>Description</th>
</tr>
</thead>
</table>
| **Audiometric assessment**                                           | - Document sensorineural hearing loss
- Assess for inner ear conductive hearing loss
- Consider performing with suspected ear up Fistula test
- Subjective dizziness with pneumatic otoscopy
- Observed nystagmus with pneumatic otoscopy (Hennebert sign)
- Enhanced by use of Electronystagmography/Videonystagmography (ENG/VNG) recording
- Posturography
- Can enhance by performing fistula test during posturography Fistula Test
- Sensitive during active perilymph leak
- Electrocochleography
- Can identify a unilateral weakness
- Can combine with fistula test for greater sensitivity
- Vestibular Evoked Myogenic Potentials (VEMPs)
- May have lower thresholds with PLF (rule out superior semicircular canal dehiscence) Fluoroscein
- Intrathecal injection may label perilymph (not FDA approved in the United States)
- A diagnostic test to distinguish from perilymph Protein markers
- Compare overall protein concentration to serum and CSF (slow, expensive)
- Beta-2-transferrin may indicate CSF rather than perilymph
- Beta-trace protein (in early stages of investigation) operative exploration with microscopy
- Large leak may indicate CSF (congenital, traumatic)
- May need to look for a long time; two surgeons observing may help
- Increase pressure: Valsalva, jugular compression, Trendelenburg position
- Endoscopy
- A voids potential contamination by local anesthetic
- Very low rate of positive exploration with endoscopy

### Audiologic Assessment

Audiologic assessment should be carried out to document hearing loss at the time of presentation. This should be performed on all individuals in whom the diagnosis of PLF is entertained because hearing loss occurs in over 50% of those with a fistula but is the primary complaint in only one-fourth. Serial assessments can also document hearing fluctuation and should include tests of word discrimination. No definitive audiometric pattern has been associated with PLF but low frequency sensorineural hearing loss may suggest Meniere disease as an alternative diagnosis. A low frequency conductive loss pattern should raise the suspicion of superior semicircular canal dehiscence especially if it is a pseudo-conductive loss manifest by lower than normal bone conduction thresholds rather than increased air conduction thresholds. Conductive hearing losses have also been reported in PLF presumably due to air in the labyrinth. As such, a recommendation has been made for performing the hearing testing in the lateral decubitus position with the affected ear up to enhance detection of an inner ear conductive loss. However, this has not been proven to be a diagnostically sensitive or specific test for PLF.

### Fistula Test

Pressure sensitivity is a hallmark of PLF and many authors have reported on the use of the fistula test and the relevance of a positive Hennebert sign in diagnosis. Pressure is typically applied to one ear with pneumatic otoscopy, and the patient’s eyes observed for induced nystagmus. The patient can also be questioned for the elicitation of a sense of disequilibrium in lieu of observed nystagmus. Modifications of this test have been proposed including the use of Frenzel lenses or with electronystagmography/videoystagmography (ENG/VNG) monitoring. Pressure can be applied with a tympanometer, and the response monitored objectively with VNG goggles. Others have performed the fistula test with the patient standing with eyes closed to increase subjective sensitivity or even with the patient on a posturography platform to enhance detection of altered vestibulospinal reflexes.

The utility of fistula testing is debatable as many studies have found it to lack in both sensitivity and specificity. Healy and colleagues along with Seltzer and McCabe showed a positive fistula test in only 25% of patients with confirmed fistulae on exploration. Rizer and House found no difference in positive fistula test rates between those with a fistula and those without. Vartainen and coworkers demonstrated a positive fistula test in only 33% of patients with confirmed fistulae although there was only an 8% positive test rate in those without fistula. Hain and Ostrowski found the fistula test to lack sensitivity for diagnosing PLF. In particular, they concluded that a positive fistula test may raise one’s suspicion of a PLF, but the lack of nystagmus or subjective dizziness on pneumatic otoscopy did not indicate the absence of a fistula.

### Electrococchleography (ECoG)

ECoG has been studied as a potential test for diagnosing PLFs. A guinea pig model showed abnormal ECoG summing potential to action potential (SP/AP) ratio in the acute phase after creating a fistula that reverted to normal once the fistula healed. Clinically, intraoperative ECoG was found to be abnormal in patients with fistulae only while suctioning around the round window. Patching of the round window niche in these patients led to relief of symptoms. Achenberg and colleagues in 1988 using ECoG as a
screening test found abnormalities in only about 50% of patients with surgically confirmed fistulae. Further, ECoG was unable to distinguish between vestibular symptoms due to a fistula and those related to Meniere disease. Fitzgerald noted SP/AP ratios >0.40 on ECoG in approximately 66% of patients undergoing patching procedures. There was a strong bias in his series toward patients with simultaneous cochlear hydrops which he felt was a result of a PLF as well as being associated with Meniere disease. ECoG, therefore, does not appear to be specific for PLF, but abnormal results during maneuvers causing the egress of perilymph can increase suspicion.

**ENG and VNG Test Battery**

ENG/VNG testing is the predominant method for objective vestibular evaluation. This test battery, and particularly the caloric testing, can identify a unilateral vestibular weakness, which may raise the suspicion of an inner ear insult and direct the clinician’s attention toward one ear. As noted above, ENG/VNG ocular monitoring can also be used to enhance the sensitivity of the fistula test for determining the presence of pressure-induced nystagmus. ENG alone is not particularly specific for identifying the presence of a fistula or for distinguishing PLFs from other ear disorders.

**Posturography**

Due to the high prevalence of chronic disequilibrium in patients with fistulae, posturography has been frequently employed in patient evaluation. Whereas posturography can identify disorders of balance, it cannot distinguish a fistula from other lesions. Black and colleagues have pioneered the simultaneous application of pressure to the external ear canal, that is, the fistula test, during the simultaneous application of pressure to the lesions. Black and colleagues have pioneered balance, it cannot distinguish a fistula from other abnormalities than the fistula test alone. The majority of those studies were performed before the identification of the similarly pressure-sensitive entity of superior semicircular canal dehiscence which must be kept in mind. Low-frequency sound application has also been suggested as a useful provocative stimulus during posturography for identifying PLF. However, positive test results have also been seen in Meniere disease and non-PLF inner ear hypofunction.

**Vestibular Evoked Myogenic Potentials (VEMP s)**

VEMPs have reemerged as an important test of vestibular function due to the significant thresholds changes seen with superior semicircular canal dehiscence. Although not systematically tested, VEMPs may be useful in PLF as many symptoms of pressure sensitivity are found in common between these two clinical conditions. A recent report found lowered VEMP thresholds in a series of patients without radiographic evidence of superior semicircular canal dehiscence. Consideration should be given to the possible presence of a PLF in such situations.

**Detection of Perilymph**

The absence of definitive clinical tests to diagnose PLFs has led some clinicians to look for other means of confirming the presence of perilymph in the middle ear. This has been achieved by direct means such as surgical or endoscopic exploration of the middle ear or by indirect means such as testing middle ear exudate for markers of perilymph. As with diagnostic tests, no single protocol to date has proven definitive, and controversy regarding some of these methods persists.

**Fluorescein.** Fluorescein is a commonly used labeling dye for detecting fistulas and leaks. It has most commonly been used in otolaryngology and head and neck surgery as an intraoperative marker to detect CSF leak during sinus surgery. It was shown in the 1940s and 1950s that fluorescein could enter the labyrinth by way of the cochlear aqueduct from the CSF. However, Gehring and colleagues found that clinically apparent labeling of perilymph as seen through the round window membrane on microendoscopy was rare and occurred in less than 10% of patients. Further, when directly inspecting perilymph at stapedectomy, they saw no fluorescein. Further damping the enthusiasm for use of intrathecral fluorescein has been the high rate of nervous system complications when administered quickly or in high concentrations. Currently, fluorescein is not Food and Drug Administration (FDA) approved for intrathecal use in the United States.

**Mechanical markers.** Several mechanical markers for detecting fistulas and leaks have been explored. It was initially thought that perilymph could be labeled by transudation of fluorescein across the cochlear vesselule after intravenous injection. This marker was abandoned and shown to be due to intravascular retention of fluorescein and transillumination of vascular mucosa. Another use of fluorescein is as a label for injected local anesthetic. In this manner, fluid noted in the middle ear upon exploration could be distinguished from the injected local anesthetic. A recent study found that labeled local anesthetic entered the middle ear in all their cases. When they did not use local anesthetic but explored the ear with endoscopy, all ears were dry and no fluid of any form was found. Thus, many early reports of perilymph leak could represent local anesthetic contamination of the surgical field.

**Protein Markers.** Perilymph differs from serum and CSF in average protein concentration. Attempts at characterizing overall protein composition can be time consuming and dependent upon pure samples undiluted by anesthetic or mucosal transudate. Identification of specific protein markers has largely focused on beta-2-transferrin, a protein considered to be present in perilymph and CSF but absent from serum. There is doubt, however, as to the natural occurrence of beta-2-transferrin in perilymph. Levenson and colleagues collected 13 samples of perilymph during cochlear implantation or stapedectomy and found only two to be positive for beta-2-transferrin. All four of their control CSF samples were positive. Similar findings were reported by Buchman and coworkers who showed only a 29% sensitivity of beta-2-transferrin testing for perilymph. Thus, the beta-2-transferrin protein may not be useful for identifying PLF. A another protein under investigation as a marker of perilymph leak is beta-trace protein (prostaglandin D synthase) which is present in CSF but generally absent in serum. Further investigation is needed to determine whether this can be used as a reliable marker or if it is fraught with the lack of specificity found with beta-2-transferrin.

**Beta-2-transferrin** may be useful in patients with congenital PLF in whom there may be CSF in the leak rather than pure perilymph. Concordance between positive observation of a PLF on exploration and positive beta-2-transferrin testing of middle ear fluid in congenital PLF is approximately 26%. An approximately 10% of patients with no visible leak but a history suspicious for PLF may also have a positive beta-2-transferrin test. There is a higher incidence of positive beta-2-transferrin testing in children with congenital otic capsule or middle ear abnormalities. This suggests that CSF pressure transmitted to the inner ear may cause perilymph and CSF leakage at natural or acquired otic capsule weaknesses in children with congenital malformations.

**Exploration.** Direct surgical exploration for the presence of leaking perilymph has, since the earliest recognition of this entity, been the mainstay of diagnosing PLFs. A 1993 national survey of PLFs by House and colleagues found an overall positive exploration rate of approximately 50%. This survey included a subset of surgeons who had never identified a leak and an equal subset who never failed to identify a leak. Similarly, a review of exploration outcomes in the 1980s and 1990s found an average positive exploration rate of 55%. Thus, only half of patients clinically suspected as having a leak have such on exploration, and the reliability of directly seeing perilymph has been challenged.

The total volume of perilymph is less than a tenth of a milliliter and identifying such a small volume in a moist field is difficult. If larger volumes are identified they likely represent CSF that is consistent with congenital PLF which may be due to inner ear malformations. Indeed, positive exploration rates in children appear to be higher than those reported for adults. To detect the small volumes associated with spontaneous fistulae, authors have suggested long periods of microscopic examination, looking for shifts in the light reflex, use of the Trendelenburg position, Valsalva maneuver, jugular vein compression, mineral oil to trap fluid at the oval and round windows, and the inspection of the ear by two surgeons.
As noted earlier, injected local anesthetic can enter the middle ear prior to raising a tympanomeatal flap and be mistaken for perilymph. Thus, labeling the anesthetic with fluorescein has been tried, but an alternative approach is not to use injected anesthetics. The use of topical anesthetics on the tympanic membrane and exploration by endoscopy to avoid canal injections has been reported. Interestingly, the rate of positive exploration by endoscopy is far lower than that by operative microscopy. In a report by Poe and Bottrill the positive exploration rate was 0% including notation that 48 consecutive endoscopies for PLF failed to find a leak. A report suggests limited utility of endoscopy in identifying PLFs.

Currently, there are no definitive diagnostic tests for PLF or universally accepted tests for the detection of perilymph in the middle ear. Even surgical exploration with microscopic observation is considered unreliable for confirming the presence of a spontaneous leak. The observation of perilymph leak at an otic capsule fracture secondary to trauma or leakage around the oval window following stapedectomy is considered more reliable but may also suffer from the bias of expectation. A history suspicious for PLF and exclusion of other ear diseases remain the best diagnostic criteria for spontaneous PLFs.

MANAGEMENT

Medical and conservative therapies for the treatment of PLFs are similar to those used for CSF leaks. Namely, bed rest with head elevation and the avoidance of straining or other pressure increasing activities are prescribed. The use of lumbar drain to reduce CSF pressure further in PLF has not been reported. Interestingly, ventriculoperitoneal shunting (VPS) has been used, particularly for those patients whose PLF may be secondary to trauma or leakage around the oval window following stapedectomy is considered more reliable but may also suffer from the bias of expectation. A history suspicious for PLF and exclusion of other ear diseases remain the best diagnostic criteria for spontaneous PLFs.

Outcomes of surgical management are generally good and reported improvement in vestibular symptoms range from 71 to 100% (Table 3). Hearing improvement is less common and rarely exceeds 50% of patients in most series. Stabilization of hearing is seen in a similar percentage of patients, but further progression of hearing loss or loss at surgery can approach 25%. Objective testing, even in patients who improve, may not change postoperatively. Black and coworkers found no changes in ENG or rotational chair testing but did see improvement in performance on dynamic posturography in about 30% of patients. M eyerhoff found return of ECoGs to normal SP/PA ratios in 21 of 24 patients following patching procedures. Given the fairly low morbidity and risk associated with patching procedures, surgical management may be recommended in cases where PLF is a diagnostic consideration. A protective consent and discussion of controversies with the patient are essential.

SUMMARY

The goal of this chapter has been to present the salient features of PLFs that will aid in the diagnosis and management of these disorders particularly in patients with antecedent inciting events such as implosive or explosive trauma and prior stapedectomy. A also, congenital inner ear malformations predisposing to CSF/perilymph leakage are relevant to this discussion. Less clear are patients with spontaneous PLF for whom there is little overall consensus regarding occurrence, pathophysiology, diagnosis, and treatment. It is imperative for the reader to assimilate the information presented and to use his or her own medical judgment in evaluating complaints of dizziness and hearing loss with regard to the differential diagnosis of PLF.

Hereditary Hearing Impairment

Richard J.H. Smith, MD
Amit Kochhar, BS
Rick A. Friedman, MD, PhD

Hearing impairment may be classified etiologically as either inherited or acquired and temporally as either prelingual (congenital) or postlingual (late in onset). Although useful, these types of classification belie the complex interaction of genetics and environment that make the study of hearing impairment, particularly late-onset deafness, difficult. For example, although presbyacusis and noise-induced hearing loss might be dismissed as the end result of accumulated age and environmental trauma, animal studies have shown that genetic predisposition is an important determinant of final outcome. By focusing on congenital hereditary hearing loss, the confounding effects of environment are minimized, and our understanding of aural development and auditory function is simplified.

A little more than 50% of congenital deafness is inherited,1 and among school-aged children, 1 child in 650 to 2,000 has some form of hereditary auditory function is simplified.2,3 As the incidence of deafness is classified etiologically as either inherited or acquired and temporally as either prelingual (congenital) or postlingual (late in onset), difficult. For example, although presbyacusis and noise-induced hearing loss are not necessarily caused by a genetic factor, animal studies have shown that genetic predisposition is an important determinant of final outcome. By focusing on congenital hereditary hearing loss, the confounding effects of environment are minimized, and our understanding of aural development and auditory function is simplified.

PATTERNS OF INHERITANCE

Genetic information is passed from one generation to the next encoded in the human genome. The human genome comprises 46 chromosomes, 22 pairs of autosomes, and the sex chromosomes, XY in males and XX in females. The autosomes vary in size and can be arranged by karyotype from largest to smallest (Figure 1). Variances in shape are caused by the centromere, which divides a chromosome into two arms. A chromosome is described as metacentric if the centromere is in the center, submetacentric if it is off center or acrocentric if it is near the ends. The shorter of the two arms is designated “p” (for petite), and the longer arm is designated “q.” Each chromosome is assigned a specific number and is further labeled by the banding pattern that is produced by staining (see Figure 1A and B). Band patterns are distinct for each chromosome and are individually numbered (7q31 refers to chromosome 7, long arm, band 3, 1).

Individuals inherit half of their autosomal chromosomes from their father and half from their mother. Therefore, every gene exists as a pair, with 1 copy of paternal origin and the other copy of maternal origin. Each copy is referred to as an allele. The alleles of a gene pair may be identical, or subtle differences may be present. If the alleles are identical, and individual is said to be homozygous for that gene pair; alternatively, if the alleles are different, an individual is said to be heterozygous. Figure 1A (A) Male karyotype, 23, XY. (B) Female karyotype, 23, XX.

If the affected gene is inherited through the father, there are no affected offspring, although all daughters are carriers. Mitochondrial deafness is inherited only through the mother,2,4 and sons and daughter may be affected equally.

When hereditary deafness is classified by mode of inheritance, 60 to 70% of cases are autosomal recessive, 20 to 30% are autosomal dominant, and 2% are X-linked.2,7 In nearly 33% of cases, other phenotypic characteristics cosegregate with the hearing loss. These types of hearing impairment are known as “syndromic” and make the unequivocal diagnosis of hereditary deafness much easier. Typically a wide range of phenotypes occurs, even in individuals carrying the same deafness-causing mutation, a phenomenon known as variable expressivity. An affected individual may exhibit a few, some, or all of the phenotypic manifestations typically associated with a particular genetic abnormality. On rare occasions, an individual may have no abnormal physical findings, and the genetic mutation is said to be nonpenetrant. In the absence of cosegregating physical findings, inherited deafness is said to be “nonsyndromic.” Nonsyndromic deafness is subclassified by mode of inheritance as DFNB, DFNB, or DFNB for dominant, recessive, or X-linked, respectively, (DFN for deafness). Loci are numbered in order of discovery. Mitochondrial deafness is designated by mutation type.
SYNDROMIC HEARING IMPAIRMENT

Over 400 forms of syndromic deafness have been described in which hearing loss is an intrinsic part. Though many classifications exist, one of the more useful is based on the involved organ system (Table 1). Some of the more common forms of syndromic hearing impairment are discussed in more detail with particular reference to recent advances in the understanding of their genetic basis (Table 2).

Autosomal Dominant Hearing Impairment

Branchio-Oto-Renal Syndrome (BOR). In 1864, Heusinger first recognized an association between hearing impairment, preauricular pits, and branchial fistulae. However, it was not until a century later that Melnick and Fraser comprehensively described the specific phenotypes. The BOR was defined to include hearing loss, auricular malformations, branchial arch remnants, and renal anomalies.10 Table 3 outlines the most common features of BOR syndrome. These include cup-shaped pinnae, preauricular pits, branchial fistulae, and mild renal anomalies; however, preauricular tags, lacrimal duct stenosis, renal aplasia or agenesis, a constricted palate, a deep overbite and a long, narrow face may also be seen (Figure 3).

BOR syndrome is now recognized as one of the more common forms of autosomal dominant syndromic hearing impairment. It has an estimated incidence of 1:40,000 and has been reported in 2% of profoundly deaf children.11 Penetrance is high, but incomplete and variable expressivity has been documented between and within families.12-14 No anticipation or parent of origin effect has been implicated in the transmission of BOR syndrome.15,16 Hearing impairment is found in 70 to 93% of affected persons; however, age of onset may vary from early childhood to young adulthood. The severity of hearing loss ranges from mild to profound and may be conductive, sensorineural, or mixed.1,2,7,17,18

The first BOR gene was mapped to chromosome 1q31. This confirmed previously hypothesized thoughts of genetic heterogeneity within BOR syndrome.22 In 2003, yet another locus for BOR was isolated on chromosome 14q and this time a new causative gene was cloned, SIX1.23,24 Like EYA1, SIX1 is also involved in the development of both the ear and kidney and is believed to be downstream of EYA1.

Identification of a second locus associated with BOR syndrome was achieved in 1998 on chromosome 1q31. This confirmed previously hypothesized thoughts of genetic heterogeneity within BOR syndrome.22 In 2003, yet another locus for BOR was isolated on chromosome 14q and this time a new causative gene was cloned, SIX1.23,24 Like EYA1, SIX1 is also involved in the development of both the ear and kidney and is believed to be downstream of EYA1.

As of July 2006, 117 different mutations of EYA1 had been associated with BOR syndrome. A full list of the mutations is available on the Pendred/BOR web page (www.medicine.uiowa.edu/pendredandbor). However, only 30 to 40% of patients affected with BOR syndrome have known mutations in EYA1, and the number of patients with SIX1 mutations is still unknown. Work is currently underway to identify new mutations that may be involved in the molecular pathology leading to the BOR phenotype.

Crouzon Syndrome (CS). In 1912, Crouzon defined an autosomal dominant syndrome characterized by cranial synostosis, hypertelorism, exophthalmos, parrot-beaked nose, short upper lip, hypoplastic maxilla, and a relative mandibulofacial prognathism.19-21 CS is the most distinctive and common autosomal dominant disorder of the craniofacial complex.22 It represents

Adapted from reference 8.
Aheity has been observed in other craniosynostosis syndromes including CS. They are tyrosine kinases that span the cell membrane and are important in mitogenesis and cell migration, development, and differentiation. Molecular analysis identified mutations in FGFR2 on chromosome 10q25-26 as being responsible for CS in approximately 50% of affected patients. As for the unidentified mutations, genetic heterogeneity has been observed in other craniosynostosis syndromes (Apert and Pfeiffer syndromes), and may play a role in CS as well.

Neurofibromatosis 2 (NF2). NF2 is a central form of neurofibromatosis characterized by bilateral vestibular schwannomas. Other features include meningiomas, spinal cord dorsal root schwannomas, and posterior subcapsular cataracts. Criteria for diagnosis include 1 of the following: (1) bilateral internal auditory canal/cerebellopontine angle tumors; (2) a first-degree relative with NF2 and a unilateral eighth nerve tumor; (3) a first-degree relative with NF2 and 2 of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity. Vestibular schwannomas most commonly present with auditory sequelae. They are typically slow growing and cause gradual deterioration in hearing as well as impairment of vestibular and other cranial nerve function.

The causative gene encodes a protein called merlin that shows similarity to a group of cell membrane-cytoskeleton protein linkers that regulate cell adhesion and morphogenesis. Studies indicate that it may act as a regulator of growth, motility, and cellular modeling. Inactivation of merlin in the mouse by targeted mutagenesis produces a variety of malignant tumors with a high rate of metastasis, suggesting that merlin also functions as a tumor suppressor. It appears that there is some genotype/phenotype correlation as truncating or inactivating mutations lead to severe phenotypes with an earlier age of onset, whereas missense mutations are associated with milder disease and a later age of onset.

Stickler Syndrome. STL, also known as hereditary arthro-ophthalmopathy, is an autosomal dominant disorder of collagen connective tissue characterized by marfanoid features, spondyloepiphysial dysplasia, joint hypermobility, midface hypoplasia, severe myopia, and varying degrees of Robin sequence (cleft palate, micrognathia, and glossoptosis). Because of the substantial risk for retinal detachment, ophthalmologic assessment is mandatory. Approximately 15% of affected patients also have a mixed hearing loss.

Gene linkage studies have demonstrated considerable genetic heterogeneity in STL, with known mutations in genes for type II collagen. COL2A1, COL11A2, and COL11A1 are implicated in STL1, STL2, and STL3, respectively, and there is evidence for at least 1 additional STL locus. Because COL11A2 is not expressed in the eye, persons affected with STL2 do not have myopia. Approximately two-thirds of STL cases are associated with COL2A1 gene mutations. However, there is considerable variability in expression, and knowing the mutation genotype has not been found to assist in prediction of phenotype severity for STL.

Treascher Collins Syndrome (TCS). TCS is a disorder of craniofacial development affecting structures derived from the first branchial arch. It is characterized by midface hypoplasia, micrognathia, macrostomia, colobomas of the lower eyelids, downward slanting palpebral fissures, cleft palate, and conductive hearing loss owing to external and middle ear abnormalities. Inner ear abnormalities are rare although enlargement of the utricle and aplasia of the horizontal semicircular canal have been reported. The incidence of TCS is about 1 in 50,000 live births with wide intrafamilial variation yet small intersibling variation.

The TCS locus has been mapped to chromosome 5q33.1. The causative gene, TCOF1, encodes a protein called treacle that is structurally related to nucleolar phosphoproteins and may play a role in nuclear-cytoplasmic transport. Up to 60% of affected persons have TCOF1 mutations with the majority leading to the introduction of a premature termination codon that generates truncated proteins. These truncated proteins are then mislocalized within the cell during development of the affected structures. The observation that these mutations are spread throughout the gene and lead to premature stop codons suggests that the developmental anomalies result from haploinsufficiency of TCOF1. The role of TCOF1 in the inner ear is still unknown.

In 2004, TCOF1 mutations were identified in 28 of 36 patients with a clinically unequivocal diagnosis of TCS. Although there was inter- and intrafamilial variation ranging from mild to severe, there were no genotype/phenotype correlations. Four clinically unaffected parents were heterozygous for the TCOF1 mutation leading to the conclusion that modifying factors are important for phenotypic expression.

Waardenburg Syndrome (WS). The WS, first comprehensively described in 1951, is a genetically heterogeneous condition with a wide clinical spectrum and a very high degree of phenotypic expressivity in each of its forms. WS is an autosomal dominant disorder with an incidence of 1 in 40,000 that manifests with sensorineural deafness and pigmentation defects of the hair, skin, and iris. Common to the various WS types is a deficiency of melanocytes, which are neural crest derivatives. This deficiency is responsible for the pigmentation defects and also for the high incidence of deafness, secondary to the loss of melanocytes from the stria vascularis.

WS is classified into 4 types, depending on the presence or absence of additional symptoms (see Table 2). The 2 most common forms, type 1 (WS1) and type 2 (WS2), are distinguished by the presence or absence of dystopia canthorum, respectively. The presence of limb abnormalities distinguishes the severe type 3 WS (WS3, Klein-Waardenburg syndrome) from WS2. Type 4 WS is referred to as Shah-Waardenburg or Waardenburg-Hirschsprung disease (WS4) and is characterized by the presence of aganglionic megacolon.

Formal clinical criteria have been adopted to diagnose WS1, and criteria have been suggested for WS2, although the clinical definition of WS2 covers any auditory–pigmentary syndrome that cannot be clearly classified (Table 4). As such,

</tbody>
</table>

*A an affected individual must have at least 2 major criteria or 1 major criterion and 2 minor criteria. Criteria for Waardenburg syndrome type 2 have been suggested that include premature graying as a major criterion instead of dystopia canthorum. W = Waardenburg index.

WS2 includes a mixed collection of melanocyte defects and is likely to exhibit considerable genetic heterogeneity. Aside from dystopia canthorum, all features of WS1 and WS2 show marked interindividual and intrafamilial variability.62,63

Dystopia canthorum is the most common feature of WS1 and results from fusion of the eyelids medially leading to a reduction in the visible sclera medial to the iris (Figure 4). Hearing loss occurs in over 60% of cases of WS1 and in over 80% of WS2 cases. The loss is typically sensorineural, prelingual, and nonprogressive and varies from mild to profound with profound bilateral loss being most common.

Mutations in the PAX3 gene, a member of the paired class of homeodomain family of transcription factors, are responsible for WS1 and WS3.64–66 Some WS2 cases are associated with mutations in the microphthalmia-associated transcription factor (MITF) gene71,72 or with the SLUG/snailed zinc-finger transcription factor (SNAI2) gene.68 The WS4 phenotype can result from mutations in the endothelin B receptor gene (EDNBR)69,70 or with the Sry-box 10 (SOX10) gene, a co-transcription factor that functions during neural crest development.71

Several lines of evidence suggest that a functional relationship exists between these WS-related transcriptional factors. Numerous different allele variants in these genes have been reported as causing deafness.

Autosomal Recessive Syndromic Hearing Impairment

Biotinidase Deficiency. Biotinidase deficiency is a preventable autosomal recessive form of hereditary hearing loss. A mutation in the biotinidase gene (BTD), located on chromosome 3p25, causes a deficiency in the enzyme required for the normal recycling of the vitamin biotin.74 Thus infants with severe deficiency (<10% of normal serum enzyme activity) are dependent on dietary sources of biotin to meet their nutritional requirements. Without early recognition and prompt initiation of biotin therapy, affected infants will typically develop skin rashes, seizures, hair loss, hypotonia, vomiting, and acidosis within the first few months of life. This may leave the infant with varying degrees of neurological sequelae, including mental retardation, seizures, coma, and death.75–77

If untreated, 75% of affected infants develop hearing loss, which can be profound, and persists despite the subsequent initiation of treatment.78 Since the symptoms of the disease, including the hearing loss, can be completely prevented by presymptomatic diagnosis and the administration of supplemental biotin, this disease has been included in many newborn screening programs throughout the world.79–81 The incidence of affected homozygotes with severe enzyme deficiency is about 1 in 60,000.82

Jervell and Lange-Nielsen Syndrome (JLNS). In 1957, Aton Jervell and his associate Fred LANGE-NIELSEN published the first report on a familial disorder characterized by the presence of a markedly prolonged QT interval, congenital deafness, and a high incidence of sudden cardiac death in childhood.83 Today, JLNS is characterized by profound prelingual sensorineural hearing loss, syncope, and sudden death secondary to a prolonged QT interval signifying a defect in cardiac repolarization. Diagnostic criteria include a QTc >440 ms in males and >460 ms in females. JLNS may account for 1 in 1,000 children with profound deafness, and in Norway, where it was first described, the estimated prevalence is 1 in 200,000.84 Syncopal attacks are usually associated with exertion or emotion such as fear, and without prompt diagnosis and care by a cardiologist, may precipitate sudden cardiac death. Treatment with drugs such as beta-adrenergic blockers or devices that help to regulate heart rate may reduce the high mortality rate of JLNS.

JLNS is caused by a homozygous or compound heterozygous mutation in either 1 of 2 genes, KCNQ1 and KCNE1. These genes encode subunits of voltage-gated potassium channel proteins.85–87 However, there is likely to be considerable genetic heterogeneity as mutations have not been identified in a number of families with JLNS. Persons related to JLNS affected patients may be heterozygous for JLNS mutations and can have a prolonged QT interval in the absence of hearing loss. These individuals are prone to life-threatening arrhythmias, thus, genetic counseling should be offered to affected persons and their families to diminish potential morbidity and mortality.88

Pendred Syndrome (PS). Pendred syndrome, the most common syndromic form of deafness, is an autosomal recessive disorder associated with developmental abnormalities of the cochlea, congenital sensorineural hearing loss, and diffuse thyroid enlargement (goiter). It is believed to account for up to 10% of all hereditary hearing impairment. Prevalence estimates range from 1 to 7.5 per 100,000 newborns, suggesting that it may cause up to 7.5% of all childhood deafness.89,90 Hearing loss in PS is prelingual, and in at least 80% of patients is associated with structural defects of the temporal bone and inner ear that include dilation of the vestibular aqueduct and the Mondini defect of the cochlea, respectively (Figure 5).90,91 Hearing loss is usually profound but can be variable in onset, rapidly progressive, and even unilateral. Goiter may be apparent at birth but typically presents in mid-childhood. The thyroid defect involves organization of iodine and can be diagnosed by administering perchlorate, which releases unbound iodide from thyroid follicular cells. Despite this abnormality, affected individuals usually remain euthyroid.

PS is caused by mutations in PDS, the gene that encodes pendrin. Pendrin is a transmembrane protein of 780 amino acids, predicted to have either 11 or 12 membrane spanning domains.92 It is a member of the solute carrier 26A gene family (SLC26A), a group of genes involved in sulfate anion transport. However, functional studies suggest pendrin is primarily involved in the transport of iodine and chloride ions and mediates the exchange of chloride and formate, properties that suggest tissue-specific function.93

PDS mRNA is expressed in the thyroid, kidney, and cochlea.93 In the thyroid gland, pendrin has been immunolocalized to the apical membrane of the thyroid follicular cells,94,95 where it may allow intracellular iodide to pass into the colloid space to be bound to thyroglobulin. In the kidney, pendrin seems to function as a chloride/formate exchanger in the proximal tubule and, in the intercalated cells of the cortical collecting duct, has an essential role in bicarbonate secretion.96 The role of pendrin in the inner ear is less clear. It has been hypothesized that the chloride transport function of pendrin is important in the homeostasis of the endolymp with ionic
imbalance potentially responsible for auditory developmental malformation.98

Over 50 different deafness-causing PDS mutations have been reported that are distributed throughout the coding sequence, having been identified in 18 of 21 exons. The majority of mutations are missense, with a smaller number of insertions, deletions, frameshift, and splice site mutations also having been reported.68,99–104 The wide distribution of mutations and lack of clustering to any domain of the gene, together with the variable phenotype, serve to compound efforts to correlate phenotype with genotype. Mutations in PDS are also known to cause certain forms of nonsyndromic deafness.

**Usher Syndrome (USH).** USH is one of the most common autosomal recessive syndromic forms of hearing impairment. Characterized by bilateral sensorineural hearing loss and visual loss secondary to retinitis pigmentosa (RP), it is responsible for 50% of all deaf-blindness in the United States and an estimated 3 to 10% of all congenital deafness.105 The prevalence is estimated to range from 2 to 6.2 per 100,000.106

Three different clinical classifications exist for USH based on presentation (Table 5). USH1 and USH2 are most common, whereas USH3 is quite rare, accounting for only 5 to 15% of all USH.107,108 In USH1, hearing loss is severe to profound across all frequencies, vestibular function is absent, and RP presents during childhood. Hearing aids are usually not helpful, but recently cochlear implantation has shown to be beneficial for some.109 USH1 patients primarily integrate into the Deaf community. The degree of hearing loss in patients with USH2 increases from moderate in the low frequencies to severe in the high frequencies and remains stable. USH2 patients have normal vestibular function, and the age of onset for RP is usually during the teenage years. Carefully fitted hearing aids work well in this population and persons affected with USH2 may communicate orally. USH3 is distinguished from USH1 and USH2 by the progressive nature of its hearing loss. The age of onset for RP and the degree of vestibular dysfunction in USH 3 are both variable. A degeneration of cochlear hair cells and rod photoreceptor cells underlies the hearing loss and RP observed in USH. Hair cells of the ear and photoreceptor cells of the eye share similar structural features such as cilia and microvilli,110 thus deciphering the molecular bases of USH may help to explain the biological processes involving these and other common structures.111 Visual impairment usually begins as night blindness with constriction of the visual fields accompanying the loss in visual acuity. By the fifth decade, 40% of USH affected persons are blind; and, by the seventh decade 70% are blind.112,113 Electroretinography (ERG) may uncover early RP and should be considered in all cases of congenital deafness to identify early USH.114

Usher syndrome demonstrates considerable clinical and genetic heterogeneity. Eleven different loci have been mapped, and specific mutations in 7 genes have been associated with USH. For at least 3 of these genes, some mutations cause USH while others result in nonsyndromic hearing loss. Seven different USH1 loci (USH1A to USH1G), 3 USH2 loci (USH2A to USH2C), and only 1 USH3 locus have been identified.115–120 Six of the relevant genes have been cloned: MYO7A, USH1C, CDH23, PCDH15, SANS, and USH2A and their mutations cause USH1B, USH1C, USH1D, USH1F, USH1G, and USH2A, respectively.121–126

**MYO7A** is an unconventional myosin expressed mainly in inner and outer hair cells that causes 75% of USH1 in the form of USH1B. Extensive studies in MYO7A suggest that it has a role in transport and adhesion of membrane-associated proteins at apical surfaces of cells and, in the inner ear, it may be essential for adhesion between stereocilia. In the eye, it is localized to microvilli projections in retinal pigmented epithelial cells and photoreceptor cells.127,128 Mutations in this gene also cause DFNB2 and DFNA11. The USH1C gene encodes a PDZ domain-containing protein called harmonin, which may function as a rafting protein in gating complexes within stereocilia.122 Several mutations have been found in USH1C patients, and USH1C has also been associated with DFNB18. USH1D is the second most common form of USH1, and its gene CDH23 is a member of the cadherin gene family whose encoded protein is important for the formation of tight junctions. Mutations in this gene also cause DFNB12.

USH2A accounts for 70% of all Usher syndrome patients. The USH2A gene encodes a protein designated usherin, which has both laminin epidermal growth factor and fibronectin type III domains.123,124 USH2As transcript is expressed primarily in the cochlea and the cells of the outer nuclear layer of the retina.125 The 2299delG-allele variant is the most frequent mutation and is found in greater than 20% of USH2A patients in Europe and the United States as well as some persons with USH3.130

**X-Linked Syndromic Hearing Impairment**

**Alport Syndrome (AS).** In 1927, Alport reported that deafness was a feature of a previously described familial nephropathy that caused uremia in males but spared females.131

HI = hearing impairment.
Progressive glomerulonephritis, sensorineural hearing loss, and specific eye findings characterize AS, which can be inherited as an X-linked or autosomal disorder. To facilitate diagnosis, four clinical criteria were established in 1988. In the presence of unexplained hematuria, a person can be considered affected if 3 of the following criteria are met: (1) a positive family history of hematuria or chronic renal failure; (2) electron microscopic renal biopsy evidence of AS; (3) characteristic eye signs of anterior lenticonus, white macular flecks, or both; and (4) high frequency sensorineural hearing loss.

Since light microscopy of renal biopsy specimens is usually normal in children and because findings are nonspecific in adults, electron microscopy is essential. This degree of resolution reveals splitting of segmental areas of the glomerular basement membrane, accompanied by thickening and electron-lucent areas that contain dense granulations. Serial biopsies will demonstrate progressive deterioration. The eye findings characteristic of AS are rarely noted in childhood and may become apparent only with renal failure. These include anterior lenticonus (conical projection of the anterior surface of the lens), macular flecks, and peripheral coalescing flecks. The progressive myopia caused by anterior lenticonus is considered by some authors to be sufficient to diagnose AS. Hearing loss is postlingual, progressive, and sensorineural.

The typical male with X-linked AS presents with hematuria at age 3 to 4 years, often following an upper respiratory tract infection. Toward the end of the first decade, hearing loss is detectable, and in the mid-teens, hypertension develops. By 25 years of age, over 90% of affected males have abnormal renal function. The clinical course in female carriers is much more variable. Most are clinically asymptomatic through life. Although nearly all have evidence of microscopic hematuria, about one-third will have macroscopic hematuria. Chronic progressive external ophthalmoplegia, cardiomyopathy, neuromuscular and psychiatric manifestations as well as renal deficiency. Both implantable hearing aids and cochlear implantation have been successful in rehabilitating these patients.

Recent evidence supports the notion that patients with MIDD may present with 2 distinct phenotypes (MIDD1, MIDD2) that may be related to a variable severity of the disease. Compared with patients with MIDD, those with MIDD1 are younger at onset of diabetes by 9 years on average, and the age at onset was below 35 years twice more often.

Mitochondrial Myopathy, Eencephalopathy, Lactic Acidosis, and Stroke-Like Episodes Syndrome (MELAS). The clinical characteristics of the MELAS syndrome are episodic vomiting, seizures, and recurrent cerebral insults resembling strokes and causing hemiparesis, hemianopsia, or cortical blindness. Hearing loss occurs in approximately 30% of patients and in the majority, a sudden, stepwise loss of hearing occurs usually in association with stroke-like episodes. Patients with MELAS syndrome may also present with sensorineural hearing loss that usually affects the higher frequencies. Bilateral hearing loss is a well-recognized feature in affected patients, and the common histopathological finding is atrophy of the stria vascularis.

Myoclonic Epilepsy with Ragged Red Fiber Myopathy (MERRF). The phenotype of MERRF varies greatly with pedigree and is characterized by myoclonus, epilepsy, and ataxia. Dementia, optic atrophy, and deafness occur frequently with a variable degree of hearing loss. A total of 80 to 90% of patients with MERRF have their disease as a result of an A to G mutation at nucleotide 8344. Biochemically, the mutation produces multiple deficiencies in the enzyme complexes of the respiratory chain, most prominently involving reduced nicotinamide adenine dinucleotide coenzyme Q (NADH-Q) reductase (complex I) in cytochrome c oxidase (COX) (complex IV), consistent with a defect in translation of all mtDNA genes.

NONSYNDROMIC HEARING IMPAIRMENT

Over 80 different nonsyndromic hearing impairment loci have been mapped, and a number of the relevant genes have been cloned. The protein products of these genes include ion channels, membrane proteins, transcription factors, and structural protein.
For example, DFNA1, DFNA6, DFN14, and DFN15 are characterized by low frequency hearing loss that progresses to involve the remaining frequencies. With other loci, hearing loss starts in the mid-or high-frequencies before progressing. The DFN2, DFN3, DFNA12, and DFNA23 phenotypes are exceptional as they are congenital hearing losses on which age-related changes become superimposed. Many of the genes for ADNSHI have been cloned (Table 6); however, the complexity is underlined by the fact that several of the genes are involved in both dominant and recessive nonsyndromic deafness or in both nonsyndromic and syndromic deafness.8,163

### Autosomal Recessive Nonsyndromic Hearing Impairment

Up to 85% of cases of nonsyndromic hearing loss are inherited in a recessive Mendelian fashion (ARNSHI).164 The typical phenotype is more severe than ADNSHI, accounts for the majority of cases of congenital profound deafness, and is almost exclusively due to cochlear defects.165

An exception is DFNB8 as it presents as a postlingual, progressive hearing loss. To date, 54 ARNSHI loci have been identified and 23 genes cloned (Table 7). The first locus was published in 1994, 6 years after the first X-linked locus and 2 years after the first dominant locus were reported.166 Three years later, the gene responsible for DFNB1, GJB2 (gap junction beta 2), was discovered.167 This gene encodes connexin 26 (Cx26), one of a class of proteins involved in gap junction formation. A group of 6 connexins oligomerize to form a hexamer (connexon) in the plasma membrane. Two connexons dock to form a transmembrane channel that links neighboring cells and facilitates the exchange of molecules up to 1 kDa in size.168 Connexons are important for the recycling of potassium ions into the cochlear endolymph through the network of gap junctions that extends from the epithelial supporting cells to the fibrocytes of the spiral ligament and to the epithelial marginal cells of the stria vascularis.169,170

Ion homeostasis is essential for normal hearing, and mutations in several genes encoding connexins or ion channels lead to hereditary deafness.171

The most significant discovery in the field of genetic deafness to date has been the finding that mutations in Cx26 are responsible for over half of the moderate-to-profound congenital deafness in many world populations.172,173 In certain regions of the Mediterranean, the prevalence may be as high as 79%, although studies in India and Pakistan reveal a much lower incidence.174,175

Numerous different deafness-causing allele variants have been identified. In the United States and much of northern Europe, the most prevalent mutation is the deletion of a single guanine nucleotide from a sequence of six guanines at position 30 to 35. Referred to as the 35delG mutation, this shift in codon reading frame results in premature termination of translation.172 In the midwestern United States, the carrier rate for this mutation is 2.5%, whereas the carrier rate for all deafness-causing Cx26 mutations is 3%.176 In the Mediterranean population, the carrier rate for the 35delG mutation is even higher and approaches 3.5 to 4.0%, implying that deafness due to homogyosity for this mutation could affect as many as 1 in 2,500 newborns in these populations.177,178 Other “common” mutations are found in different populations, such as the 167delT mutation in

Ashkenazi Jews,\textsuperscript{179} 235delC in Japanese,\textsuperscript{180} and R143W in Africans,\textsuperscript{181} suggesting founder events. Approximately 90 different GJB2 mutations have so far been reported to be associated with recessive, nonsyndromic hearing loss.\textsuperscript{182,183} These discoveries had an immediate application within clinical practice. In many populations, a definitive diagnosis can be made in 50% of cases of suspected hereditary hearing loss. The ability to establish causality affects recurrence risk estimates and makes genetic counseling an essential part of the evaluation of hereditary deafness. However, it is important to note that the degree of hearing loss in 1 child with Cx26 related deafness cannot be used to predict the degree of deafness in another offspring. There can be enough intrafamilial variability to make 1 affected child a candidate for cochlear implantation, whereas a sibling effectively uses hearing aids (Figure 6).\textsuperscript{184}

### X-Linked Nonsyndromic Hearing Impairment

X-linked nonsyndromic hearing impairment is rare and makes up only 1 to 3% of nonsyndromic hearing loss (Table 8). It exhibits considerable phenotypic heterogeneity, but most affected males have a congenital hearing loss, which can vary from severe to profound. Hearing loss is mild to moderate in carrier females. The losses associated with DFNB1 and DFNB6 may be progressive.\textsuperscript{184}

### Mitochondrial Nonsyndromic Hearing Impairment

The first genetic defect causing nonsyndromic sensorineural hearing loss was isolated in 1993 and was a mitochondrial mutation.\textsuperscript{185} Various other mitochondrial DNA (mtDNA) mutations have been identified that produce progressive, nonsyndromic, and symmetric bilateral hearing impairment. Nonsyndromic deafness mtDNA mutations are frequently homoplasmic or at high levels of heteroplasmy, suggesting a high threshold for pathogenicity.\textsuperscript{186} Phenotyping expression of these mtDNA mutations requires the involvement of nuclear modifier genes, environmental factors, or mitochondrial haplotypes (polymorphisms).\textsuperscript{78} Mitochondrial mutations may play a role in age-related hearing loss and have been implicated in a type of nonsyndromic deafness associated with increased susceptibility to aminoglycoside toxicity.\textsuperscript{187}

### Age-Related Hearing Loss

Age-related hearing loss (presbyacusis) is a condition associated with increased heteroplasmic mitochondrial mutations. Since mitochondrial DNA mutations, and the resulting loss of oxidative phosphorylation activity, seem to play an important role in the aging process,\textsuperscript{188} it is likely that acquired mitochondrial mutations in the auditory system may also lead to age-related hearing loss.

Ueda and colleagues detected high rates of mitochondrial DNA deletions in lymphocytes of persons with idiopathic sensorineural hearing loss and noted that the number of deletions increased with increasing hearing loss.\textsuperscript{189} They postulated that at least some cases of sensorineural hearing loss should be categorized as a mitochondrial phosphorylation disease. Temporal bone studies have also shown that a proportion of people with age-related hearing loss have a significant load of mitochondrial DNA mutations in auditory tissue when compared to controls with great individual

Adapted from reference 8.
use of these drugs can frequently lead to toxicity.\(^{219}\) In the United States alone, close to 4 million people are affected by hearing loss.\(^{190,191}\) The 961 mutation localizes at the C-cluster of the 12S rRNA gene: insertion or deletion at position 961, of several ototoxic mtDNA mutations in the 12S rRNA gene: insertion or deletion at position 961, \(^{205}\) indicating that aminoglycoside hypersensitivity is often maternally transmitted.\(^{206}\) The A1555G mutation is one of the most common causes of aminoglycoside-induced deafness.\(^{208-212}\) In particular, this mutation makes the 12S rRNA transcript more similar to bacterial rRNA and thus a target for aminoglycoside binding.\(^{206}\) This new G-C pair in 12S rRNA is also expected to create a binding site for aminoglycosides, which facilitates interaction with these drugs.\(^{219}\) In the United States, over 15% of persons with aminoglycoside-induced hearing loss carry this mutation, a point of major clinical relevance for the prevention of aminoglycoside hearing loss.\(^{220}\)

Recently, a homoplasmic C-to-T transition at position 1494 (C1494T) in the 12S rRNA gene was found in a large Chinese family with maternally transmitted aminoglycoside-induced and nonsyndromic deafness.\(^{211}\) Members of this family showed variable severity and age of onset for the hearing impairment. The C1494T mutation is expected to form a novel 1494U-A base-pair, in the same position created by the deafness-linked A1555G mutation, at the highly conserved A-site of 12S rRNA. Since this site has been implicated as the main target of aminoglycoside toxicity, it is anticipated that this alteration in the tertiary structure of 12S rRNA may lead to sensitivity to aminoglycosides.

**Familial Aminoglycoside Ototoxicity.** Aminoglycoside antibiotics exert their antibacterial effects by binding to the 16S ribosomal RNA (rRNA) in the 30S subunit of the bacterial ribosome, thus leading to mistranslation or premature termination of protein synthesis.\(^{192-194}\) However, use of these drugs can frequently lead to toxicity involving the renal, auditory, and vestibular systems,\(^{195,196}\) due to concentration in renal tubular cells and in the perilymph and endolymph of the inner ear.\(^{197,198}\) Renal damage is usually reversible, however, the auditory and vestibular ototoxicity are often not.

In the United States alone, close to 4 million courses of aminoglycosides are administered each year.\(^{199}\) It is estimated that at least 2 to 5%, and in some studies up to 25%, of patients treated with these antibiotics develop clinically significant hearing loss.\(^{200-202}\) Numerous studies have documented that aminoglycoside hypersensitivity is often maternally transmitted, suggesting that mtDNA mutation(s) are involved in aminoglycoside ototoxicity.\(^{203,204}\) Sequence analyses of the mitochondrial genome in patients with aminoglycoside ototoxicity have led to the identification of several ototoxic mtDNA mutations in the 12S rRNA gene: insertion or deletion at position 961, A1555G, and C1494T mutations.\(^{205}\)

**Clinical Diagnosis of Hearing Impairment**

**History**

An evaluation should be conducted as soon as hearing loss is suspected. Directed questions should focus on prenatal, perinatal, and postnatal history, specifically reviewing maternal illnesses, drug use, alcohol intake, and smoking. Recognized risk factors for hearing loss in the
perinatal period include low birth weight, prematurity, time spent in a neonatal intensive care unit, hyperbilirubinemia, sepsis, use of ototoxic medications, and birth hypoxia. Risk factors in the postnatal period include viral illnesses such as mumps and measles as well as bacterial meningitis. A record of speech and language milestones can establish whether the hearing loss is pre- or postlingual. However, even deaf infants coo and babble naturally up to the age of 6 months. A history of poor motor development may also indicate vestibular dysfunction.

An inquiry into hearing loss in first- and second-degree relatives is essential, especially if the loss started before the age of 30 years. Consanguinity or common origins from ethnically isolated areas should increase suspicion of hereditary deafness. If there are a number of family members with hearing loss, constructing a pedigree may delineate the mode of inheritance.

Physical Examination

The majority of cases of hereditary hearing impairment are nonsyndromic, thus physical findings are often absent. However, even in cases of syndromic hearing impairment, physical findings may be subtle or hard to identify. Hence, the physical examination should include a general inspection and orderly evaluation of all systems. Careful notation should be made for hair color, the presence of a white forelock, facial symmetry, and skull shape. Fundoscopy and eye color and relative position should also be noted, taking specific biometric measurements in suspected cases of WS1. The ears should be examined for auricular pits or sinuses and skin tags. Note the shape and size of the pinnae, and check for abnormalities of the external ear canal and tympanic membrane. Observe the neck for branchial anomalies and thyroid enlargement as well as the oral cavity for possible clefts. Note the number, size, and shape of the digits and complete a thorough inspection of the skin for areas of pigmentation/hypopigmentation and café-au-lait spots. Do a complete neurologic examination, including tests of gait and balance to assess for vestibular function.

Audiology

In 2000, the Joint Committee on Infant Hearing endorsed universal newborn hearing screening (UNHS) to provide hearing screening to all newborns before the age of 1 month, with confirmation of hearing loss in infants who do not pass the initial, or a subsequent screening, through an audiologic evaluation by the age of 3 months. Most children identified through this program have parents with normal hearing.

Hearing loss can be identified by several different complementary methods. Following the guidelines from the National Institutes of Health, all states in the United States have adopted UNHS, but testing algorithms and requirements vary. A nater test of choice for infants and young children with suspected hearing impairment is the auditory brainstem response, which gives accurate hearing thresholds from 1 to 4 kHz. It is important to note that the UNHS may fail to identify children with progressive hearing loss, which accounts for approximately 15% of preschool children with SNHL. The UNHS test is only the first step in a successful and cost-effective program. The main goal is early diagnosis and management, normal language development, and long-term success after intervention.

In older children or adults, a standard audiogram can be obtained. The presence or absence of hearing loss in other family members should be documented by formal audiometric testing.

Laboratory Testing

Laboratory testing should be individualized and directed toward the suspected diagnosis on the basis of history, physical examination, and age of the patient (Table 9). Such testing may include an IgM antibody assay in the first few years of life to assess the possibility of intrauterine infection, testing for hemoglobinopathies as these may be associated with SNHL, urinalysis and renal function tests in children with possible Alport syndrome, thyroid testing to rule out a deficiency, TSH and a perchlorate discharge test in suspected Pendred syndrome, and an evaluation of metabolic disorders such as lysosomal storage diseases. An electrocardiogram to assess the QT interval should be performed if there is a history of syncopal episodes or a family history of sudden infant death syndrome (SIDS), as might be seen in JNLS.

Any evaluation of hearing loss requires a multidisciplinary approach, which should include counseling and support for parents. A recent survey revealed that identification of the cause of the hearing loss is the highest priority of parents who learn that their child is hearing impaired.

Genetic Testing

In addition to UNHS and a general medical evaluation, genetic testing can provide direct benefits for patients and their families. Defining the cause of a patient’s hearing impairment through genetic testing will accomplish the following: (1) avoid unnecessary and costly testing; (2) allow accurate recurrence risk counseling; (3) dispel incorrect notions of what caused the hearing impairment; and (4) offer limited prognostic information and guide future medical management.

Samples used for testing can include peripheral blood and tissues, but also less invasive samples such as buccal cells obtained with a swab or part of the blood spots collected for newborn screening. Mutation scanning methods need to be fully optimized to create reproducible results. Depending on the technique, conditions, and level of expertise, some of these methods are general screening methods and can therefore miss certain mutations. Sequencing is the most all-inclusive method for it can detect almost all point mutations as well as small deletions and insertions.

28.4%. An MRI may be used to visualize the acoustic nerve, exclude aplasia, and rule out infectious inner ear destruction and is especially important before cochlear implant surgery.  

Other Consultations

An ophthalmologic opinion should be obtained in all children with severe-to-profound hearing impairment as half of children with severe to profound hearing loss have concomitant oculomotor abnormalities. Although most of these abnormalities are refractive errors, the correction of which is essential, ERG may uncover signs of early ROP. Referral to a clinical geneticist should be requested to ensure that parents and patients adequately understand the issues since recurrence risk.

Management of Hearing Impairment

Hearing impairment is the only sensory defect that can be treated successfully even if the hearing loss is complete. Early identification of hearing impairment in infants and young children is essential for the development of age-appropriate speech and language skills. Children whose hearing losses are identified and in whom intervention is instituted before 6 months of age show that an almost age-appropriate level of language skills can be accomplished. The level of habilitative intervention that is required depends on the degree of hearing impairment. Counseling of the family, proper hearing aid selection, hearing aid fitting, and continued audiologic assessment are important. While very few families now choose for their child to not receive a cochlear implant, the vast majority of children with prelingual or postlingual deafness now receive cochlear implants to rehabilitate syndromic and nonsyndromic hearing impairment, which has proven to be highly beneficial. The criteria for cochlear and auditory brainstem implantation are reviewed in Chapter 32, “Cochlear Implantation.” Schools that are focused on auditory oriented education are emerging as optimal for developing early speech and language acquisition and production, although total communication programs using combinations sign language and oral-aural remain as options. It is important for the physician to remain supportive of parental choice regarding the means for rehabilitation.

A variety of support systems exist, particularly on the World Wide Web. In the United States, the National Institute on Deafness and Other Communication Disorders disseminates information about hearing impairment to professionals and families on their website, http://www.nidcd.nih.gov.

The site also contains information for individuals interested in supporting and participating in research projects and lists resources and links to other organizations.

FUTURE DEVELOPMENTS

Rapid advances in genetics and molecular biology have transformed the field of hearing loss and deafness. Genetic tests are now less expensive than ever before and available to the general population, thus making detection and treatment of hearing impairment possible for infants as young as 1 month. Furthermore, it has become easier to identify patients who are at risk for environmental damage to their hearing from noise, drugs and aging, and they too can be cared for accordingly. Molecular testing is beginning to become the first step in determination of the underlying etiology of hearing impairment and the use of these tests may impact management decisions by better defining therapeutic and habilitative options. As clinical management becomes more sophisticated, continued growth in science and technology will allow physicians to offer new, practical, and effective treatments for sensorineural hearing impairment.

Autoimmune Inner Ear Disease and Other Autoimmune Diseases with Inner Ear Involvement

Jeffrey P. Harris, MD, PhD
Quinton Gopen, MD
Elizabeth Keithley, PhD

AUTOIMMUNE INNER EAR DISEASE (AIED)

Scientific Basis

The idea that immunity might participate in the causation of inner ear disease has only recently become accepted. Using the brain as a model, the inner ear was initially viewed as an immunologically "privileged" site, separated from cellular and humoral immunity by a blood-labyrinthine barrier. Apart from inner ear inflammation associated with viral or bacterial labyrinthitis, it seemed inconceivable that the immune system could operate within the bony labyrinth. However, experiments beginning in the 1980s demonstrated that antigen introduced into the inner ear of naïve or systemically primed animals resulted in a brisk systemic immune response as well as a local one.1–4 Moreover, antigen introduced into the inner ear of a systemically immunized animal resulted in hearing loss and even profound deafness owing to a vigorous secondary immune response (Figure 1).2,5,6 The endolymphatic sac also becomes inflamed (Figure 2) and has been implicated as a site of local immune cell processing within the inner ear.7–9 The magnitude of these responses was dependent on an intact endolymphatic sac since ablation of the sac or even blockage of the endolymphatic duct reduced inner ear immune responses.8,9 Experiments then demonstrated that the inner ear, although protected by systemic immunity, was damaged by bystander injury when cell-mediated immunity became involved. For example, systemic immunity can protect the inner ear from viral infection through circulating antiviral antibodies.10,11 If, however, there is a cellular response to viral inoculation of a naïve animal, there is hearing loss and cochlear damage. This damage can be reduced by systemic immunosuppression.12 The route of entry of the inflammatory cells into the inner ear following antigen or viral challenge of the inner ear appears predominantly to be via the spiral modiolar vein (SMV) (Figure 3). During the inflammatory response, this vein takes on characteristics of an activated venule and expresses intercellular adhesion molecule-1 (ICAM-1) on the endothelial cell surface that facilitates the passage of circulating immunocompetent cells into the scala tympani.13–16 Once within the inner ear, these cells divide,16 release inflammatory mediators, and set in motion events that lead to cellular proliferation and eventually osteoneogenesis (Figure 4).6 Shortly after entering the cochlea, hearing loss occurs.17 Endolymphatic hydrops often accompanies these end-stage reactions (see Figure 4). Of note, after the single inoculation of antigen, cells may continue to be stimulated, undergoing cell division for up to 6 weeks.18

Clinical Studies

In 1979, McCabe first brought attention to a possible discrete clinical entity when he presented a series of patients with bilateral, progressive hearing loss showing improvement following
treatment with corticosteroids. Although others had over the years described patients with ear-related illnesses associated with systemic immune disorders, none had collected such a large series or speculated that these patients might have an organ-specific illness. Since that time, autoimmunity has been proposed as a cause for other inner ear disorders, including Meniere disease, sudden sensorineural hearing loss (SNHL), and acute vertigo. A relationship between inner ear disorders and systemic autoimmune disease has also been documented. A number of systemic autoimmune diseases, such as polyarteritis nodosa, systemic lupus erythematosus (SLE), relapsing polychondritis, ulcerative colitis, and Wegener granulomatosis, include auditory and vestibular symptoms. Moreover, some patients with suspected AIED have either presented with or later developed systemic autoimmune diseases.

Unlike other organs and tissues, the inner ear is not amenable to biopsy for the expressed intent of investigating the underlying immunopathogenesis of purported autoimmune disorders affecting it. What little histopathology has been published from patients with suspected AIED shows fibrosis and/or bone deposition in the labyrinth, consistent with the late sequelae of inflammation. Specific immune reactivity against inner ear antigens is often detected in patients with suspected AIED, but the results vary. Lymphocyte migration assays using inner ear tissue with suspected AIED, but the results vary. More promising results have been obtained with Western blotting. Significantly, more patients with suspected AIED show reactivity against a 68 kD antigen (Figure 5) than do match normal-hearing or disease. Because of the relative rarity of this condition and its recent recognition, as noted above, very few temporal bones with a diagnosis of AIED have been evaluated. More studies have assessed

**Epidemiology**

AIED is a rare disorder, but the true incidence remains unknown. Although patients of all ages have been described with the disorder, the disease most commonly affects middle-aged adults. Men and women are affected at equal rates. No racial predilection has been identified, although the majority of reports are in Caucasian individuals. A monoclonal antibody raised against cochlear tissues of approximately 68 kD that specifically reacts with supporting cells in the organ of Corti has been shown to produce high frequency hearing loss in mice carrying the hybridoma. More recently, Nair and colleagues infused this antibody into the cochlear perilymph using an osmotic minipump. After 13 days, an approximately 20 dB hearing loss developed, associated with minor losses of hair cells.

To explore the origin of lymphocytes in the region of the endolymphatic sac and the reaction of T cells to self-antigens in the inner ear, Iwai and colleagues used a model of graft-versus-host disease. T cells from C57BL/6 mice injected into the systemic circulation of BALB/c mice infiltrated and proliferated in the perisaccular region surrounding the endolymphatic sac, but not into other regions of the inner ear. These
findings confirm the role of the endolymphatic sac region in mediating immunity in the inner ear, as well as the communication of the normal sac with circulating lymphocytes. This provides an additional foundation for autoimmunity as an etiology in disorders involving the sac, such as Ménière disease.

Animal models have also been used to study the relationship between systemic autoimmune disease and the inner ear. The MRL-Fas1pr mouse is used as a model of SLE owing to the accumulation of autoreactive T cells normally eliminated by Fas-mediated apoptosis. This model also displays progressive hearing loss. Rückenstein and colleagues found that the most striking inner ear pathology in this model was observed in the stria vascularis, with progressive, hydropic degeneration of intermediate cells, consistent with the stria pathology observed in human SLE temporal bones as described above. In addition, Rückenstein and Hu observed the deposition of both complement-fixing and noncomplement-fixing antibodies in the stria vascularis and, to a lesser extent, in other structures. All antibodies were bound to the capillary walls and were not associated with signs of inflammation. The same group found that systemic treatment with dexamethasone suppressed antibody deposition within the stria and other structures of the inner ear. However, the treatment failed to suppress strial degeneration and hearing loss, suggesting that perhaps the hearing loss seen in these animals had a genetic basis. In contrast to this result, Wobi and colleagues found that systemic prednisolone treatment protected hearing in MRL-Fas1pr mice. The Palmerston-North mouse is also employed as a model of SLE with hearing loss. These animals develop abnormal mineralization of connective tissue in the region of the eighth nerve root within the modiolus. However, there is no deposition of antibody in or cellular infiltration of the cochlea in this strain. As better imaging becomes available, the localization of inflammatory processes to specific regions of the inner ear should become possible. Having this information will certainly improve our diagnostic capability as well as our knowledge of the basic pathogenesis of this disorder.

Diagnosis

Diagnosis of AIED is still problematic. There is no universally accepted set of diagnostic criteria or diagnostic test for a condition that appears to have several independent causes. In general, in all cases of idiopathic, rapidly progressive, bilateral hearing loss, AIED should be suspected. However, there is no doubt that involvement of the second ear may occur months or even years after presentation of symptoms in the first ear. Hearing loss may be manifested as either diminished hearing acuity, decreased discrimination, or both, and may fluctuate over time. In bilateral Ménière disease, with its triad of vestibular dysfunction, low-tone, fluctuant hearing loss, and tinnitus, AIED should also be suspected, especially when the second ear becomes affected within a short period of time. Aside from an empiric trial with high-dose corticosteroids showing improved inner ear function, Western blot assays are currently the most widely used category of diagnostic test for AIED. The initial assays used for this purpose were based on proteins extracted from bovine inner ear tissue, and inner ear extracts are still used. Reactivity to an approximately 68 kD antigen was detected in a significant proportion of patients with AIED and Ménière disease. This, or an antigen with shared epitopes, was later shown to be present in kidney and to be a member of the heat shock protein (HSP) family. Reactivity against inner ear antigens of other molecular weights, especially in the 45, 30, and 20 kD ranges, has frequently been reported. Few of these other antigens have been characterized or found to be present in statistically significant proportions of hearing loss versus control populations. For example, studies examining the antigenic profile of inner ear tissues consistently demonstrate a multitude of antigens against which human sera react; however, these bands seen on Western blot failed to reach significance when carefully matched against controls. Immuno-reactivity to a 30 kD antigen has been associated with myelin protein P0. The 68 kD antigen has been associated with HSP 70, and immuno-reactivity against the bovine HSP 70 (bHSP 70) has been found to be correlated with AIED. However, preabsorption with bHSP 70 does not remove all reactivity to the 68 kD inner ear antigen, and immunization of animals with HSP 70 does not appear to produce hearing loss. Antibodies against other antigens have also been implicated. Several investigators have reported that immuno-reactivity to inner ear proteins with molecular weights in the 42 to 45 kD range is also positively correlated with AIED, although with a lower level of specificity than the 68 kD protein or HSP 70. For example, Atlas and colleagues found that positive Western blots against 68 and/or 42 to 45 kD inner ear proteins were present in significantly more patients with Ménière disease than in normal controls, whereas reactivity against 35 to 36 and 20 kD proteins was not different in the two groups. Moreover, reactivity appeared to be related to disease state in that patients with active disease (at least one episode of vertigo within 1 month) were significantly more likely to be positive than those with inactive disease. Other specific antigen targets have also been studied. Modugno and colleagues observed antithyroid antibodies in 27% of patients with benign paroxysmal positional vertigo, significantly more than were observed in a group of normal controls. Using immunoblotting and enzyme-linked immunosorbent assay, Yamawaki and colleagues observed antibodies against the sulfoglucuronosyl glycolipid SGLPG, but not SGPG, in 37 of 74 patients with AIED, as compared with only 3 of 56 pathologic and 2 of 28 healthy controls. In a negative result, Lopez-Gonzalez and colleagues found that anti-type II collagen antibodies and stimulation indexes were unrelated to idiopathic or SNHL or M Ménière disease.

In one of the few prospective studies attempting to correlate the significance of Western blotting for the 68 kD antigen with response to treatment, Moscicki and colleagues found that a positive result for 68 kD was associated with a 75% rate of hearing improvement with corticosteroids, compared with 18% of patients who were Western blot negative. In this study, disease activity was an important predictor of a positive antibody response and response to treatment. Eighty-nine percent of patients with active bilateral progressive hearing loss had a positive 68 kD antibody, whereas patients with inactive disease were uniformly negative.

A number of other studies have focused on the diagnostic utility of antibodies against HSP 70. In a retrospective case series, Hirose and colleagues evaluated a variety of assays for systemic autoimmune disease, as well as a Western blot assay against bHSP 70, for their utility in predicting the responsiveness of rapidly progressive SNHL to corticosteroids. A gain in this study, positivity in the HSP 70 blot assay was the best predictor of corticosteroid responsiveness in AIED. Although the sensitivity was low (42%), the specificity was 90% and the positive predictive value was 91%. Bloch and colleagues tested the serum of 52 patients with bilateral, progressive, idiopathic hearing loss or M Ménière disease in Western blot assays to recombinant bHSP 70 and recombinant human HSP 70. Reactivity against recombinant bHSP 70 was observed in 40 of 52 patients. Only 12 also reacted to recombinant human HSP 70. They also tested the positive sera against a panel of recombinant peptide fragments of bHSP 70. Reactivity was observed to widely separate epitopes. However, most positive patients reacted preferentially or only to an amino acid segment from the carboxy terminus of recombinant bovine, aa 427–461. Within this dominant epitope, the bovine peptide differs from the corresponding human peptide by only one amino acid. Western blotting has also been used to explore the possibility that a subset of patients has M Ménière disease with an immunologic basis. Gottschlich and colleagues demonstrated that 32% of patients with M Ménière disease were anti-68 kD positive. Rauch and colleagues reported that anti-HSP 70 antibodies were found in 47% of patients with M Ménière disease and that level increased to 58% when the disease was bilateral. Recently, however, Rauch and colleagues had a similar level of sensitivity in 134 patients with M Ménière disease but a much lower level of specificity owing to a relatively high level of reactivity in blood donor control sera. This high rate of positivity in the control serum was unexplained and contradicts the previously low level of positives in control sera as well as those high rates of positivity reported by others. Several serum samples revealed no correlation between antibody level and the clinical course of the disease. These observations led them to question the clinical utility of the HSP 70 assay in M Ménière disease. The answer to whether
a subset of patients with classic Ménière disease is immune mediated is currently unclear.

A number of investigators have reacted patient sera against tissue sections to detect immunoreactivity against inner ear antigens. This technique has been used on a research basis since the 1980s, when Arnold and colleagues reported a high degree of labeling within the cochlea with patient serum. Bacher and colleagues detected immunoreactivity to rat cochlear sections in 14 of 15 patients showing progressive or sudden hearing loss in the cochlea opposite an ear deafened by trauma or inflammation. Using rat cryosections of the inner ear, A Barbos and colleagues detected antibodies against vestibular sensory epithelia in 8 of 12 patients with idiopathic bilateral vestibular pathology as compared with 1 of 22 healthy controls and 0 of 6 patients with systemic autoimmune disease. Ottaviani and colleagues detected immunoreactivity against endothelial cells using sections of rat kidney tissue in 8 of 15 patients with sudden hearing loss, as compared with 2 of 14 normal controls. Helmcchen and colleagues observed positive, but low, levels of immunoreactivity against inner ear sections using serum from patients with Cogan syndrome. However, unlike anticostral antibodies, the anticochlear immunoreactivity levels were not correlated with disease stage.

Classification of Autoimmune Inner Ear Disease

During the quarter century since McCabe’s article on AIED was published, many patients have been diagnosed and treated for rapidly progressive SNHL and many have had their hearing maintained or even improved with treatment. As a result of the growing experience with patients with corticosteroid sensitive hearing loss, a pattern has begun to emerge that warrants a classification scheme to better sort out patients as they present with inner ear dysfunction. Although the following classification scheme is intended specifically for that purpose, it is likely that over the next few years it will be further refined:

Type 1: Organ (Ear) specific
- Rapidly progressive bilateral SNHL
- All age ranges, although middle age is most common
- No other clinical evidence of systemic autoimmune disease
- Positive Otoblot (Western blot 68 kD or HSP 70) Negative serologic studies (antinuclear antibody (ANA), erythrocyte sedimentation rate, rheumatoid factor (RF), C1q binding assay, etc)
- Greater than 50% response rate to high-dose corticosteroids

Type 2: Rapidly progressive bilateral sensorineural hearing loss with systemic autoimmune disease
- Rapidly progressive bilateral SNHL
- Hearing loss often greatest with flare of autoimmune condition
- Other autoimmune condition is present (e.g., SLE, ulcerative colitis, polyarteritis nodosa, vasculitis, rheumatoid arthritis, or Sjögren syndrome)
- Otoblot may be positive or negative
- Serologic studies will be positive in accordance with the illness (e.g., ANA, high titers, RF positive, and circulating immune complexes)
- Corticosteroid responsive and may be managed with targeted therapies for underlying illness

Type 3: Immune-mediated Ménière disease
- Bilateral, fluctuating SNHL with vestibular symptoms that may predominate
- Subset of patients with delayed contralateral endolymphatic hydrops or recent instability of better-hearing ear in a patient with burned out Ménière disease
- Otoblot positive 37 to 58%; may show presence of circulating immune complexes
- Corticosteroid responsive; may require long-term immunosuppression owing to relapses

Type 4: Rapidly progressive bilateral sensorineural hearing loss with associated inflammatory disease (chronic otitis media, Lyme disease, otosclerosis, serum sickness)
- Evidence of profound drop in hearing with long-standing chronic otitis media
- May show inflammation of the tympanic membrane, with perforations
- Hearing loss progresses despite treatment of the infectious agent (treponemal or rickettsial)
- Otoblot negative; serologic tests for the underlying disease may be positive; patient should be evaluated for granulomatous disease and vasculitis by biopsy if tissue is available
- Corticosteroid responsive and may require long-term immunosuppression
- Serum sickness has been reported after vaccinations, although anecdotal

Type 5: Cogan syndrome
- Sudden onset of interstitial keratitis and severe vestibulolauditory dysfunction
- Otoblot negative for 68 kD but positive for 55 kD antigen
- Responds to high-dose corticosteroids, although becomes resistant over long term

Type 6: Autoimmune inner ear disease-like
- Young patients with idiopathic, rapidly progressive, bilateral SNHL leading to deafness
- Severe ear pain, pressure, and tinnitus
- Otoblot and all serology negative
- May have an unrelated, nonspecific inflammatory event that initiates ear disease
- Not responsive to immunosuppressive drugs, although they are tried

Treatment

Once a diagnosis of AIED is established or considered highly presumptive, high-dose prednisone is the mainstay of treatment for this condition. Early institution of 60 mg of prednisone daily for a month is now widely used, as short-term or lower-dose long-term therapy has either been ineffective or fraught with the risk of relapse. Prednisone is then tapered slowly if a positive response to therapy is obtained. If, during the taper, hearing suddenly falls, reinstatement of high-dose prednisone is indicated. One sensitive predictor of imminent relapse can be the appearance of loud tinnitus in one or both ears. If patients show corticosteroid responsiveness but attempts at taper result in relapse, the addition of a cytotoxic drug should be considered. Methylprednisolone, held premised initially; but, in an exhaustive multi-institutional study, it failed to be effective in maintaining hearing improvement achieved with prednisone therapy. Cyclophosphamide (Cytoxan) remains an effective agent, but its side effects are prohibitive. For patients with severe hearing losses, positive 68 kD Western blots, and nonresponsiveness to prednisone therapy, consideration should be given to a trial of cyclophosphamide. At oral doses of 1 to 2 mg per day taken each morning with liberal amounts of fluid, the risk of hemorrhagic cystitis or drug effects on the bladder can be minimized. The patient should be monitored closely for toxicity with complete blood counts, platelets, blood urea nitrogen, creatinine, liver function tests, and urinalysis. Cyclophosphamide should not be administered to children, and the risk of permanent sterility should be outlined.

If, on the other hand, no response to high-dose prednisone is achieved, and the patient is 68 kD Western blot negative, it may be futile to continue potentially toxic drugs, with little evidence for AIED as the cause. As this field continues to evolve, there are, however, no hard and fast rules, and a practitioner may be justified in trying cytotoxic drugs on an empirical basis because unrelenting progressive deafness is a serious handicap for a previously normal hearing person. Luetjen recommended plasmapheresis for difficult to manage patients, and this can be a useful adjunct to the above-mentioned immunosuppressive drugs. Based on animal studies, tumor necrosis factor (TNF) blocking agents are being investigated for efficacy in treating AIED. Etanercept (Enbrel) was evaluated in a placebo controlled study but found to be no better than placebo for the treatment of AIED. Other TNF blocking agents such as infliximab (Remicade) and adalimumab (Humira) may prove efficacious but await clinical evaluation. Rituximab (Rituxan), an antibody against selected B cells, is currently undergoing a clinical trial at the University of California, San Diego for its efficacy in treating patients with AIED.

Parnes and colleagues noted that local corticosteroids appear to be more effective in the treatment of other autoimmune disorders, such as corneal inflammation owing to Cogan syndrome. They, therefore, investigated the pharmacokinetics of hydrocortisone, methylprednisolone, and dexamethasone in perilymph and endolymph after oral, intravenous, or intratympanic administration. Dexamethasone was found to be largely excluded from the cochlea by the
blood-labyrinthine barrier. Both methylprednisolone and hydrocortisone reached inner ear fluid after systemic administration, attenuated presumably by the blood-labyrinthine barrier. Much higher levels of all three drugs were observed in cochlear fluid after intratympanic administration, with rapid declines over a 6- to 24-hour period. Similar results were noted by Chandrasekhar and colleagues. Parnes and colleagues also reported that repeated intratympanic administration of corticosteroids in a small series of patients with hearing loss of diverse origins was followed by improvement in some patients, but no control group was included. In contrast, Yang and colleagues found that local immunosuppression had no effect on experimental immune-mediated SNHL in an animal model. It should be noted that local effects are not, of course, the only basis for the therapeutic efficacy of immunosuppressants. By decreasing peripheral blood leukocytes, these agents reduce the population of cells that can be recruited to the inner ear to participate in immune and inflammatory damage. An experiment designed to prevent entry of cells into the cochlea using antibodies to ICAM-1 did show a reduced number of infiltrated inflammatory cells in the cochlea following antigen challenge. Although the inflammation was not entirely prevented, such a strategy may be worth pursuing. An analogous situation exists for ocular immune disorders such as uveitis. Despite the greater accessibility of the eye to topical drugs than the inner ear, ophthalmologists would never consider local therapy in lieu of high-dose corticosteroids for these disorders. Perhaps a lesson taken from their experience might lessen the enthusiasm that currently exists for treatment solely by local middle ear corticosteroid instillation.

OTHER AUTOIMMUNE DISEASES WITH INNER EAR INVOLVEMENT

A number of systemic autoimmune conditions have been associated with inner ear damage (Table 1). Although the majority of these conditions have vasculitides in their pathogenesis, other conditions involving connective tissue, bowel, and exocrine glands have been associated with AIED.

*Requires inner ear involvement for diagnosis.

Table 1: Systemic Autoimmune Diseases with Inner Ear Involvement

Cogan Syndrome

The first reports what is now known as Cogan syndrome came from Organ and Baumgartner, who described a patient with nonsyphilitic interstitial keratitis and audiovestibular dysfunction. However, Cogan went on to describe four patients with the same presentation. This disease is now commonly referred to as Cogan syndrome. Cogan syndrome is a rare autoimmune disease of young adults with a peak incidence in the third decade of life. It affects males and females equally with a strong predilection for Caucasians.

Cogan syndrome presents with aural, ocular, and systemic features. Patients often have constitutional symptoms as the first sign of the disease, which include headache, malaise, and myalgias. Other systemic features variably present include gastrointestinal involvement (bleeding), cardiac involvement (aortic insufficiency), renal involvement (proteinuria, hematuria), respiratory involvement (pleural effusion, cough, dyspnea), and skin involvement (nodules, rash). Patients frequently report a preceding upper respiratory tract infection. In the majority of patients, aural symptoms precede ocular symptoms. Tinnitus comes first, followed by progressive fluctuating SNHL in one or both ears. If the disease initially presents with unilateral involvement, the condition quickly progresses within days to involve both ears. Ocular symptoms include photophobia, tearing, redness and eye pain, all of which are usually bilateral. The classic finding in Cogan syndrome is interstitial keratitis. A critical criterion is that the patient does not have syphilis, an infection which can lead to an identical presentation to that of Cogan syndrome.

Diagnosis is accomplished with the clinical picture as delineated above and a negative test for syphilis. An audiologic assessment will document the characteristic SNHL. An ophthalmologic examination including a slit lamp examination is required to identify interstitial keratitis. Laboratory testing may reveal an elevated erythrocyte sedimentation rate, leukocytosis, or anemia.

Treatment is with high-dose corticosteroids. Without treatment, the hearing loss will progress over several months, leaving the majority of patients deaf. However, the prognosis for hearing recovery is quite good if aggressive corticosteroid therapy is initiated early in the disease. Vestibular symptoms are more difficult to manage and are often refractory to treatment with corticosteroids. Ophthalmic symptoms often respond to corticosteroid drops. If the patient does not respond to corticosteroid treatment, consideration to second line agents, such as cyclophosphamide or methotrexate, should be given.

Susac Syndrome

Susac syndrome was first described by John Susac in 1979. It has also been termed SICRET (infarctions of cochlear, retinal, and encephalopathic tissue) and RED-M (retinopathy, encephalopathy, deafness, and associated microangiopathy). It is an autoimmune microangiopathy of unknown cause that typically affects the small blood vessels of the retina, cochlea, and brain and results in a triad of encephalopathy, branch retinal artery occlusions, and hearing loss. Susac syndrome affects women three times as often as men, with an age range of 8 to 59 years. No racial predilection has been identified. It is considered a rare disorder, with fewer than 100 case reports in the world literature.

The clinical course is characterized by episodic exacerbations of hearing loss, encephalopathy, and/or visual loss. Symptoms persist for several years, but this is highly variable. Headaches often precede any organic brain impairment, which can include confusion, memory loss, psychiatric disturbances, or seizures. Hearing loss is typically acute, bilateral, and asymmetric. The hearing loss is sensorineural and usually involves the lower frequencies, although high-frequency losses have been documented. The hearing loss fluctuates, and some recover without residual deficits while others are left with profound hearing loss. Tinnitus often precedes or accompanies the hearing loss. Vestibular symptoms are also often present and include vertigo, ataxia, and gait impairment. Visual loss is usually mild and transient in nature.

Diagnosis is based on the clinical picture, ophtalmologic evaluation, laboratory testing, and magnetic resonance imaging. Patients require a fundoscopic examination to evaluate for branch retinal artery occlusions. The retinopathy can be extensive or occult, confounding diagnosis. Retinal fluorescein angiography is extremely useful in demonstrating branch retinal artery occlusions. Magnetic resonance imaging in Susac syndrome always reveals corpus callosum involvement. White matter lesions are typically small and multifocal and frequently enhance in the acute stage. Deep gray matter involvement can also be seen and is reported in 70% of cases. Lesions are typically multiple, small, hyperintense foci on T2 images that enhance with contrast in both the white and gray matter. There is no correlation between the lesions evident on magnetic resonance imaging and the extent of the clinical encephalopathy. Cerebral arteriography findings are almost always normal, as the involved precapillary arteries are beyond the resolution of the arteriogram.

Biopsies of lesions have shown small artery sclerosis with a mononuclear perivascular infiltrate and microinfarctions, but without necrotizing vasculitis. Other laboratory testing is nonspecific. The cerebrospinal fluid may show an elevated protein level with mild pleocytosis. No coagulopathy has been identified.

Therapy usually begins with antiplatelet agents such as aspirin, as well as calcium channel blockers such as nimodipine. If the symptoms progress, high-dose methylprednisolone is employed. Failure of corticosteroids usually leads to initiation of treatment with cyclophosphamide. A ticagrelor has no role in treatment for the disorder. Some investigators have
advocated treatment with immunoglobulins as well as plasmapheresis. The prognosis is variable, but to date no deaths directly attributable to Sjögren syndrome have been documented. One case has had recurrence after remission.

Although both Cogan syndrome and Sjögren syndrome require inner ear manifestations as one of the diagnostic criteria, the remaining systemic autoimmune conditions have only occasional inner ear involvement. Many of these conditions share vasculitis as their underlying pathology.

**Wegener Granulomatosis**

Wegener granulomatosis is a vasculitis of small blood vessels, which leads to pulmonary, renal, and aural manifestations. Patients often present with cough and hemoptysis. The kidney involvement is glomerulonephritis, which leads to hematuria and proteinuria. Middle ear effusions are common from granulomatous involvement of the eustachian tubes or the middle ear space. Granulomatous involvement of the middle ear space can also result in chronic otorrhea with tympanic membrane perforation, conductive hearing loss due to ossicular chain involvement, and rarely facial paralysis. AIED is also occasionally seen in the disorder, with SNHL found in 8% of patients in one large study. Although the disease is fatal if untreated, the prognosis is good with appropriate therapy. Cyclophosphamide along with prednisone are standard therapy, with the corticosteroid discontinued after adequate control of the disease, whereas the cyclophosphamide is continued for 1 year. Patients with SNHL also benefit from this therapy, with many demonstrating an improvement in hearing levels.

**Temporal Arteritis**

Temporal arteritis, also known as giant cell or cranial arteritis, is another vasculitis which may produce inner ear dysfunction. Temporal arteritis is a vasculitis of large vessels with a predilection for the superficial temporal artery. Typical presentation is in an elderly patient with headaches and pain in the jaw when chewing. Untreated patients have a substantial risk of developing blindness. AIED occurs in 12% of patients diagnosed with temporal arteritis and is readily treatable with an oral corticosteroid.

**Behçet Disease**

Behçet disease is a vasculitis which results in recurrent aphthous ulcers, genital lesions, ocular injury, and skin eruptions. It often occurs in young adults. Inner ear manifestations are common. Two recent studies demonstrated a high proportion of SNHL (32 to 55%) as well as vestibulopathy (30%). Corticosteroids are useful in the treatment of AIED associated with Behçet disease. Remicade (infliximab) has had excellent results in maintaining remission in Behçet disease, but has not been evaluated for its efficacy for the treatment of AIED in the disorder.

**Systemic Lupus Erythematosus**

SLE is an autoimmune condition, which results in both direct cytotoxic cell damage and vasculitis from immune complex depositions. Although the disease is diverse in its manifestations, the most common presentation includes fever, anorexia, arthralgias, alopecia, malar rash, and visceral organ involvement, most often of the kidney. It most commonly involves young women, with a racial predilection for African Americans, Hispanics, and Asians. Patients with SLE who have an increased incidence of AIED, and those with antiphospholipid antibodies have an even higher risk to have SNHL, presumably from vascular occlusion. Treatment for AIED related to the disorder is with corticosteroids, but patients with antiphospholipid antibodies may also benefit from anticoagulation.

**Relapsing Polychondritis**

Relapsing polychondritis is an autoimmune disorder directed against cartilage. Typically, the auricle, nose, and trachea are involved, although joints can also be affected. Ocular involvement is not uncommon. A key feature of the disorder is that the lobule of the auricle is spared from the inflammatory process, as it possesses no cartilage. AIED is frequently present and can be manifested by either sudden SNHL or a slow gradual decline in hearing. The hearing loss may be unilateral or bilateral and varies in severity. Vestibular dysfunction, such as vertigo, ataxia, or disequilibrium, is commonly present. The treatment for AIED related to this disorder is a corticosteroid.

**Rheumatoid Arthritis**

Rheumatoid arthritis is an autoimmune disorder directed at the synovial tissues and most commonly seen in young women. Presentation is with joint pain along with anorexia, fever, and malaise. Although the ossicular joints can be involved in the disorder, leading to a conductive hearing loss, a high incidence of SNHL has been identified in patients with rheumatoid arthritis. The majority of these patients have a slowly progressive bilateral SNHL. Corticosteroid treatment is reserved for patients with sudden or fluctuating SNHL.

**Scleroderma**

Scleroderma is an autoimmune disorder directed against connective tissue, as well as capillaries. It most commonly involves women in their fifth decade of life. As the skin sustains injury by the autoimmune process, it becomes thickened and fibrosed. Raynaud phenomenon is quite common. SNHL has been identified in 20% of patients with scleroderma in a large, prospective study. Corticosteroids are not considered effective in the disorder and have not been evaluated in their efficacy for treating AIED related to the disease. Only cyclophosphamide has been evaluated for the treatment of SNHL in this disorder, with highly variable results.

**Sjögren Syndrome**

Sjögren syndrome is an autoimmune disorder directed against the exocrine glands. The salivary and lacrimal glands are primarily involved, and patients consequently present with dry mouth (xerostomia) and dry eyes (xerophthalmia). The lack of saliva can lead to dysphagia and dental caries, whereas the lack of tears can lead to corneal abrasions and loss of visual acuity. A 20% incidence of SNHL has been found in this disorder in two large studies. Currently, corticosteroids and other immunosuppressants have not been proven efficacious in treating AIED related to Sjögren syndrome.

**Inflammatory Bowel Disease**

Inflammatory bowel disease encompasses ulcerative colitis as well as Crohn disease. Both conditions involve an autoimmune injury to the bowel mucosa, which leads to bloody diarrhea, abdominal pain, and anorexia. Presentation is usually in young adults and there is a slight female predominance. Sudden and slowly progressive SNHL vestibulopathy, as well as, have been identified in patients with inflammatory bowel disease. High-dose corticosteroids are the treatment of choice for AIED related to inflammatory bowel disease. Infliximab (Remicade) is a new anti-TNF-α agent which holds promise in the treatment of inflammatory bowel disease as well as its associated AIED.

**SUMMARY**

Debate continues as to whether AIED exists as a separate entity. Some authors prefer to refer to this condition as immune-mediated inner ear disease. Clearly, the evidence for specific autoimmunity is indirect. Hearing and vestibular problems that are diagnosed as autoimmune in origin are often responsive to corticosteroids. Although this suggests that the condition involves inflammation, one cannot infer the involvement of specific immunity. The fact that inner ear disease is often present in systemic autoimmune disorders provides strong evidence that autoimmune processes can damage the labyrinth, but does not speak to the issue of organ-specific disease. Animal models of hearing loss and/or vestibular dysfunction secondary to immunization with inner ear antigens provide stronger evidence of specific autoimmunity.

AIED is difficult to diagnose. Although it is generally agreed that the condition should be bilateral and rapidly progressive, the involvement of the second ear may take months or even years to occur. Although rapidly progressing conditions are more readily held to be autoimmune, AIED is increasingly considered as a potential cause of Ménière disease and as a less likely cause of sudden hearing loss. Improved diagnostic tests are clearly required. No one test appears to be positive in more than 30 to 40% of patients who otherwise fit the criteria for autoimmune disease. One possible explanation for this is that rapidly
progressive SNHL has a number of different causes, including autoimmune, viral, genetic, developmental, vascular, and perhaps metabolic. Many of these cannot be separated by their presentation, therefore, it would not be unusual or unexpected for many of these patients to have negative antibody testing, and some who were not autoimmune, for example, those with a viral origin, might even improve with corticosteroids. A further possibility is that autoimmune exists to a variety of inner ear antigens. Given the variety of autoimmune disorders that can affect the inner ear, the variety of antigens with which sera from patients with AIED will react, and the fact that immunization with a variety of proteins can lead to hearing loss in animal models, this would appear to be a strong possibility.

The usefulness of Western blotting for antibodies directed against the 68 kD or HSP 70 antigen as diagnostic assay seems clear, although there is little evidence to support an etiologic role for HSP 70. It is possible that HSP 70 shares one or more epitopes with an inner ear antigen, although reactivity to widely variable epitopes of HSP 70 argues against this. Alternatively, HSP 70 immunoreactivity may all be a well-correlated epiphenomenon, perhaps produced by immunization of self-proteins during inflammatory responses arising from other causes. Lastly, initial studies with serum tested by Western blotting were accompanied with the use of 68 kD inner ear tissue as the target antigen. After the recognition that HSP 70 showed results similar to 68 kD by several investigators, a number of groups have adopted HSP 70 as the target for immunologic testing. In fact, this may be the wrong approach if HSP 70 merely shares epitopes with but is not the actual antigen in 68 kD inner ear immunoreactivity. Future studies will certainly improve our knowledge of the actual antigenic target(s) involved in AIED. Despite uncertainty over etiology and difficulties in diagnosis, this condition is frequently responsive to treatment with immunosuppressive drugs. Since there are few of the HLAs that can be treated other than symptomatically, AIED represents a unique opportunity to reverse SNHL and vestibular disorders. For this reason alone, the diagnosis should be considered when symptoms are appropriate, and both clinical and basic research on this condition is warranted.

INTRODUCTION

Dizziness is one of the most frequent symptoms prompting referral to an otolaryngologist–head and neck surgeon. Dizziness, however, takes many forms, and it is up to the otolaryngologist–head and neck surgeon to decipher the nature of the dizziness and whether it represents an otologic pathology or the patient requires evaluation by other specialties, such as neurology, cardiology, or even psychiatry. If the dizziness is otologic in nature, it is the role of the otolaryngologist to determine the cause of the disorder and the appropriate treatment. One of the most important components in the evaluation of dizziness is the patient’s history.

It is critical in the history taking process to understand what the patient means by the term “dizzy.” Patients will use the term “dizzy” to describe lightheadedness, wooziness, fatigue, disconnectedness, disequilibrium, imbalance, as well as vertigo. Vertigo is the sensation of inappropriate motion, most commonly rotational or spinning in nature, but also applicable to sensations of being pulled or pushed in one direction. According to the Committee on Hearing and Equilibrium of the American Academy of Otolaryngology–Head and Neck Surgery, vertigo is the sensation of motion when no motion is occurring relative to Earth’s gravity.2 Vertigo may be perceived by the patient as “the world moving around me” or as “spinning inside my head.” Some patients may not relate a sensation of spinning when recounting episodes of vertigo, but a history of intensity such that walking was not feasible should be considered significant. Vertigo is the most common sensation referable to otologic forms of dizziness, and it is thus important to distinguish vertigo from the other common uses of the word dizzy.

It is also important in the history taking process to determine the temporal pattern of a patient’s dizziness. That is, does the dizziness last for seconds, minutes, hours, or days; does it occur daily, weekly or at longer intervals; was it a single episode or multiple similar attacks? Also, the clinician must piece apart an episode of dizziness and determine whether there was a few seconds of vertigo with a subsequent hour of malaise or a full hour of vertigo. The most useful information from the patient’s history that will assist in determining the cause of dizziness will frequently come from answers to the following 5 questions: (1) Does the patient have vertigo? (2) Are the patient’s symptoms episodic or continuous? (3) If the symptoms are episodic, what is their duration? (4) Are the symptoms positional in character? and (5) Are there associated auditory symptoms? By carefully questioning and re-questioning the patient an accurate picture of the symptoms can be developed which will help to distinguish attacks of Menière disease from those of vestibular neuritis, benign paroxysmal positional vertigo (BPPV), vestibular migraine or superior semicircular canal dehiscence. This chapter will focus on these disorders and describe the typical presentations, characteristic features, and pitfalls in diagnosis and management.

VESTIBULAR PHYSIOLOGY

It is not the purpose of this chapter to review vestibular physiology (see Chapter 4, “Physiology of the Auditory and Vestibular Systems”), but it is important to understand the basic premise of peripheral vestibular input to the central nervous system to understand the disorders discussed. Each vestibular end organ maintains a baseline of spontaneous activity which is transmitted centrally via the vestibular division of the eighth cranial nerve to the vestibular nuclei. The brainstem and cerebellum integrate and compare the input from both sides to determine aspects of head motion including direction, distance, and velocity. Motion in the direction and plane of a semicircular canal causes an increase in activity in that canal along with a decrease of activity in its paired canal on the opposite side. For example, a head rotation to the left, in the horizontal or yaw plane, causes an increase in the discharge rate of vestibular-nerve afferents innervating the left horizontal canal and a decrease in the discharge rate of afferents innervating the right horizontal canal. The difference in activity between the ears is centrally computed, and the eyes move to the right the appropriate distance. The purpose of the vestibulo-ocular reflex (VOR) which is controlled by this neural information arising in the labyrinth is to maintain the stability of images on the retina during head movements. In so doing, the VOR enables us to maintain steady fixation on objects even during head movements.

Sudden changes in unilateral vestibular activity will likewise provoke eye movements according to the canal and side affected. If the change in activity is nonphysiologic, such as loss of unilateral function due to vestibular neuritis, the brain receives mismatched input. That is, there is abnormal input from the affected canal suggesting head motion, but the input from the rest of the body is inconsistent with actual motion. This asymmetry in activity from the 2 labyrinths results in nystagmus: a rapid, to-and-fro motion of the eyes with slow and fast components. The slow component (sometimes referred to as slow phase) represents the eye movement elicited by the VOR. The fast component (the direction of nystagmus) represents a correction for this erroneous movement of the eye. For example, loss of neural activity in the right labyrinth is interpreted as a head movement to the left because of the asymmetry in resting rate between the two sides with activity in the left horizontal canal being much higher than that in the right horizontal canal. The VOR that results from such a pattern of activation consists of an eye movement reflective of the asymmetry in resting rate and in this case causes a slow phase to the right. The fast component of nystagmus to the left occurs because of the limit of the oculomotor range such that a resetting movement is required to bring the eye back toward the center. The direction of the nystagmus is named with respect to the fast component. This nystagmus is visible to the observer and is experienced by the patient as repetitive movements of the visual field. The nystagmus due to asymmetries in neural activity between the two labyrinths typically displays three cardinal features: (1) it is a horizontal–torsional nystagmus with fast components that beat toward the...
side of increased activity, (2) the nystagmus can be reduced when the patient fixates on an object in the external environment, and (3) the nystagmus increases in amplitude when the patient looks in the direction of the fast component and is decreased when the patient looks in the direction of the slow component.

MENIÈRE DISEASE

The link between symptoms of vertigo and imbalance and the inner ear was first established in 1861 by Prosper Menière although the patients that he described may not have had the syndrome that is currently known by his name. Menière syndrome can occur following injuries to the labyrinth as can occur following measles or rubella infections. When the symptom complex occurs without any known underlying cause, it is frequently referred to as Menière disease. Hallpike and Cairns, in 1938, clarified the pathophysiology of this disorder and demonstrated “endolympathic hydrops” as an associated feature of Menière disease. Often overlooked is work by Portmann a decade earlier who proposed the endolympathic sac as a cause of Menière disease and even performed the first endolympathic sac decompression in humans. Currently, Menière disease is recognized as a primary otologic disorder characterized by fluctuating hearing loss, episodic vertigo, tinnitus and aural fullness. Unfortunately, the nuances that differentiate Menière disease from other otologic disorders are often overlooked and Menière disease is frequently misdiagnosed, almost always being underdiagnosed rather than missed.

The American Academy of Otolaryngology-Head and Neck Surgery Committee on Equilibrium and Balance has issued guidelines for the proper diagnosis and classification of Menière disease. This report defines key properties of the symptoms of Menière disease and establishes diagnostic categories to be used for reporting on Menière disease and to guide treatment decisions. The report stresses the triad of vertigo, hearing loss, and tinnitus in defining the syndrome and recognizes idiopathic endolympathic hydrops as the physiologic cause.

Vertigo is a mandatory symptom in the accurate diagnosis of Menière disease. The vertigo should be rotational, recurrent (ie, 2 or more distinct episodes), last from 20 minutes to 24 hours and occur spontaneously. The latter indicates that there should be no provoking stimulus such as head position or specific activity as occurs with BPPV or superior semicircular canal dehiscence. The vertigo should also occur in the absence of other neurologic symptoms such as parasthesias or visual scotomas, which would be more consistent with vestibular migraine. The vertigo is of such intensity that complaints of associated nausea and/or vomiting are common.

The hearing loss of Menière disease must be sensorineural and typically involves low frequencies. The hearing loss should fluctuate and a stronger case for Menière disease can be made if fluctuations are documented with audiometric testing on at least 1 occasion. The hearing loss is typically unilateral and usually increases in severity with time. Profound hearing loss in affected ear(s) occurs in only 1 to 2% of severely affected patients. Those patients with bilateral profound sensorineural hearing loss as a consequence of Menière disease are benefited from cochlear implantation. Lermoyez, in 1919, described improvement in hearing thresholds in some patients associated with an attack of vertigo.

A common associated feature of hearing loss is a sense of pressure in the ear. Aural fullness is frequently noted in Menière disease and often gets worse leading up to or concurrent with attacks. There may also be baseline aural fullness on the affected side.

The tinnitus of Menière disease is generally low pitched and is often described as a rumble, machine sound, ocean/seashell sound, hum, or low buzzing. It should be distinguished from the common high pitched steady tone tinnitus usually seen with hearing loss due to presbycusis. The tinnitus should localize to one side and be consistent with the suspected side of involvement based upon audiometric and vestibular testing. Commonly the tinnitus increases in volume during, or leading up to, attacks of vertigo. Care should be taken to distinguish this form of tinnitus from the bilateral or “head-buzzing” tinnitus common in migraine sufferers or those with panic attack.

The diagnosis of Menière disease includes possible, probable, definite, and certain categories (Table 1). Possible Menière disease has the vertigo of Menière disease without documented hearing loss or has hearing loss characteristic of the disorder without true episodic vertigo. This category is akin to the outdated terms of cochlear Menière disease or vestibular Menière disease, and other disorders should be excluded. Possible Menière disease is just that, possible, and it should be explained as such to the patient and the initiation of therapy or observation carefully weighed. Often patients with a single episode of vertigo or an unexplained hearing loss will be erroneously labeled with Menière disease and detrimentally carry that diagnosis with them in all future physician contacts. It is the authors’ opinion that “possible Menière disease” is a diagnosis in evolution and follow-up examinations and tests should be used to rule-in or rule-out Menière disease before initiating therapy.

Probable Menière disease is a category in which both cochlear and vestibular signs and symptoms are present. There should be at least 1 episode of vertigo and at least 1 occasion of hearing loss that has been documented with audiometric testing. The vertigo should be a discrete episode of rotation but does not necessarily need to fulfill the strict criterion of duration. The duration of the vertigo should, however, factor into the differential diagnosis to distinguish BPPV, vestibular migraine, vestibular neuritis, or superior semicircular canal dehiscence. Tinnitus or aural pressure in the suspected ear is a diagnostic criterion for probable Menière disease. Other causes for the patient’s symptoms should be excluded.

Definite Menière disease has all the symptomatic features as described above, but the vertigo should be recurrent with discrete, spontaneous episodes lasting greater than 20 minutes. Hearing loss on at least 1 occasion should be documented with audiometric testing. Tinnitus or aural pressure is present in the affected ear and commonly fluctuates in intensity with attacks. Other causes for the symptoms should be excluded. If a patient with this history expires and histopathologic confirmation of endolympathic hydrops is present then this represents a case of certain Menière disease.

Presentation

The patient with Menière disease will most commonly seek treatment for attacks of vertigo. Less often is the patient seeking evaluation for unilateral hearing loss, and uncommon is the patient with Menière disease seeking evaluation for isolated tinnitus. This pattern is principally due to the severity associated with the presentation of each of these aural symptoms. The vertigo of Menière disease is quite intense and typically lasts hours. That it recurs, often without warning, is particularly troublesome to the patient and prompts immediate evaluation. The hearing loss of Menière disease is typically low frequency, moderate, and fluctuating with initial attacks showing recovery to or near baseline. This hearing loss may initially be considered by some physicians to be due to eustachian tube dysfunction or serious otitis media. It is not until such attacks recur or fail to return to baseline that referral and specialty evaluation is initiated. The tinnitus of
Menière disease is usually low frequency and less intrusive than that seen with noise exposure and presbycusis. It is also unusual to develop Menière disease-type tinnitus without hearing loss or vertigo; and, thus, it is rare that tinnitus is the principal presenting complaint. The prevalence of Menière disease is typically between the ages of 40 and 60 years. A slight female to male preponderance (1.3:1) in the prevalence of Menière disease has been reported. Menière disease most commonly presents as a disorder affecting 1 ear. Subsequent involvement of the contralateral ear has been reported to vary between 2 and 78%. Lack of consensus about diagnostic criteria and varying lengths of time over which patients were followed are likely to be responsible for this wide range of values. A typical finding from longitudinal studies is that involvement of both ears occurs in about 20 to 30% of patients. A recent retrospective review of a large series of patients with Menière disease revealed that 11% of patients had bilateral disease at the time of diagnosis with an additional 12% developing Menière disease in the contralateral ear after initial diagnosis in one ear. The average time interval for conversion from unilateral to bilateral Menière disease was 7.6 years.

**Evaluation and Diagnostic Testing**

There is no single test or group of tests that can be used to make the diagnosis of Menière disease. The patient’s history as well as the findings on audiometric testing offer the most useful information.

A significant reduction of the caloric response in the affected ear has been observed in 48 to 74% of patients with Menière disease, and the caloric response is absent in the affected ear in 6 to 11% of patients. When rapid, rotatory accelerations in the planes excitable for each of the 6 semicircular canals were used to test the function in each canal, it was found that responses were most often normal in all canals (including the horizontal canal) even when the caloric response was diminished. This preservation of function when evaluated with the head thrust in comparison to diminished function when evaluated with the caloric test may have one or more of the following explanations. Menière disease may have more adverse effects on the mechanisms controlling low frequency responses (tested by the caloric stimulus) in comparison to responses to stimuli that have high frequency, velocity, and acceleration (tested by the head thrust test). In this case, the low velocity and acceleration of endolymph movement resulting from a caloric stimulus would be insufficient to generate a normal response. However, the high velocity and acceleration of endolymph flow resulting from a head thrust would be adequate to generate a compensatory eye response. A second possibility is that the response to head velocity by vestibular nerve afferents in Menière disease is diminished for stimuli of both high and low frequency amplitudes, but the central gain for inputs of high frequency and amplitude is greater.

Electrocochleography has also been used in the diagnosis of Menière disease although interpretation of the findings remains a topic of controversy. The cochlea responds to repeated presentations of sound with a summating potential (SP) and an action potential (AP). The SP has been reported to be larger and more negative in patients with Menière disease. This is thought to reflect the distention of the basilar membrane into the scala tympani causing an increase in the normal asymmetry of its vibration. The utility of electrocochleography in the identification of Menière disease has been questioned.

**Treatment**

There is no proven cure for Menière disease, and current therapy is directed at reduction of associated symptoms. The optimal treatment should stop vertigo, abolish tinnitus, and reverse hearing loss. Unfortunately, long-term hearing impairment does not seem amenable to treatment. Most previous studies of the effects of therapy have analyzed the treatment of the most distressing aspect of Menière disease: vertigo.

Medical regimens aimed at prevention of vertigo are directed at decreasing the production and/or accumulation of endolymph. Salt restriction and diuretics are believed by many to be the best medical therapy for Menière disease. These treatment measures have been reported to control vertigo in 58% of patients and to stabilize hearing in 69%. Other studies, conducted using double-blind methodology, have shown no effect of diuretics. Corticosteroids, administered orally and/or through intratympanic injection, have also been used in the management of the auditory and vestibular consequences of Menière disease.

Vertigo persists despite optimal medical therapy in approximately 10% of patients with Menière disease. Other forms of treatment are indicated in such situations. Surgical procedures performed on the endolymphatic sac are designed to decompress the sac and/or to drain endolymph from it. These procedures typically lead to complete resolution of vertigo in 50 to 75% of patients. Recurrence of vertigo is common in patients followed up to 10 years. The efficacy of endolymphatic sac procedures has been questioned based upon comparisons involving sham surgery.

In individuals failing medical therapy and/or sac surgery, definitive treatment for vertigo consists of one of several modalities of vestibular deafferentation with or without hearing preservation. Selective vestibular neurectomy, performed via a middle cranial fossa or posterior cranial fossa approach, has also been used to achieve control of vertigo in >90% of patients in whom this symptom was intractable. The potential complications of these procedures, although uncommon, include hearing loss, facial nerve paralysis, cerebrospinal fluid (CSF) leak, and headache. Excellent control of vertigo is also achieved with surgical labyrinthectomy although remaining hearing in the operated ear is sacrificed.

Intratympanic aminoglycosides have long been used in the treatment of Menière disease. Schuknecht, in 1957, using streptomycin, and Lange, in 1976, using gentamicin, gave multiple intratympanic injections of these antibiotics each day until patients developed disequilibrium or until caloric responses were abolished. Intratympanic gentamicin was controlled in most of these patients (100% in Schuknecht’s series; 88% in Lange’s series), but the rates of sensorineural hearing loss attributed to the aminoglycosides were unacceptably high (62 and 48%, respectively). Subsequent reductions in the number and frequency of doses have resulted in control of vertigo in 70 to 90% of patients and a reduction in the incidence of sensorineural hearing loss attributable to gentamicin. Most recently, it has been shown that a single intratympanic injection of gentamicin is effective in the control of vertigo in most patients. The long-term hearing outcome with these low dose gentamicin protocols is comparable to the hearing outcome in patients with Menière disease whose symptoms are medically managed.

Recent studies have identified changes in vestibular function after intratympanic gentamicin; and, in so doing, these investigations are providing new insights into the mechanism through which gentamicin leads to control of vertigo. Carey and colleagues, in 2002, studied vestibular function as measured by caloric tests and by the 3-dimensional angular VOR (AVOR) elicited by rapid rotary head thrusts in the planes of the semicircular canals before and after low doses of intratympanic gentamicin. Analyses of the AVOR were based upon the head thrust test.

Subjects with complete surgical unilateral vestibular destruction (SUVD) on one side fail to maintain visual fixation on a target when the head undergoes a rapid rotation toward the lesioned side. The test relies on Ewald’s second law which specifies that there is a greater effect from excitation of a semicircular canal than from inhibition of a canal. When the head is horizontally rotated toward the intact side in the head thrust test, the horizontal canal on the intact side is excited. The usual—but small—contribution of inhibition from the canal on the lesioned side is missing, but the response (eye velocity) generated by the excited canal is sufficient to yield an AVOR that is compensatory and only minimally changed. However, when the head is horizontally rotated toward the lesioned side, the horizontal canal on the intact side is inhibited. Without the large excitatory contribution from the horizontal canal on the lesioned side, the asymmetry between excitation and inhibition becomes manifest, and the AVOR is noncompensatory. On clinical examination this noncompensatory AVOR is manifested as a delay in the eye movement response followed by a rapid, corrective eye movement that brings the eye back to the target.

The head thrust test has been quantitatively validated using magnetic search coil recordings of eye and head movements. AVOR gain values (the ratio of eye to head velocity) near 1.0 have been demonstrated in normal subjects. Subjects...
with SUVD have markedly diminished gains for head thrusts that would excite the canals on the lesioned side.⁴⁰ Head thrusts in the planes of the vertical semicircular canals likewise demonstrate hypofunction and can even isolate hypofunction affecting only 1 canal.⁴¹

Quantitative evaluation of the three-dimensional AVOR in response to head thrusts has shown that patients with intractable vertigo due to unilateral Menière disease typically have symmetric gains of the horizontal VOR prior to intratympanic gentamicin. In contrast, a reduction of the caloric responses from the affected ear is seen in approximately 75% of these same patients. When tested after treatment with intratympanic gentamicin, a reduced horizontal canal gain for rapid head movements that were excitatory for the horizontal canal on the treated side was noted in each subject. Figure 1 shows the representative head (dashed gray) and eye (solid gray) velocity traces for a 38-year-old woman with a 3-year history of episodic vertigo as well as right fluctuating sensorineural hearing loss and tinnitus. Her caloric tests showed a 23% right unilateral vestibular weakness. Each panel of Figure 1 shows the traces of the subject’s eye and head velocities for head thrusts that excited the indicated canal. For example, the panels in the column labeled “Ipsi” show the AVOR for head thrusts that excited the canals on the side affected with Menière disease. For ease of comparison, the signs of the eye and head velocity traces have been given as positive values in all panels. Figure 2 shows data from the same subject tested 49 days after a single injection of gentamicin into the right middle ear. She did not experience any further episodes of vertigo after the single dose. Following gentamicin treatment, her caloric tests showed a 92% unilateral vestibular weakness on the right side. Her AVOR data also showed marked decrements in the gains for head thrusts that excited any of the treated canals. Her AVOR gains for excitation of the contralateral canals also changed, but much less. This slight reduction in gain attributed to excitation of the contralateral canals is due to a reduction in the inhibitory contribution to the response from semicircular canals on the treated side.

AVOR gains for head thrusts that excite canals on the gentamicin-treated side exceeded those seen for the same stimuli in subjects with SUVD and gain asymmetries were smaller after gentamicin than after SUVD. This finding indicates that gentamicin is not producing a complete loss of vestibular function on the treated side. Electrophysiological studies in chinchillas have shown that gentamicin administered intratympanically in a manner similar to that used in humans produces a marked reduction in the sensitivity of afferents to motion. Resting discharge rate, although somewhat reduced after gentamicin treatment, is preserved as are the groups of afferents that can be distinguished based upon discharge regularity.⁴²

Reduction in the gain of the AVOR for head thrusts that are excitatory for semicircular canals on the treated side have been shown to be correlated with control of vertigo following a single intratympanic injection of gentamicin.⁴³ Patients treated with intratympanic gentamicin may develop recurrent episodes of vertigo 6 to 18 months after treatment. These recurrences are treated successfully with an additional intratympanic injection of gentamicin.

Figure 1. Responses to head thrusts in a patient tested immediately before intratympanic gentamicin treatment. Each panel shows head velocity (light gray dashed) and eye velocity (dark gray and black) for rotations in the excitatory direction for each semicircular canal (AC = anterior canal, HC = horizontal canal, PC = posterior canal). Data from 8 to 12 stimulus repetitions are shown for each canal. Head velocity has been inverted to permit a direct comparison of the stimulus and the response. The interval over which gain was analyzed (30 ms prior to peak head velocity) is shown in black for each trace. The eye velocity before and after this analysis interval is shown in dark gray. A gain value was calculated as eye/head velocity for every point in time during the analysis interval. The response gain for each stimulus repetition was defined as the maximum gain value during the interval of analysis. The response gain (mean ± SD for all stimulus repetitions) is given in each panel’s upper right corner. (Published with permission from reference 13.)

Figure 2. Responses to head thrusts that excited each of the six semicircular canals in the same patient as in Figure 1 measured 49 days after a single intratympanic injection of gentamicin. Panels, traces, and gain values are as described for Figure 1. (Published with permission from reference 13.)
The caloric test in vestibular neuritis most commonly referred to as vestibular neuronitis. This test is based upon effects of the symptoms on patients’ quality of life. Progress in the treatment of Menière disease has led to the development of effective treatment protocols involving intratympanic injection of gentamicin (low-dose) in patients for whom vertigo has not been controlled by medical means. Ongoing research is providing a greater understanding of the effects of gentamicin on vestibular function and of the mechanisms through which gentamicin leads to control of vertigo. Future directions for research related to Menière disease include genetic studies to define specific genotypes that may be associated with the development of the inner ear abnormalities. Investigations of mechanisms of inner ear injury and of autoimmune disorders that affect the ear should also help to understand the underlying cellular pathophysiology.

VESTIBULAR NEURITIS

One of the most common causes of dizziness for which an individual seeks emergency attention is vestibular neuritis. Overall, vestibular neuritis is the second most common cause of vertigo arising from a disorder of the labyrinth with an incidence of about 3.5 per 100,000 population per year. The presenting symptoms and signs include sudden onset of sustained rotary vertigo (lasting days to weeks), spontaneous nystagmus (with fast phase components beating toward the unaffected ear), and postural imbalance. Various theories have been proposed to account for the cause of vestibular neuritis including inflammation of the vestibular nerve and ischemia of the labyrinth. Many of the histological features of vestibular neuritis when evaluated in postmortem studies are similar to those observed in other sensory epithelia in known viral disorders. Herpes simplex virus type 1 (HSV-1) DNA has been detected on autopsy with the use of polymerase chain reaction in about two of three human vestibular ganglia. Reactivation of a latent infection with HSV-1 is an often-cited mechanism to account for the occurrence of vestibular neuritis. Vestibular neuritis appears to affect the superior division of the vestibular nerve more commonly than the inferior division. Anatomic differences between the bony channels of the superior and inferior vestibular nerves may make the superior division more susceptible to injury. The superior division has a longer course through bone than does the inferior division. The superior division could, therefore, be more susceptible to ischemic injury and entrapment. Because of the putative association of the disorder with reactivation of HSV-1, the condition is sometimes referred to as vestibular neuronitis. The caloric test in vestibular neuritis most commonly reveals a reduced response on the affected side. In contrast, a vestibular evoked myogenic potential (VEMP) can be elicited from the affected ear in 61 to 88% of people affected with vestibular neuritis. The VEMP response appears to arise from the saccus so preservation of this response provides evidence that function of the inferior vestibular nerve and its end organs are intact. Also, quantitative assessment of the three-dimensional properties of the spontaneous nystagmus and of the vestibuloocular reflex evoked by rotations in the planes of different semicircular canals indicate that function in the posterior canal on the affected side is typically preserved whereas that in the horizontal and superior canals is diminished.

Presentation

Due to the intensity of the vertigo, many patients are initially seen in the emergency room, treated supportively and discharged with instructions to follow-up with an otolaryngologist. These patients will complain of severe dizziness and vertigo, will have difficulty walking, will have nausea and commonly emesis and will try to remain still with their eyes closed so not to exacerbate their symptoms. Nystagmus will be present and in most cases beats toward the nonaffected ear as the insult results in loss of vestibular function on the affected side. In irritative cases of vestibular neuritis, the nystagmus may beat toward the affected ear, but this is rare. The patient should be made to walk, however difficult it may be, as severe gait ataxia strongly raises the suspicion of a central cerebrovascular event such as cerebellar infarction. In a recent review of a large number of patients with isolated cerebellar infarction, 10% of patients (25/240) were noted to have a clinical picture that closely resembled vestibular neuritis. The territory of the posterior inferior cerebellar artery (PICA) was most commonly involved in these patients. All these patients with infarction in the PICA territory had a normal head thrust test and normal caloric test in the affected ear. In practice, the possibility of brainstem or cerebellar infarct must be considered in any patient presenting with the acute onset of vertigo. Cranial magnetic resonance imaging (MRI) with diffusion weighted images should be performed when indicated based upon clinical suspicion of an infarct.

Hearing should be intact in cases of vestibular neuritis. The presence of hearing loss in the affected ear may indicate labyrinthitis, an acute Menière disease attack or infarct of the brainstem or cerebellum (often in the territory of the anterior inferior cerebellar artery). The intense vertigo of acute vestibular neuritis can last from hours to days and rarely weeks. The patient is commonly first seen by an otolaryngologist in the subacute phase that lasts weeks, or occasionally months, following the initial attack. This phase is characterized by imbalance and disequilibrium that noticeably improves over this time. Patients will have sensitivity to motion and may avoid head turns and rapid movements. They may develop brief attacks of vertigo that are not as intense as the initial attack. Vestibular rehabilitation during this phase may speed recovery.

At the end of the subacute phase the patient will be near their baseline balance function but may notice small disturbances of equilibrium with rapid motions or in challenging environments. If evaluated for dizziness at this late stage, a diagnosis of vestibular neuritis is based largely on a suspicious history of severe vertigo within the prior months to year. A bilateral testing, as described below, may also demonstrate a unilateral weakness confirming an insult to the inner ear. Commonly in this stage anxiety plays a major role in the patients’ perception of their debility. Many patients with acute vertigo will develop anxiety regarding their balance and potential for having recurring vertigo. They will often limit activities such as driving, withdraw socially and become intensely fixated on any abnormal sensation of equilibrium. A multidisciplinary approach to treating these patients is necessary, and consideration should be given for early psychological intervention in any vestibular neuritis patient with a dependent or insecure personality type.

It is rare for vestibular neuritis to recur. A recent retrospective review of 103 patients in whom vestibular neuritis was diagnosed identified a second occurrence 29 to 39 months after the first episode in only 2 patients. The contra-lateral ear was affected in both of these patients, and vertigo was less distressing than the initial episode in both patients.

Although vestibular neuritis typically affects only the superior vestibular nerve, isolated involvement of the inferior division with diminished function in the posterior canal and saccus but preserved function in the lateral and superior canals has been identified in some patients. BPPV can occur following vestibular neuritis in cases where function in the inferior vestibular nerve is preserved.

Evaluation and Diagnostic Testing

Physical Examination. Findings on physical examination will generally depend upon the stage of vestibular neuritis. In the acute phase, the examiner will note spontaneous nystagmus with a directional component that depends upon the affected semicircular canals. In the case of vestibular neuritis affecting the superior vestibular nerve, the fast phases will consist of horizontal and torsional components beating toward the unaffected ear. There may also be an up beating component reflecting preservation of function in the posterior canal on the affected side. The directional components of the nystagmus are reflective of Ewald’s first law, which states that the eyes move in the plane of the affected semicircular canal(s). Alexander’s law is obeyed, and the nystagmus will increase in amplitude with gaze toward the horizontal fast phase component, which is usually toward the nonaffected ear. The nystagmus...
should suppress with visual fixation but may be of such intensity as to be reduced in amplitude but remain noticeable. Direction changing nystagmus and lack of visual suppression should raise the suspicion of a central event and prompt imaging for stroke evaluation. The presence of ataxia is also suggestive of central vestibular dysfunction or, rarely, a drug reaction.

Hearing should be checked during the acute phase, but this may only be feasible with tuning forks due to the severe nausea and emesis experienced by these patients. The Weber test will help to determine a unilateral loss of hearing, and the Rinne test will suggest whether that loss is sensorineural or conductive. A hearing loss is inconsistent with vestibular neuritis, and the practitioner should consider labyrinthitis, Menière disease, perilymphatic fistula, or acute otitis media among otologic causes of acute cochleovestibular symptoms.

The spontaneous nystagmus has usually resolved in the subacute phase although nystagmus may be observed with gaze toward the unaffected ear (Alexander’s law). Evidence for a recent unilateral vestibular insult can be identified with the Halmagyi maneuver or head-thrust test. In this test, the patient is asked to fixate on a point, for example, the examiner’s nose, and the head is rotated left and right along the horizontal plane. If there is a weakness, the patient will exhibit a refixation or “catch-up” saccade as the eyes jump back to the fixation point. In the normal condition, the eyes will remain fixed on the target due to the rapidity of the vestibular-ocular reflex. The horizontal canal is most commonly tested although head thrusts in the oblique planes can be performed to test the superior and posterior semicircular canals. Beyond the subacute phase, the head thrust examination may be positive in uncompensated cases. However, this most commonly returns to near normal due to peripheral vestibular recovery and central compensation. A residual unilateral vestibular paresis may be detected clinically with the head shake test. With Frenzel lenses on, the head is rotated left and right along the horizontal plane at about 1 to 2 Hz for 10 to 15 seconds. This takes advantage of Ewald’s second law, which states that the range of encoding of motion is greater for activation than for inhibition of a semicircular canal. This repetitive maneuver thus loads each horizontal canal with compounding excitatory activity. At the end of the head shake, this activity discharges and will control eye movements. If both sides have equivalent function, the eyes will remain stable. If one side has vestibular paresis, the discharge from the good side will predominate and horizontal nystagmus toward the good ear will be observed.

Electronystagmography/Videoelectronystagmography (ENG/VNG). Objective testing can be used to identify the unilateral vestibular hypofunction characteristic of vestibular neuritis. Caloric testing showing an asymmetry is consistent with a history of unilateral vestibular insult. This test is more sensitive than either head thrust or head shake for identifying such an asymmetry. The ENG/VNG battery of tests can also be used to assess for the presence of BPPV which occurs often after vestibular neuritis. In the acute and subacute phases, ENG/VNG can identify and document spontaneous and gaze evoked nystagmus as well as determine their direction thus helping to identify the affected side.

Imaging. The acute phase of vestibular neuritis is of such severity and duration that clinical examination alone may not be sufficient to rule-out central vascular events. Thus, computed tomography (CT) scan is the initial imaging test of choice to look for an acute hemorrhage involving the brainstem or cerebellum. MRI of the internal auditory canals during an acute phase of vestibular neuritis may show subtle enhancement of the superior vestibular nerve at the region of Scarpa ganglion. Beyond the acute phase, MRI with gadolinium enhancement is most useful for evaluating for other intracranial lesions that could account for an attack of vertigo or prolonged vestibular dysfunction. T1-weighted images with contrast can demonstrate the presence of vestibular schwannoma. Sudden vertigo is the initial presenting sign for vestibular schwannoma in approximately 15% of cases although its prevalence in vestibular schwannoma is about 40%. It is rare in isolation and usually accompanies hearing loss. The presence of Chiari I malformation, cerebello-tumoral, cerebelopontine angle arachnoid cyst, old brainstem infarct, or vascular loop can also be identified with MRI.

Management. Supportive treatment should also be given during the acute phase of vestibular neuritis. Patients should be hydrated if they are having significant emesis and provided antiemetics. Several medications can be used for nausea including the phenothiazines: prochlorperazine (Compazine), and promethazine (Phenergan); the antihypertensive metoclopramide (Reglan); and the 5-HT receptor antagonist odansetron (Zofran). The authors prefer phenergan as it can be administered by intramuscular injection acutely and can be provided as a suppository if emesis continues as an outpatient. Vestibular suppressants can also be prescribed to attenuate the severity of the attack. Commonly emergency room and primary care physicians will use meclizine (Antivert) which commonly has side effects of urinary retention and sedation. Its efficacy has not been established for either acute phase vertigo or chronic disequilibrium although it can be effective for motion sensitivity. Low dose valium is an effective vestibular suppressant, and minimally sedating dosages of 2 mg every 6 hours as needed can be provided. A tremor should be made to wean the patient off of vestibular suppressants as soon as possible to allow central compensation of the unilateral hypofunction.

The use of corticosteroids and antiviral medications in the treatment of vestibular neuritis has been investigated in a prospective randomized double-blind study. Placebo was compared with methylprednisolone, valacyclovir, and combination therapy of methylprednisolone and valacyclovir. Methylprednisolone dosage was 100 mg daily for the first 3 days tapered by approximately 20 mg every 3 days for a total treatment time of 22 days. Valacyclovir was administered as 1,000 mg three times per day for 1 week. This study showed a significant benefit of corticosteroids but no added benefit of antiviral therapy nor any benefit of antiviral therapy alone. Some authors, however, have advocated antiviral therapy for recurrent vestibular neuritis and recommended intratympanic application of the antiviral medication if oral therapy fails to control symptoms.

Once the patient has entered the subacute phase of their attack, vestibular rehabilitation exercises should be recommended. VOR exercises can speed central compensation for the unilateral weakness, and the interaction with a therapist through this stage can be reassuring to many patients. Those patients who are more distant from their acute attack but have evidence of continued failure to achieve compensation can also benefit from vestibular rehabilitation. Patients experiencing chronic daily disequilibrium should be evaluated for psychogenic dizziness triggered by the initial neurologic disorder. Additionally, an attack of vestibular neuritis may exacerbate underlying psychiatric or anxiety disorders.

VESTIBULAR MIGRAINE

Vestibular migraine (migraine-associated dizziness) is an extremely common disorder afflicting approximately 17% of women and 6% of men in the United States. Although typically considered by many physicians and lay public alike to be a disorder of headache, migraine commonly manifests numerous additional neurological symptoms. Among these are disturbances of vision, parasthesias, fatigue, disordered thought, and disturbances of balance. Vestibular migraine is often misdiagnosed, specifically it is underdiagnosed and should be considered in any patient presenting with dizziness, vertigo, or disequilibrium.

Migraine is classified into several subtypes by the International Headache Society (IHS). Of importance to the otolaryngologist are migraine without aura and migraine with aura which has subcategories of basilar migraine, typical aura with migraine headache, and typical aura with nonmigraine headache and without headache (Table 2). To diagnose migraine without aura, the patient must have a headache lasting 4 hours to 3 days with at least 2 of the following 4 symptomatic characteristics: unilateral site, pulsating quality, moderate to severe in intensity or aggravation by physical activity. In addition, the headache phase must also be associated with nausea and/or vomiting, or photophobia or phonophobia. Migraine with aura has at least 3 of the following 4 features: at least 1 fully reversible neurological symptom suggesting brainstem or cortical dysfunction; at least 1 symptom developing
The association between migraine and vestibular symptoms has been well established. In practice, however, it is common to find patients and even some consulting neurologists resistant to the idea that dizziness may be related to migraine, particularly in headache free periods. While vestibular symptoms are present in over 50% of migraineurs, attacks of vertigo do not always occur with headache. In fact, vestibular attacks occurred consistently in association with headache, that is, true aura, in only 24% of patients studied by Neuhauser and colleagues. Thus, the majority of vestibular attacks occur in headache-free intervals. Indeed, vestibular symptoms may be the only sign of recurrent migraine in a patient with a distant history of severe headaches. It is not uncommon to be presented with a middle-aged woman with new onset dizziness in the absence of headache but with a history of headache or migraine as a teenager. This patient will also commonly have a family history of migraine or headache in first-degree relatives.

**Presentation**

The patient with vestibular migraine may present in several ways. The individual with migraine aura will typically report discrete attacks of vertigo, usually lasting minutes to hours, associated with nausea that can occur before, concurrent or following the onset of dizziness. They will also note fatigue and commonly photophobia. Phonophobia, osmophobia, tinnitus, and a sense of hearing impairment are also not unusual. The hearing loss and tinnitus may suggest Meniere disease but during migraine are typically bilateral. Further, the hearing loss is less of a threshold shift than a sense of not processing auditory information. Additionally, the tinnitus is often high pitched or a roaring within the head rather than the classic Meniere disease low pitched sound localized to one ear. Following or toward the end of these symptoms, the patient will develop headache or a sense of pressure in their head. They will typically sleep several hours and note that they awaken symptom free and at baseline. The episodic and intense form of vestibular migraine, that is, migraine with aura, is often difficult to distinguish from Meniere disease but due to the recurrent nature, duration of symptoms and associated neurological complaints can usually be distinguished from BPPV, vestibular neuritis, or even panic attacks.\(^{71,74}\) Complicating the differential diagnosis can be the lack of severe headache with these episodes. Specific questioning of the patient, however, can often reveal forms of attenuated headache such as head pressure, scalp paresthesias or neck pain and stiffness, that is, migraine classification 1.2.2: typical aura with nonmigraine headache.

The more common, but more difficult to diagnose, presentation of vestibular migraine is that which occurs without headache or with less distinct episodes of vertigo. A progressively 50% of vertigo attacks related to migraine occur in headache-free intervals.\(^{75}\) Additionally, migraine dizziness is often nonepisodic with complaints of chronic disequilibrium and waves of increasing severity that may crescendo to vertigo or severe imbalance. Other descriptions of dizzy attacks include lightheadedness, a swimming or drunk feeling, floating, or a sensation of disconnectedness from the environment. There may be positional complaints, but they often differ from BPPV on testing. Migraine postural sensitivities do not generally have a latency of onset and persist without fatigue during maneuvering. Nystagmus may or may not be present during postural changes, and the direction of nystagmus should be correlated with the vestibular labyrinth orientation to identify peripheral origin.

Patients with vestibular migraine will commonly note attacks provoked by visual stimuli and motion. They will often have difficulties in stores with long and wide aisles and fluorescent lighting. Visually challenging situations such as watching a train pass, watching scrolling movie credits or a news ticker, or watching video games may provoke dizziness. Crowds may similarly pose problems. Repetitive activities such as computer work, particularly transcribing papers, and gardening may precipitate attacks or worsening of baseline dizziness. Approximately 50% of migraineurs will note histories of childhood ear sickness, avoidance of amusement park rides, or sea-sickness. Oftentimes such sensitivity will have abated in adulthood, but recurred at the time of presentation.

The occurrences of attacks or exacerbations are often timed to the menstrual cycle or reflect irregularities in menstruation. Clusters of attacks may occur around menarche, pregnancy, and the perimenopausal period. Hormone replacement therapies or changes in an established regimen should be noted. Other common stimulants for vestibular migraine include stress, foods, weather changes, and travel.\(^{76}\) Attacks tend to cluster around holidays, and they represent good temporal references in acquiring a history. These likely are due to stress of holiday activities, travel and dietary changes, most notably chocolate, red wine, and smoked meats such as ham. Commonly patients will note the onset of attacks after a period of intense stress such as the hospitalization of a family member or moving. The attack may represent a “decompression” of built up stress and anxiety. Travel by car, especially as a passenger, is very stimulating and is more troublesome than airplane travel. Boat trips and cruises can precipitate attacks and may lead to chronic migrainous-like disequilibrium after disembarking, the aptly named “mal de debarquement” syndrome.\(^{77}\)

Many of these patients will show signs of depressed mood or heightened anxiety. It is not clear whether the migraine dizziness is a symptom of their psychological disorder, an antecedent and triggering factor for the development of mood disturbance, or a separate but associated psychopathology.\(^{53,54}\) Commonly, patients with chronic dizziness will have seen a psychiatrist, psychologist, or therapist and will readily admit to having an “anxious” personality. A history of panic disorder is also not unusual. In these anxious patients, it is important to get a detailed vestibular history. One can often find that the first attack was the most severe and of greater intensity and duration than those following. Careful questioning may reveal this primary attack to be consistent with vestibular neuritis and a prolonged compensation period. Postvestibular neuritis BPPV may have also been present and caused exacerbation of anxieties related to vestibular function. At the time of presentation, the patient has had months of various forms of dizziness and developed significant fear of having attacks in public.\(^{13,34}\) Once the VOR has recovered and the BPPV has been treated or spontaneously resolved, the patient is left with a severe mood disorder and anxiety which serves as the predominant trigger for their dizziness. They appear to have attacks of vestibular migraine with chronic disequilibrium and of anxiety filling the interval periods. Indeed, in the susceptible patient, a peripheral vestibular insult such as vestibular neuritis may be a sufficient stressor to provoke the onset of vestibular migraine.

**Diagnostic criteria based upon clinical presentation have been proposed for vestibular migraine.**\(^{78}\) This proposal is similar to the Meniere disease classification and notes 2 categories of vestibular migraine, definite, and probable (Table 3). The patient with “definite” vertigo due to migraine should have moderate or severe episodic vestibular symptoms, a current or previous history of migraine according to IHS criteria, symptoms of headache, phonophobia, photophobia, visual or other aura on at least two occasions of vertigo, and other potential causes ruled out. The patient with “probable” vertigo due to migraine is similar, but the requirement for

Table 4 Food Triggers for Migraine

- Alcohol: red wines, beer, champagne, vermouth
- Anchovies
- Aspartame, nitrates, sulfites, food dyes, additives
- Avocados
- Broad, lima, and other beans
- Caffeine-containing products
- Caffeine withdrawal
- Cheeses which have been aged, i.e. cheddar
- Chicken livers
- Chocolate
- Citrus fruits, bananas
- Cured or dried meats (hot dogs, bacon, ham, and salami)
- Dairy products, ice cream
- Fatty or fried foods
- Meat and vegetable extracts
- Monosodium glutamate (MSG)
- Nuts, peanuts, and peanut butter
- Pickled herring
- Pickled herrings
- Sauerkraut
- Yeast, sourdough breads
- Yogurt, sour cream

in normal social interactions and family dynamics that such a chronic condition incurs.

**Vestibular Rehabilitation.** Vestibular rehabilitation is an effective treatment for many causes of peripheral vestibulopathy, and patients with idiopathic and posttraumatic vestibular migraine have likewise shown subjective and objective improvement. Migraine sufferers, however, may not subjectively improve as much as patients with other vestibular disorders. Specifically, migraine sufferers appear to perceive their handicap as worse than matched controls despite similarities in overall function. This is consistent with the increased prevalence of anxiety and depression among these patients and a distorted perception of self and their interaction with their environment. Vestibular rehabilitation should be used in this population but may require more frequent visits and higher levels of support and encouragement from the therapist. Additionally, many of these patients will benefit from additional psychological supportive measures.

**Pharmacotherapy.** Migraine is treated with 2 broad categories of medications: abortive and prophylactic. Abortive medications are taken at the first sign of an attack to stop the physiological process, shorten the time of disability and reduce the severity of the episode. Most abortive medications fall into the category of triptans (migraine drugs that have triptan in their names) which are labeled as contraindicated in the treatment of basilar-like migraine. The 2004 IHS migraine classification considers vertigo only as a symptom of basilar-like migraine. The 2004 IHS migraine classification considers vertigo only as a symptom of basilar-like migraine and does not recognize vertigo separately as an aura symptom for migraine with or without headache. Recognition of vestibular migraine as a separate entity is increasing, and reclassification of this syndrome will allow the performance of studies to investigate the safety and efficacy of abortive medications in this condition. Such reclassification and studies would also remove the potential medico-legal ramifications of using triptans to abort attacks of vestibular migraine. Limited reports of using triptans in migraineurs with vertigo are mixed.

Vertigo is often the first sign of a migraineous attack, and abortive medications may stop the ensuing headache but will not necessarily attenuate the more troublesome vertigo. Antivertiginous medications or antiemetics may be of benefit during an attack. Medications used for vestibular neuritis such as the phenothiazines: prochlorperazine (Compazine), and promethazine (Phenergan), the anticholinergic metoclopramide (Reglan), or diazepam (Valium) can reduce symptoms. However, for most patients with vestibular migraine the use of prophylactic medications to prevent attacks is preferred. For those patients with elements of chronic dizziness, a prophylactic medication will also ensure daily dosing. Currently there are several FDA-approved medications for migraine prophylaxis and nearly 100 off-label medications commonly employed.

Propranolol and timolol (beta blockers) are FDA-approved for use in migraine prophylaxis. Other beta-blockers such as nadolol, atenolol, and metoprolol have also been used, but are not explicitly approved for migraine. Twice daily dosing or extended release tablets are recommended to ensure consistently therapeutic drug levels. Dosing can be tapered upward over several weeks and titrated to efficacy and side effects. Beta-blockers are contraindicated in patients with active asthma, moderate to severe chronic obstructive pulmonary disease, bradycardia, secondary and tertiary AV (atrioventricular) block, severe peripheral vascular disease, and brittle diabetes. Side effects of beta-blockers include orthostatic hypotension and dizziness, and patients should be counseled to this regard. A good response would be reduction of attacks by 50%, and the medication can be tapered off over several weeks if there is complete remission for 6 months.

Among the calcium channel blockers, verapamil is FDA-approved for the treatment of migraine, and it has shown reasonable efficacy with few side effects. Flunarizine has effectiveness equivalent to that of propranolol. Other calcium channel blockers, such as nimodipine, nicardipine, and diltiazem have been tried with little data to support their use over established treatments. Dosing is typically tapered upward, and therapeutic efficacy is at least 240 mg daily. Side effects include constipation and cardiac arrhythmias, and these medications should not be used in patients with bradycardia and heart block. Conflicting reports link calcium channel blockers to increased risk of cancer, and this should be considered particularly in pediatric patients.

Tricyclic amine antidepressants have a good track record of efficacy in migraine treatment. This class of drug includes amitriptyline, nortriptyline, imipramine, trimipramine, doxepin, dothiepin, clomipramine, and protriptyline. Amitriptyline (Elavil) has well-documented effectiveness for migraine, as does nortriptyline (Pamelor). These drugs are sedating and thus useful in patients with sleep disturbance in addition to migraine. Amitriptyline, and clomipramine and have been tried with bedtime. Tricyclic antidepressants are also useful in patients with depression as either a coexisting or resultant phenomenon of their dizziness. Dosing of amitriptyline usually starts at 10 mg nightly and can be increased weekly up to a dose of 50 mg daily. These medications can cause blurred vision, dry mouth, constipation, urinary retention, gastroesophageal reflux disease, and weight gain. The selective serotonin reuptake inhibitor (SSRI) class of antidepressants has been considered for migraine prophylaxis, but clinical trials are disappointing. Paroxetine may be effective in patients with anxiety disorder as a component of their symptoms.

Other medications that have been used for migraine include benzodiazepines, in particular the longer acting clonazepam (Klonopin). This medication may be useful in patients with anxiety and panic disorder as part of their symptom complex. A cetazolamide (Diamox) has been proposed and may be effective in those with Menière-like attacks as well as those with familial migraine syndromes. Anticonvulsants represent a more recent option for migraine prophylaxis and divalproex sodium (Depakote) and topiramate (Topamax) are FDA-approved for migraine prevention. Depakote can be started at low doses (250 mg to 500 mg daily) and, if effective, only limited liver enzyme surveillance may be necessary. Side effects include weight gain, nausea, sedation and tremor. Topamax is usually started at 25 mg daily and tapered upward to 100 mg/d with clinical response seen within one month. Unlike Depakote, Topamax can cause weight loss but must be used with caution in patients with a history of renal calculi. Gabapentin (Neurontin) has also been frequently used in migraine prophylaxis and has a good safety profile. Minimal dosage should be 600 mg/d and dosages at 2,400 mg/d have been well tolerated and shown good effectiveness for migraine.

**Summary**

Vestibular migraine is a common disorder manifested by recurrent spontaneous attacks of dizziness. Its presentation may be similar to Menière disease but typically lacks the full constellation of ear-specific signs and symptoms. Diagnosis is made by history, a high index of suspicion, and subsequent exclusion of primary aural pathology. Multiple treatment options are available, but effective therapy also requires attention to associated psychological conditions. Increasing experience and diagnostic criteria regarding migraineous vertigo will aid in better defining this disorder and appropriate interventions.

**BENIGN PAROXYSMAL POSITIONAL VERTIGO**

BPPV is the most common aural cause of vertigo. Due to its propensity for spontaneous remission, it probably occurs in far more people than present to an otolaryngologist for evaluation. The diagnosis of BPPV can be strongly suspected based upon the characteristic history. The specific finding of nystagmus triggered by changes in head position and having the classic directional and time-dependent features establishes the diagnosis of BPPV with certainty. Treatments are very effective, and both patient and physician satisfaction with management and treatment outcomes are high.

Unlike many other causes of dizziness which arise from abnormalities in cellular physiology, BPPV is essentially an anatomical condition with physiological findings precisely related to the anatomical and structural events. Otoconia (calcium carbonate crystals that are normally a part of the otocional membrane) from the utricle and saccule become dislodged and migrate into the semicircular ducts. The posterior semicircular duct is most commonly affected because of its dependent location in the labyrinth. Otolith crystal briefly float within the semicircular duct produce the condition referred to as canalithiasis
and represent the vast majority of all cases of BPPV. Motion of these crystals, by gravitational forces with changes in head position, accounts for the characteristic short-lived, but intense vertiginous episodes of BPPV. Crystals that become adherent to the cupula or reside against the cupula opposite the duct lumen, produce the condition of cupulolithiasis. Cupulolithiasis can present with discrete vertigo but also with position or head motion induced dizziness. Cupulolithiasis may occur more commonly in the lateral (horizontal) semicircular duct whereas canalithiasis is by far more common in the posterior semicircular duct. Diagnosis of BPPV typically involves reproduction of symptoms by causing otolith crystal motion within the affected semicircular duct and treatment is directed at relocating those crystals back into the vestibule. Although the lesion is in the membranous labyrinth, in clinical parlance, reference is made to the semicircular canal rather than the semicircular duct.

The predominant canal affected by BPPV is the posterior semicircular canal, which accounts for 80 to 90% of all cases. The next most commonly affected canal is the horizontal semicircular canal which accounts for about 10% of cases and the least affected is the anterior canal only involved in 2% of cases.58 As discussed above, the incidence of canal involvement in BPPV is likely related to the anatomical orientation of the semicircular canals: it is easiest for otolith crystals to “fall” into the posterior semicircular canal and most difficult for them to displace superiorly into the anterior semicircular canal. BPPV can affect more than 1 semicircular canal simultaneously and can also present bilaterally. Classic BPPV is that which involves the posterior semicircular canal, and the presentation, diagnosis, and treatment are presented below. This section will also address the less common variants of BPPV and their distinctive characteristics aiding in diagnosis.

Presentation

The majority of patients with classic BPPV will present with descriptions of discrete episodes of vertigo induced by specific head motions. Typical head motions include turning over in bed or looking up. Other motions involve bending to look under something with the affected ear down. Common activities that precipitate vertigo are reaching to retrieve an object from a high shelf (i.e., top shelf sign), changing a light bulb, or ringing one's hair in a shower or getting into and out of bed. Occupationally, nurses report vertigo with cal head motions include turning over in bed or looking under a car. Occupationally, nurses report vertigo with cal head motions include turning over in bed or looking under objects with traffic or looking under objects with

visual fixation. The patient sits upright at the edge of an examination table, and the head is turned 45° to the tested ear. The patient is then rapidly reclined with the head hanging over the edge of the examination table (Figure 3). This places the posterior semicircular canal in the tested ear in the vertical plane, which causes maximal stimulation in most cases of canalithiasis. The patient’s eyes are examined for geotropic up beating nystagmus. That is, the fast phase of the nystagmus should beat vertically toward the vertex of the head. A torsional component of the nystagmus is also observed with torsional fast phases beating toward the test ear (ie, the ear nearer the ground). This nystagmus is due to the ampullofugal motion of the particles in the posterior canal, which is excitatory for the posterior canal. Each side is tested independently and the affected ear is the one toward the ground at the time of positive response.

The nystagmus of BPPV should also follow rules consistent with the anatomic pathology of the disorder. There should be a period of latency prior to the onset of nystagmus or subjective dizziness. This is typically a few seconds but it may take as long as 20 to 30 seconds for gravity to accelerate otolith particles sufficiently to cause vestibular stimulation. The vertigo and nystagmus should crescendo (corresponding to motion of the cupula of the posterior canal), and decrescendo as the particles settle in the dependent portion of the canal. Once the particles stop moving, the stimulus is removed, deflection of the cupula ends, and the patient should no longer experience vertigo nor should the examiner observe nystagmus. If either persists, an alternative diagnosis, particularly central pathology, should be entertained. BPPV should also fatigue. That is, repeated applications of the Dix-Hallpike test should lead to diminishing subjective and objective response. The fatigue of the nystagmus may be due to dispersion of the crystals within the canal.

BPPV may occasionally affect semicircular canals other than the posterior canal. The incidence of horizontal canal BPPV is between 10 and 15% while the anterior canal is affected in less than 5% of cases. In these cases, the Dix-Hallpike test may not be positive or will give results divergent from those expected with posterior canal BPPV. If the anterior canal is affected, the Dix-Hallpike maneuver will cause excitatory ampullofugal particle motion when the affected ear is up (Figure 3). This will generate nystagmus opposite of that seen in classic BPPV, but with similar latency and fatigability. Specifically, the examiner will see down-beating nystagmus with torsional components directed toward the opposite side. If the torsional component is not strong, purely vertical, down-beating nystagmus may be observed.91,98

If the horizontal semicircular canal is affected, Dix-Hallpike positioning may not provoke otolith crystal motion at all due to the orientation of the canal and cupula relative to the ground during this maneuver (Figure 3). Symptoms can be elicited by having the patient lie supine with the head elevated at 30° and quickly rotating the head 90° to the side. This maneuver orients the horizontal canal orthogonal to the ground and maximizes the movement of otolith particles in the lumen (Figure 4). It also maximizes the gravitational pull on otolith particles relative to the cupula in cases of cupulolithiasis. Cupulolithiasis is commonly associated with horizontal semicircular canal BPPV.

Horizontal semicircular canal BPPV may cause symptoms with the head turned in either direction.99 The nystagmus elicited may beat toward (geotropic) or away from (apogeotropic) the downward ear depending on the presence of canalithiasis or cupulolithiasis. In canalolithiasis, head rotation toward the affected ear will cause ampullopetal particle movement in the lateral canal leading to horizontal nystagmus beating toward the dependent ear (ie, geotropic). Head rotation away from the affected ear will cause ampullopetal particle movement, which results in inhibition of the horizontal canal and nystagmus beating away from the affected ear. Since
The resultant nystagmus is thus away from the affected ear. This is inhibitory in the horizontal canal (Figure 4). Head rotation away from the affected ear causes inhibition of activity and nystagmus away from the affected ear, which will also appear as geotropic. The ear that is dependent during the maneuver causing more intense symptoms or nystagmus is considered the affected ear. In cupulolithiasis, the displaced otolith crystals are adherent to the end organ and cause gravity dependent deflection. Opposite of canalithiasis, the direction of nystagmus with the affected ear up or down will appear as apogeotropic. (Published with permission, copyright © 2007 D.R. Friedland, MD, PhD.)

**Figure 4** Movement of otolith crystals and deflection of the cupula in horizontal canal BPPV. In canalithiasis, head rotation toward the affected canal leads to excitation of the canal and geotropic nystagmus (ie, toward the ground). Head rotation away from the affected ear causes inhibition of activity and nystagmus away from the affected ear, which will also appear as geotropic. The ear that is dependent during the maneuver causing more intense symptoms or nystagmus is considered the affected ear. In cupulolithiasis, the displaced otolith crystals are adherent to the end organ and cause gravity dependent deflection. Opposite of canalithiasis, the direction of nystagmus with the affected ear up or down will appear as apogeotropic. (Published with permission, copyright © 2007 D.R. Friedland, MD, PhD.)

The absence of recordable nystagmus in the presence of subjective dizziness on positional ENG/VNG can reassure the examiner of negative objective findings and lead to evaluation for central abnormalities such as Chiari I malformation, orthostatic hypotension, postconcussive syndrome or migraine. The oculomotor and nystagmus tests may find abnormalities of gaze that can interfere with the interpretation of eye movements during Dix-Hallpike testing. The caloric component of ENG/VNG testing can identify a unilateral vestibular hypofunction, which may suggest an antecedent vestibular neuritis as the inciting event leading to the development of BPPV. Recall that vestibular neuritis typically affects the superior vestibular nerve, which innervates the anterior and horizontal semicircular canals. BPPV most commonly affects the posterior semicircular canal, which is innervated by the inferior vestibular nerve and will retain function after vestibular neuritis.

**Management**

The main treatment option for BPPV is to reposition the otolith particles out of the semicircular ducts or cupula. Canalith repositioning is the preferred first step in therapy and is often very effective. Additional medical, pharmacological, and surgical options are reserved for the small percentage of patients that fail repeated attempts at canalith repositioning and in whom other vestibular abnormalities have been excluded.

**Canalith Repositioning Maneuvers.** The mainstay of treatment for classic posterior canal canalithiasis is the Epley maneuver. In this maneuver, the free floating otolith crystals are sequentially advanced through the posterior
canal until they are released into the utricle at the common crus (Figure 5). Initially the patient is reclined with the head turned 45° toward the affected side and extended back just as in the Dix-Hallpike test. The patient is maintained in this position until nystagmus and subjective sensations of vertigo have fully passed. The minimum time that the patient should be in this position is 30 seconds. The patient’s head is then rapidly rotated 90° toward the opposite side so that the unaffected ear is down. This would be the same position as if performing a Dix-Hallpike test on the contralateral ear. The patient may experience vertigo as the otolith crystals move further along the posterior canal. After complete cessation of nystagmus and/or vertigo the patient is rotated another 90° away from the affected ear so that the eyes are looking directly at the ground. This aligns the common crus vertically with respect to gravity allowing the crystals to fall into the utricle and out of the posterior duct. After approximately 30 seconds, the patient is seated upright.

Some clinicians use a vibration device placed on the mastoid during the maneuver to facilitate otolith crystal migration. Also, some physicians will repeat the Dix-Hallpike test immediately after performance of the Epley maneuver to confirm satisfactory treatment. The overall success of the canalith repositioning maneuver is greater than 75% and over 90% of patients will respond well to repeated maneuvers. The patient should be instructed to refrain from lying flat for at least 24 to 48 hours. Sleeping with the head elevated at 45° during this time is recommended. Although these postural restrictions are commonly employed, recent studies suggest no difference in recurrence rates between patients with imposed restrictions and those without.

A posterior semicircular canal BPPV is a rare entity, but also responds well to canalith repositioning. The maneuver is the same as for posterior semicircular canal BPPV but should be performed starting with the affected ear up. For example, treatment of right posterior semicircular canal BPPV would entail the performance of an Epley maneuver starting with the left ear down and rotating toward the patient’s right. Occasionally, treatment of BPPV can release otolith crystals into a different semicircular canal and thus repeat therapies should be preceded by confirmatory Dix-Hallpike testing to re-identify the affected ear and semicircular canal. Treatment of bilateral BPPV is best performed in stages, and the authors will treat the subjectively worse ear or canal first and address the second site 1 to 2 weeks later after confirming resolution of initial symptoms.

Other repositioning maneuvers for the treatment of canalithiasis include the Semont libratory maneuver. The patient is rapidly moved laterally from a sitting position to a position with the affected ear down on the treatment table. After 4 minutes the patient is rapidly swung over to the opposite side so that the affected ear is pointing upward. This maneuver is more time consuming and difficult to perform than the Epley maneuver, but has similar success rates with over 90% of patients responding after four sessions. The Semont maneuver may be beneficial in patients not responding to the Epley maneuver and, due to the sudden impulse with position changes, may be effective in dislodging material in cupulolithiasis.

An alternative to repositioning maneuvers are the Brandt-Daroff exercises which the patient performs at home. The patient is instructed to sit on the edge of the bed and lie laterally to the affected side with the head slightly rotated upward similar to the positioning in the Semont maneuver. The patient remains in this position for 30 seconds before sitting up for 30 seconds and repeating the maneuver to the opposite side for another 30 seconds. The patient performs five sets of these maneuvers three times daily for 7 to 10 days. Excellent response has been noted to these exercises, and cure rates are not statistically different from those achieved with canalith repositioning. This exercise may cause central habituation to the position induced vertigo rather than relocation of the otolith crystals from the semicircular canals. Brandt-Daroff exercises may also be useful in preventing the recurrence of BPPV.

**Figure 5** Canalith repositioning maneuver for treatment of BPPV affecting the posterior semicircular canal. Panel 1 shows a patient with right posterior canal BPPV. The patient’s head is turned to the right at the beginning of the canalith repositioning maneuver. The inset shows the location of the debris near the ampulla of the posterior canal. The diagram of the head in each inset shows the orientation from which the labyrinth is viewed. In Panel 2, the patient is brought into the supine position with the head extended below the level of the table. The debris falls toward the common crus as the head is moved backward. In Panel 3, the head is moved approximately 180° to the left while keeping the neck extended with the head below the level of the table. Debris enters the common crus as the head is turned toward the contralateral side. In Panel 4, the patient’s head is further rotated to the left by rolling onto the left side until the patient’s head faces down. Debris begins to enter the utricle. In Panel 5, the patient is brought back to the upright position. Debris collects in the utricle. Illustration by David Rini. (Published with permission from reference 101.)
for horizontal canal canalithiasis is the Lempert 360° roll. The patient starts supine, and the head is rotated 90° to the unaffected side every 30 to 60 seconds. The first turn is 90° to the side so that the unaffected ear is down. With the head stable the patient turns his/her body prone in preparation for the next steps. Subsequently the patient’s head is rotated another 90° so the face is directly toward the ground and then another 90° so that the affected ear is down, and then the patient returns to the upright position. The Lempert maneuver has demonstrated success for geotropic horizontal BPPV, but has not proven as effective as apogeotropic BPPV. Geotropic horizontal canal BPPV may also have a high rate of spontaneous remission. Additional therapies for apogeotropic BPPV can include Brandt-Daroff exercises and other liberatory or habituation maneuvers. Overall, however, the success rate in treating apogeotropic horizontal canal BPPV is approximately 50%. Recurrences and long-term failures should be examined for potential conversion to classic posterior canal BPPV after performance of repositioning maneuvers.

Pharmacologic Therapy. Pharmacologic management of BPPV is directed principally at suppressing the vestibular response and alleviating nausea associated with vertigo. Pharmacologic therapy does not treat the underlying cause of BPPV. The symptoms of BPPV can be treated similar to those of vestibular neuritis with low dose valium and antiemetics such as the phenothiazines (e.g., Phenergan or Compazine). Symptoms of cupulolithiasis, which may include chronic disequilibrium due to inertial changes in the cupula, can be addressed with longer acting vestibular suppressants such as clonazepam (i.e., Klonopin) or with medications for motion sensitivity such as meclizine (Antivert). Pharmacologic therapy should not be used in management of symptoms in BPPV. Instead, repositioning maneuvers as described above should be used to address the underlying cause. Diazepam (Valium) can be used prior to canalith repositioning maneuvers in the extremely sensitive or anxious patient.

Surgical Management. Failure of repositioning maneuvers to alleviate symptoms in BPPV are rare. In such cases consideration should be given to surgical interventions to ablate responses from the offending semicircular canal. One approach is to transect the posterior ampullary (singular) nerve, which provides innervation to the posterior semicircular canal. In this method, a tympanomeatal flap is elevated to expose the round window niche and the bony overhang is removed. Subsequently, bone of the otic capsule just inferior to the round window membrane is drilled away to expose the singular nerve where it is transected. Singular neurectomy has largely been abandoned. However, in other surgeons’ hands, singular neurectomy has had an unacceptably high rate of sensorineural hearing loss and has largely been abandoned.

The currently preferred method of surgically addressing BPPV is semicircular canal occlusion or plugging. The posterior canal is exposed and thinned (blue-lined) via a transmastoid approach, and the canal is gently entered to avoid disruption of the endolymphatic membrane. The canal is plugged with bone chips, fascia, or fibrous tissue which can be further bolstered with bone wax or fibrin glue. Postoperative hearing loss is generally temporary and persistent sensorineural hearing loss is rare. This technique can be theoretically applied to any affected semicircular canal and has been utilized to treat therapy resistant geotropic horizontal canal BPPV. Canal plugging has also been applied to the superior semicircular canal for superior semicircular canal dehiscence as described later in this chapter.

Summary
BPPV is an anatomical disturbance within the vestibular labyrinth caused by displacement of otocoria to the semicircular ducts. The posterior semicircular canal is most commonly affected followed by the horizontal and anterior semicircular canals. Specific changes in head position will lead to gravity-induced motion of displaced otocoria relative to the ampulla and cause canal-specific nystagmus and vertigo. Treatment involves repositioning of the otolith crystals into the utricle and is highly effective. Surgical management of BPPV is reserved for canalith repositioning failures and is rarely needed.

SUPERIOR SEMICIRCULAR CANAL DEHISCENCE SYNDROME
Dehiscence of bone overlying the superior semicircular canal can result in a syndrome of vestibular
and auditory abnormalities. The vestibular abnormalities include vertigo and oscillopsia induced by loud sounds or by stimuli that change middle ear or intracranial pressure. These patients may exhibit a Tullio phenomenon (eye movements induced by loud sounds) or Hennebert sign (eye movements induced by pressure in the external auditory canal). They may also experience chronic disequilibrium. The auditory abnormalities include an apparent conductive hearing loss (manifested as an air-bone gap on audiometry that is not due to middle ear pathology), autophony, and pulsatile tinnitus. A recent report described the clinical manifestations of superior semicircular canal dehiscence in 65 patients. Vestibular manifestations were present in 60 and exclusively auditory manifestations without vestibular symptoms or signs were noted in five patients. The auditory symptoms and signs may be subtle and may not prompt a patient to seek medical evaluation. The overall incidence of auditory compromise in the absence of vestibular symptoms and signs may, therefore, be higher than that suggested by the findings in this study.

The pathophysiology of superior semicircular canal dehiscence can be understood in terms of the effects of the dehiscence in creation of a "third mobile window" into the inner ear (Figure 6). Under normal circumstances, sound pressure enters the inner ear through the stapes footplate in the oval window and, after passing around the cochlea, exits through the round window. The presence of a dehiscence in the superior semicircular canal allows this canal to respond to sound and pressure stimuli. The direction of the evoked eye movements support this mechanism. Loud sounds, positive pressure in the external auditory canal, and Valsalva maneuver against pinched nares cause ampullofugal deflection of the superior semicircular canal, which results in excitation of afferents innervating this canal. The evoked eye movements can involve a nystagmus that has slow components directed upward with torsional motion of the superior pole of the eye away from the affected ear. Conversely, negative pressure in the external auditory canal, Valsalva against a closed glottis, and jugular venous compression cause ampullopetal deflection of the superior canal which results in inhibition of afferents innervating this canal. The evoked eye movements in these situations are typically in the plane of the superior semicircular canal but in the opposite direction (downward with torsional motion of the superior pole of the eye toward the affected ear).

**Vestibular Manifestations of Superior Semicircular Canal Dehiscence**

In a recent report of 65 patients with superior semicircular canal dehiscence, vestibular symptoms were identified in 60 patients (43 males and 17 females). The age range at the time of diagnosis was 13 to 70 (median = 41; mean = 43) years. The right ear alone was affected in 27 patients and the left ear alone in 23 patients. There were 10 patients with vestibular symptoms and signs and CT findings indicative of bilateral superior semicircular canal dehiscence. Vestibular symptoms induced by loud sounds were noted in 54 (90%) patients and pressure-induced symptoms (coughing, sneezing, and straining) were present in 44 (73%). There were 40 (67%) patients who had both sound- and pressure-induced eye movements. In these 60 patients with vestibular symptoms associated with superior semicircular canal dehiscence, vestibular signs associated with superior semicircular canal dehiscence were present in 57 (90%). The vestibular signs in these 57 patients could be grouped into 4 categories. Sound-evoked eye movements were noted in 46 (82%) patients. A sound-induced tilt of the head in the plane of the superior canal was noted in 11 (20%) patients. There were 42 (75%) patients with eye movements induced by Valsalva maneuvers. Eye movements evoked by pressure in the external auditory canal were noted in 26 (45%) patients. A sign in only one of these 4 categories was noted in 17 (27%) patients. Signs in 2 categories were noted in 16 (29%) patients. Signs in 3 categories were noted in 20 (36%) patients. Signs in all 4 categories were noted in 4 (7%) patients.

The eye movements induced by sound and pressure stimuli can have an important role in making the diagnosis. These stimuli often lead to a nystagmus. The direction of the slow phase components of this nystagmus can be understood based upon the action of these sound and pressure stimuli on the affected superior canal. These eye movement findings have been...
documented with three-dimensional search coil techniques and can be observed on clinical examination (Figure 7). Frenzel lenses (<20 magnifying lenses that blur images and preclude visual fixation in patients wearing the lenses) should be used for this examination because visual fixation can lead to suppression of the evoked eye movements. An enlarged, low threshold click-evoked VOR has also been noted in superior semicircular canal dehiscence.129

Auditory Manifestations of Superior Semicircular Canal Dehiscence

Audiometric symptoms and signs in patients with superior semicircular canal dehiscence have also been described.125,130 Symptoms indicative of hyperacusis for bone-conducted sounds were found in 31 of 60 patients with vestibular manifestations of superior canal dehiscence.126 These symptoms included hearing heartbeat or eye movements in the affected ear and hearing the impact of the feet during walking or running. There were 30 of these patients with autophony in the affected ear. The Weber tuning fork test (512 Hz) typically lateralizes to the affected ear in the affected ear. The Weber tuning fork test was found in 31 of 60 patients with vestibular manifestations of superior canal dehiscence.129

Several reports have discussed the air-bone gaps in patients initially thought to have otosclerosis but who were subsequently found to have superior semicircular canal dehiscence.124,130,134 Air conduction thresholds did not improve in these patients following stapes replacement surgery. Earlier studies have described “inner ear conductive hearing loss” in patients with a conductive hearing impairment on audiometry but no evidence of tympanic membrane or ossicular abnormality found on exploratory middle ear surgery.135 Superior semicircular canal dehiscence now appears to be one cause of such inner ear conductive hearing loss. The acoustic reflex test provides a useful screening test in the identification of patients in whom the conductive hearing loss on audiometry may be due to superior semicircular canal dehiscence rather than to a middle ear problem such as otosclerosis. The acoustic reflex is the contraction of the stapedial muscle in response to a sudden loud sound. Even mild limitation of the motion of the ossicles abolishes this reflex. Thus, patients with intact acoustic reflex responses and an air-bone gap on audiometry should undergo further investigation for superior semicircular canal dehiscence, such as a high resolution CT scan of the temporal bones.

The air-bone gap that is frequently noted on the audiogram of patients with superior semicircular canal dehiscence is typically greatest at the lower frequencies (250 to 1,000 Hz). Laser-Doppler vibrometer measurements of sound-induced umbo velocity in patients with superior semicircular canal dehiscence have revealed hypermobility of

![Image](image-url)

**Figure 8** Computed tomographic images of the temporal bones in a 37-year-old man with left superior semicircular canal dehiscence syndrome. He developed vertigo, oscillopsia, and apparent movements in the plane of the left superior semicircular canal in response to tones of 500 to 1,000 Hz at 110 dB HL in the left ear. Dehiscence of the bone over the left superior semicircular canal was confirmed at surgery. (A) Coronal 0.5 mm-collimated CT scan through right temporal bone demonstrates an intact layer of bone (arrow) over the superior canal. (B) Multiplanar reformation in an oblique sagittal orientation through the left temporal bone demonstrates an area of dehiscence (arrow) over the left superior canal. (C) The sound-induced velocity measured within the perilymph or endolymph of a superior semicircular canal dehiscence demonstrated sound flow through the dehiscence. Measurements of the cochlear potential showed that superior semicircular canal dehiscence causes an increase in the bone-conducted sound.

Bone conduction thresholds on audiometry in patients with superior semicircular canal dehiscence can be less than 0 dB normal hearing level (NHL) because these individuals have better hearing via bone. An air-bone gap can, therefore, exist in these individuals even though their air conduction thresholds are in the normal range.125,130 Distinguishing an air-bone gap on audiometry due to superior semicircular canal dehiscence from an air-bone gap due to middle ear pathology is important in determining the appropriate treatment options.

Several reports have discussed the air-bone gaps in patients initially thought to have otosclerosis but who were subsequently found to have superior semicircular canal dehiscence.124,130,134 Air conduction thresholds did not improve in these patients following stapes replacement
the tympanic membrane. The pattern of changes in velocity and angle on laser-Doppler vibrometry in these patients is similar to that noted in ears with ossicular interruption.133

Further studies will be required to determine why some patients with superior semicircular canal dehiscence have exclusively vestibular abnormalities, some exclusively auditory effects, and others both vestibular and auditory manifestations. Factors that may contribute to differences in the auditory and/or vestibular manifestations of superior semicircular canal dehiscence include whether or not the cochlear aqueduct is patent and the relative compliance of the round window membrane. One patient in a recent clinical series was noted to have exclusively auditory manifestations at the time superior semicircular canal dehiscence was identified but later developed vestibular symptoms and signs.126

Vestibular Evoked Myogenic Potentials Responses

Patients with superior semicircular canal dehiscence syndrome have a lowered threshold for eliciting a VEMP response in the ear(s) affected by the disorder.131,136,137 The VEMP response can also have a larger than normal amplitude in superior semicircular canal dehiscence. The mechanism responsible for these abnormalities in the VEMP response in patients with superior canal dehiscence is most likely related to the “third mobile window” created by the dehiscence. The dehiscence creates a low impedance pathway that increases the sensitivity of vestibular receptors to sound and pressure stimuli.

Temporal Bone Computed Tomography Scans in the Diagnosis of Superior Semicircular Canal Dehiscence

High resolution temporal bone CT scans have been used to identify dehiscence of bone overlying the superior canal (Figure 8). The parameters used for these CT scans are important for maximizing the specificity of the scans. Conventional noncontrast enhanced temporal bone CT scans are performed with 1.0 mm collimation, and images are displayed in the axial and coronal planes. These scans have a relatively low specificity (high number of false positives) in the identification of superior semicircular canal dehiscence because of the effects of partial volume averaging. The specificity and positive predictive value of these scans are improved when 0.5 mm collimated helical CT scans are performed with reformation of the images in the plane of the superior canal.138 Even with these improved CT methods, imaging alone should never be used to make the diagnosis of superior semicircular canal dehiscence. Instead, the diagnosis should be based upon the findings on CT imaging in conjunction with the physiological tests, characteristic symptoms, and findings on clinical examination.

CT studies have shown that the thickness of bone overlying the intact superior semicircular canal in a patient with unilateral dehiscence is significantly less than that found in individuals without superior semicircular canal dehiscence.139 This finding and observations from a review of 1,000 histologically processed temporal bones sectioned in a plane perpendicular to the petrous ridge suggest an underlying developmental or congenital abnormality that leads to the dehiscence.140 The onset of symptoms and signs associated with this syndrome has typically occurred during adulthood. Patients in whom the normal thickness of bone fails to develop may then manifest the syndrome when the abnormally thin layer of bone is disrupted by trauma or is eroded over time as a consequence of the pressure from the overlying temporal lobe.

Surgical Repair of Superior Semicircular Canal Dehiscence

Many patients with superior semicircular canal dehiscence are not debilitated by the disorder and are able to avoid the stimuli that elicit the symptoms and signs. These patients may not need any specific treatment for the disorder. In other patients, symptoms such as sound- or pressure-induced vertigo, pulsatile oscillopsia, and chronic disequilibrium may be disabling. Surgical repair of superior semicircular canal dehiscence was initially described by Minor and colleagues.123 The success of surgical procedures to correct the dehiscence has been confirmed by others.141 The surgery is typically performed through the middle cranial fossa approach (Figure 9). The surgical procedure has involved either canal plugging with obliteration of the canal lumen with fascia and bone or canal resurfacing that involves covering the dehiscence with fascia and a bone graft but without plugging of the canal lumen. Recent comparisons of surgical outcomes in patients who underwent either canal plugging or resurfacing (without plugging of the canal lumen) revealed
that complete resolution of vestibular symptoms and signs is more commonly obtained with canal plugging than with resurfacing alone.\textsuperscript{132,142}

Primary middle fossa repair of superior semicircular canal dehiscence is associated with a low incidence of sensorineural hearing loss and, in some cases, can lead to normalization of conductive hearing loss.\textsuperscript{143} Revision middle fossa repair or previous stapes surgery may be associated with postoperative sensorineural hearing loss. A recent study of the function of individual semicircular canals before and after surgical correction of superior semicircular canal dehiscence has shown reduction in the function of the operated superior canal but the function of other ipsilateral semicircular canals is typically preserved.\textsuperscript{144}

Presbyacusis and Presbyastasis

John H. Mills, PhD
Cliff A. Megerian, MD
Paul R. Lambert, MD

Presbyacusis, defined generally as age-related hearing loss, and presbyastasis, defined generally as age-related balance disorders, are high prevalence problems today and will be even more prevalent in the immediate future. A according to the National Center for Health Statistics in the quarter century between 1976 and 2000, the number of persons below age 75 increased by 23%, the number between age 75 and 84 increased by 57%, and the number over age 84 increased by 91%. Indeed, by the year 2030, the elderly will comprise 32% of the population, an increase of 250%. A total of 60 to 80% of these older persons will have clinically significant hearing and balance problems. Because of the increasing number of older Americans, high prevalence problems such as age-related hearing and balance problems and other chronic disabling conditions (vision, arthritis) will place extensive, novel, and expensive demands on the health care system.1

TERMINOLOGY OF PRESBYACUSIS

There are several definitions of the term presbyacusis. Indeed, even the spelling is an issue, that is, presbyacusis versus presbycusis. Here we use “presbyacusis.” It is used loosely to describe a seemingly endless list of genetic, environmental, and disease states that can cause hearing loss in an older person. Often presbyacusis is used to refer to hearing loss purely caused by the natural process of aging. More often, hearing loss is called presbyacusis if the person is beyond the fifth decade, without consideration of disease, genetics, or other factors. In many studies, older persons are considered homogeneous and are grouped regardless of hearing levels or are grouped if their hearing loss exceeds an arbitrary criterion. Some of the confusion associated with the use of the term can be eliminated or reduced by the appropriate use of the terms presbyacusis, socioacusis, and nosoacusis.2 A generic definition of presbyacusis is age-related hearing loss that is the effect of aging in combination with lifelong exposures to nonoccupational noise, ototoxic agents, diet, drugs, exercise, and other miscellaneous factors. It is conceptually useful to view presbyacusis as a mixture of acquired auditory stresses, trauma, and otological diseases superimposed upon an intrinsic, genetically controlled, aging process. A more restrictive, precise definition of presbyacusis is hearing loss that increases as a function of chronologic age and is attributable to “aging” per se. This “purely aging” hearing loss probably has a genetic basis. It may be correlated with age-related deterioration or declines in other senses, especially balance, vision, and touch.

Socioacusis is defined as the hearing loss produced by exposure to nonoccupational noise in combination with lifestyle factors such as diet and exercise. Nosoacusis is the hearing loss attributable to diseases with ototoxic effects.2 Thus, the hearing loss assessed in a person into the fifth decade and beyond is the combined effects of aging, nosoacusis, socioacusis, and possibly, for many persons, exposure to occupational noise. Oftentimes it is important for medical and legal reasons to differentiate presbyacusis from socioacusis, nosoacusis, and occupational hearing loss.

Some laboratory (with animals) and field studies suggest that hearing losses caused by exposure to noise are additive (in decibels) with the hearing loss attributed to presbyacusis (in the narrow sense of the word). A small sensorineural hearing loss (SNHL) of 25 dB at age 25, for example, seemingly has little social or medical relevance; however, by age 70, a hearing loss of 25 dB caused almost entirely by the aging process is added to the existing SNHL. The result is a moderate-to-severe SNHL of 50 dB. In other words, a seemingly minor hearing loss at a young age becomes a severe loss when the effects of presbyacusis become evident.

Rules for combining hearing losses attributable to presbyacusis, nosoacusis, and socioacusis are not always straightforward. In the medicolegal assessment of hearing loss, it is assumed that presbyacusis effects (aging plus socioacusis plus nosoacusis) add in decibels to the hearing loss produced by noise. As stated above, this approach is supported by some laboratory and field data for groups of subjects under a limited set of conditions; however, for individual subjects and for complicated noise exposures, there are few data available. As a consequence, the procedures for the allocation of hearing loss into different components, as required by many medicolegal questions, are controversial.3

TERMINOLOGY OF PRESBYASTASIS

The vestibular system, like the auditory system, undergoes a progressive decline over the lifetime of an individual. However, there exists a number of important distinctions between these 2 age-related disorders that renders the description, characterization and measurement of age-related vestibular disorders much more difficult than age-related hearing loss. The term presbyacusis is a well-accepted term used daily among members of the medical community, unlike the analogous term “presbyastasis” which is used to characterize disequilibrium of aging. This is likely due in part to the difficulty in accurately measuring the latter condition. Hearing loss of age or any etiology can be accurately measured with audiometric testing not only in magnitude, but also qualitatively along frequency ranges. For example, one can be reasonably sure that a complaint of hearing loss with audiometric evidence of a high frequency hearing loss harbors a deficiency at the level of the basilar turn of the cochlea and the magnitude of this loss can be measured in decibels. Conversely, the complaint of “dizziness” or “vertigo” can be the result of a myriad of abnormalities that may or may not even involve the vestibular system. Even after a detailed history has been taken and the patient’s complaints point to a vestibular issue, it is often difficult to arrive at the conclusion that 1 particular portion of the vestibular system gives rise to the symptomatology. This is not necessarily the case in well-demarcated conditions such as benign paroxysmal positional vertigo (BPPV) or vestibular neuritis in a young healthy patient, but more so in the elderly patient presenting to the clinician with complaints of chronic imbalance or “constant vertigo.” This is due to the fact that for the most part, normal hearing requires the proper function of the cochlear end-organ whereas proper balance and stable gait necessitate a choreographed interplay between not only the vestibular end organs, and also the visual, proprioceptive, musculoskeletal, and central nervous systems (CNSs). Thus most complaints of imbalance associated with aging are in reality a “multi-system decay” involving the systems previously mentioned, but can even include the cardiac and endocrine systems when issues related to orthostatic hypotension confound the clinical picture.
Terminology is also an issue that remains a challenge to accurate diagnosis and treatment. Many patients and referring physicians will report “dizziness” regardless of whether the patient harbors true rotatory vertigo or postural hypotension (lightheadedness). Also contributing to the paucity of information that accurately describes patterns of age-related vestibular loss with clinical correlation are the challenges associated with quantifying functional deficits. Electronystagmography can indirectly measure the activity of only 1 (lateral semicircular canal ampulla) of 5 vestibular neuroepithelial organs, whereas audiometry measures dynamic range of all useful auditory function. A number of newer tests have emerged which allow physicians to begin collecting and quantifying additional vestibular functional parameters including dynamic platform posturography, rotatory chair testing, videonystagmography (VNG), and vestibular evoked myogenic potentials (VEMP). In time these testing modalities will likely lead to a better understanding of the types and patterns of vestibular decline in the aging population and its relationship to presbyastasis overall. These will only yield clinical dividends, however, when a more thorough understanding emerges regarding the intricate interplay between the vestibular system and the rest of the body. The majority of this chapter will focus on the evidence that directly pertains to specific, measurable vestibular pathology that plays an integral role in presbyastasis.

**EPIDEMIOLOGY OF PRESBYACUSIS**

Over the past quarter century, there has been a significant epidemiologic effort to describe hearing levels as a function of chronologic age. Two sets of data have survived extensive scrutiny and are now part of an international standard, International Standards Organization (ISO) 1999, “Acoustics: Determination of Occupational Noise Exposure and Estimation of Noise-Induced Hearing Impairment.” Figure 1A shows age-related permanent threshold shifts at audiometric frequencies for males and females. These data are referred to as Database A in the ISO 1999 standard and are considered to represent highly screened subjects. That is, the data in Figure 1A represent “pure aging” effects as well as socioacusis. Most of the hearing loss attributable to occupational hearing loss has been eliminated, although a small nosoacusic effect may be present. Figure 1B gives epidemiologic data, referred to as Database B in the ISO 1999 standard, which are considered to reflect “pure aging” effects, socioacusis, some nosoacusis, and some effects attributable to occupational hearing loss. As shown in Figure 1, hearing loss in the higher frequencies is measurable by age 30; it increases systematically to age 60 (and beyond), is largest at 4 and 6 kHz, and is much larger in males than in females. There are also significant differences between Figure 1A (Database A), and Figure 1B (Database B), presumably owing to differences in subject selection. Small effects caused by occupational noise and nosoacusis were eliminated in Database A. Significant debate exists currently about the appropriateness and validity of Database A and B, particularly in a medicolegal context involving the assessment of occupational noise-induced hearing loss.

Data from Figure 1A and B, have been replotted in Figure 2 to show the average hearing loss at 0.5, 1, 2, and 3 kHz as a function of chronologic age. The mean hearing loss at these particular audiometric test frequencies is especially meaningful because this combination of test frequencies comprises those used in the computation of hearing handicap as recommended by the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS). As Figure 2 shows, hearing loss increases systematically from age 20 through age 75. There are at least 2 remarkable features to Figure 2. One is that the largest difference between the worst case (males, Database B) and best case (females, Database A) is about 5 dB. One could suggest, perhaps strongly, that much of the ongoing debate about Database A and B is “much ado about nothing,” that is, 5 dB. This line of thinking is supported by the fact that, even at age 75, the hearing loss is only about 20 dB. According to the AAO 1979 definitions of hearing handicap, the average hearing loss at 0.5, 1, 2, and 3 kHz must exceed 25 dB to be considered a hearing handicap. In other words, according to the data of Figure 2 and the AAO-HNS 1979 definition of hearing handicap, substantially less than 50% of the population, male or female, have a hearing handicap even at age 75.

Other less selective epidemiologic data suggest that the prevalence of hearing handicap among older persons is substantially higher than that indicated by the epidemiologic data used in the ISO 1999 standard. Using 1,662 subjects from the famous Framingham study of cardiovascular
disease, Gates and colleagues\(^4\) reported that 55% met or exceeded the AAO 1979 medicolegal definition of hearing handicap. The difference between the results of Gates and colleagues and those of ISO 1999 reflect sampling differences and the inclusion of subjects older than age 75 in the Gates and colleagues sample.

In addition to an audiologic assessment, hearing handicap can be assessed more subjectively using questionnaires such as the Hearing Handicap Inventory for the Elderly.\(^5\) The correspondence between objective, audiologic measures of hearing handicap and subjective measures from self-reports and questionnaires suggests that the AAO-HNS measure of handicap tends to overestimate handicap for older persons with severe hearing losses. Of course, there are many reasons for discrepancies between subjective and audiologic estimates of hearing handicap. One general rule emerges from questionnaires and epidemiologic studies of hearing handicap in older persons, namely, that the pure-tone average (PTA) of 0.5, 1, 2, and 3 kHz must exceed about 30 dB before most older persons consider themselves to have a hearing problem. Thus, there are indeed millions of older hearing-handicapped persons in the United States.

Although much of the discussion has centered on the audiometric frequencies from 0.5 to 3 kHz, 1 of the more dramatic features of age-related hearing loss is the decline of auditory sensitivity at higher frequencies.\(^6,7\) Figure 3A shows increasing hearing loss from age 20 to 29 to age 50 to 59 for test frequencies at and above 8 kHz. By age 50 to 59, the hearing loss at 16 kHz is greater than 60 dB. Figure 3B shows longitudinal threshold changes (the same group of observers) over the age range of 70 to 81 years, including thresholds for test frequencies up to 8 kHz. Hearing levels at 4 and 8 kHz exceed 50 dB by age 70 and at 8 kHz exceed 70 dB by age 79. Hearing loss at frequencies above 8 kHz is even more pronounced and is not predictable by hearing levels in the 1 to 4 kHz range.\(^8\) Clearly, there is a dramatic age-related decline in auditory sensitivity at high frequencies. It appears that hearing loss starts in the second decade (or earlier) in the frequency range between 16 and 20 kHz, proceeds systematically in magnitude in the 16 kHz region, and spreads systematically downward in the frequency domain. By the eighth decade, the hearing loss is moderate to severe, even at 1 and 2 kHz.

The interpretation of epidemiologic data that show a loss of high frequency sensitivity at 16 to 20 kHz, when 10- and 19-year-olds are compared with 20- to 29-year-olds, is not straightforward. One point of view is that these age-related changes in hearing thresholds, as well as systematic declines in the number of outer hair cells starting at birth and continuing throughout the lifetime of the individual,\(^9\) are genetically determined, age-dependent events. That is, these age-related events are totally endogenous in origin. They are independent of exogenous

**Figure 3**

(A) Hearing loss at high frequencies. (A) Hearing levels above 8 kHz over the age range 20 to 59 years. (B) Hearing levels from 0.25 to 8 kHz covering the age range 70 to 81 years, measured longitudinally. (A adapted from references 6 and 7.)

**Epidemiology of Presbyastasis**

In contrast to age-related hearing loss, there are no international standards which quantitatively describe age-related vestibular disorders. The relevant data come mostly from clinical studies. In 1953, Droller and Pemberton noted that approximately 50% of otherwise self-sufficient English subjects in their middle to late 60s experience a balance problem.\(^14\) Similarly, another study showed that 50% of patients in a geriatric clinic admitted to dizziness, however on closer questioning, more than 90% noted that their symptoms were “postural” and were most problematic with changes in head or body position and were devoid of the sensation of rotation. True rotatory vertigo was present in only one-third of the group.\(^15\) As patients age further, balance-related problems become more pervasive. In a study conducted among patients in an outpatient medical clinic, “dizziness” was the most common presenting complaint in patients 75 years of age or older and is a central issue related to the occurrence of falls and hip fractures.\(^16\) Although sometimes, specific causes of dizziness are found (such as BPPV) most patients are found to have multifactorial issues otherwise known as presbyastasis (disequilibrium of aging) or multisystem balance decline. Belal and Giorgi reviewed the clinical findings of 740 patients at the House Ear Institute presenting with a complaint of dizziness and noted that nearly 80% did not have a specific vestibular diagnosis and hence classified them as having presbyastasis.\(^17\) The fact that multifactorial balance deficits are clearly known to affect the aging population coupled with the fact that the aging population is expanding are central reasons why falls are a major factor in fatal and nonfatal injuries for persons 65 years of age and older.\(^18,19\)

**Laboratory Studies:**

**Presbyacusis in Humans and Animals**

In the discussion which follows, the focus will largely be on the auditory periphery with only minor consideration given to the auditory CNS. Of the many investigations of presbyacusis, perhaps the most quoted and most extensive source of histopathologic data are the temporal bone studies of Schuknecht and colleagues.\(^20\) From
a number of studies of human temporal bones, they have identified 4 types or categories of presbyacusis: (1) sensory, characterized by atrophy and degeneration of the sensory and supporting cells; (2) neural, typified by loss of neurons in the cochlea and CNS; (3) metabolic, characterized by atrophy of the lateral wall of the cochlea, especially the stria vascularis; and (4) mechanical, where the inner ear changes its properties with a resulting inner ear conductive hearing loss. Each of these categories was hypothesized to have a characteristic audiometric configuration, that is, sloping, flat, and therefore to be audiometrically identifiable. In subsequent studies, considerable difficulty was encountered in correlating the audiometric configuration with histopathologic observations and in differentiating 1 type of presbyacusis from another on the basis of the audiometric configuration. The problem is that the audiometric configurations of older persons do not form clearly defined categories, and histopathologic changes at the level of light and electron microscopy are almost always observed at multiple sites in a given aging ear.

In 1993, Schuknecht and Gacek revised the traditional categories of presbyacusis described above. The revision was based on hundreds of observations of human temporal bones and is summarized: (1) Sensory cell losses are the least important type of loss in the aged; (2) neuronal losses are constant and predictable expressions of aging; (3) atrophy of the stria vascularis is the predominant lesion of the aging ear; (4) no anatomical correlation for a gradual descending hearing loss reflect a cochlear conductive loss; and (5) 25% cannot be classified using light microscopy.

This conclusion by Schuknecht and Gacek is important for at least 2 reasons. One is that the significance of sensory cell losses is deemphasized in presbyacusis. The second is that the dominance of strial degeneration is emphasized. These 2 points bring a consensus to human temporal bone results and those obtained from experimental animals. Perhaps the most dramatic feature of age-related hearing loss in laboratory animals is the variability between animals. For example, in a longitudinal study of aging gerbils, some animals, at the one extreme, had normal or nearly normal auditory sensitivity from 1 to 16 kHz, whereas at the other extreme, some animals did not respond to signals presented at levels of 80 dB SPL. Variability of this magnitude is remarkable given that chronologic age, environment (temperature, humidity, and air quality), acoustic history, and diet of the animals were virtually identical. These data and others involving different inbred strains of mice are consistent with human data showing a strong genetic role in age-related hearing loss.

In addition to a qualitative/quantitative correspondence between age-related hearing loss measured in aging rodents and audiograms of 60-70-year-old humans, many of the histopathologic observations made on human temporal bones have been confirmed and extended on experimental animals. In aging rodents, there is usually a small loss of sensory (outer) hair cells in the most basal and the most apical regions of the cochlea. Nerve loss, as indicated by loss of spiral ganglion cells, is pronounced throughout the cochlea. The lateral wall of the cochlea, including the stria vascularis, usually shows degeneration originating in both the base and apex and extending to midcochlear regions as the animal ages; however, in some animals, there is a patchy loss of stria vascularis. Thus, in several species of animals, anatomic studies of cochlear material demonstrate at least 3 of the histopathologic conditions described in humans by Schuknecht and colleagues, namely, sensory, neural, and metabolic presbyacusis. In animals, all 3 types are usually present in each animal.

As with humans, the most prominent (dominant) type of presbyacusis in laboratory animals (with the exception of mice, C57) is the metabolic category. In addition to age-related, systematic degeneration of the stria vascularis starting in both the apex and base of the cochlea and proceeding to the midcochlear region, is a loss of the protein Na, K-adenosine triphosphatase (Na, K-ATPase). The stria vascularis and underlying spiral ligament have a prominent role in generating electrochemical gradients and regulating fluid and ion homeostasis in the cochlea. In accordance with its name, the stria is heavily vascularized and has an extremely high metabolic rate. Conceivably, alterations in stria microvasculature could compromise cochlear blood flow and ultimately lead to strial degeneration. Histopathologic studies on aging gerbil have provided strong evidence for vascular involvement in age-related hearing loss. Morphometric analyses of lateral wall preparations stained to contrast blood vessels (Figure 4) have revealed losses of strial capillary area in aged animals. The vascular pathology first presented as small focal lesions mainly in the apical and lower basal turns and progressed with age to encompass large regions at both ends of the cochlea. Remaining strial areas were highly correlated with normal microvasculature and with the endocochlear potential (EP, described below). Not surprisingly, areas of complete capillary loss invariably correlated with regions of strial atrophy. Subsequent ultrastructural analysis has revealed a significant thickening of the basement membrane, which is accompanied by an increase in the deposition of laminin and an abnormal accumulation of immunoglobulin, as shown histochemically. Thus, considerable support exists for the major involvement of stria microvasculature in age-related degeneration of the stria vascularis; however, the question of what constitutes the initial injury remains unanswered. Although it is tempting to speculate that atrophy of the stria vascularis occurs secondarily to vascular insufficiency resulting from capillary necrosis, the reverse could very well be true. While the sequence of events is not clear, substantial data indicate that age-related alterations in the lateral wall of the cochlea (stria vascularis and spiral ligament) affect the mechnoelectric transduction process, which is dependent upon the development and maintenance of transcellular potassium gradients and the 80 to 100 mV EP of scala media.

The 2 most prominent changes in the physiologic properties of the aging ear are reductions/losses of the EP and losses of auditory nerve function as indicated by increased thresholds of the compound action potential (CAP) of the auditory nerve. Slopes of input-output functions of the CAP in aging animals are decreased even when the loss of auditory thresholds is only 5 to 10 dB. In other words, as the signal...
intensity is increased, the amplitude of the CAP increases by a fraction of that observed in young animals with normal hearing or young animals with noise-induced or drug-induced hearing losses. These shallow input-output functions of the CAP are also reflected in shallow input-output functions of auditory brain-stem responses (ABRs). Thus, what appears to be abnormal function of the auditory brainstem in older animals possibly reflects only the abnormal output of the auditory nerve. The reduced amplitudes of action potentials observed in aging ears are probably reflective of asynchronous or poorly synchronized neural activity in the auditory nerve. The pathologic basis of asynchronous activity in the auditory nerve is unknown but probably involves the nature of the synapse between individual auditory nerve fibers and the attachment to the inner hair cell, primary degeneration of spiral ganglion cells, and reductions in the EP, which are described below.

The EP, that is, the 80 to 100 mV DC resting potential in the scala media of the cochlea, is often reduced significantly and proportionally to losses/regeneration of the stria vascularis. Reductions in EP produce elevations in auditory thresholds, about 1 dB reduction in threshold for every 1 mV reduction in EP in the base of the cochlea. In the apex thresholds declined only about 20 dB even for large reductions in EP. Most importantly, the audiometric configuration of threshold shifts produced by reductions of EP is strikingly similar to the audiometric configurations observed in aging animals and aging non-noise exposed humans (Figure 1). Thus, the correspondence between EP shifted thresholds in aged animals and in aged, nonnoised exposed humans suggests a common mechanism, namely a reduction in the EP. It is hypothesized that the EP produces the voltage or power to the cochlear amplifier which has a gain of 20 dB or so apically increasing to as much as 60 to 70 dB in the base of the cochlea. Thus, age-related hearing loss as shown by the audiogram can be explained almost entirely by age-related degeneration of the lateral wall with a resultant disruption in potassium recycling and a reduction in EP. Moreover, in aging experimental animals, hearing losses can be reduced/eliminated by introducing a DC voltage into scala media and raising a low EP, that is, 15 mV, to a value approaching 60 to 70 mV. Thresholds of the CAP can be improved by as much as 40 dB in aging animals and 60 dB in animals where the EP has been reduced by the application of furosemide. Efforts to develop a hearing aid based on current injection into scala media are in progress.

A significant difference between the physiology of the aging ear and the ear with noise-induced or drug-induced injury of the cochlea involves the nonlinear phenomenon of two-tone rate suppression, that is, activity of the auditory nerve elicited by 1 tone is suppressed or eliminated by the addition of a second tone of different frequency. In ears of quiet-reared aging animals, the mechanism of two-tone rate suppression appears to remain intact even for threshold shifts of 30 dB. In contrast, noise-and drug-exposed animals with minimal injury of the cochlea, and minimal threshold shifts, reduction or complete loss of two-tone rate suppression may be the first indicator of injury of the cochlea, usually outer hair cells. These data are an excellent indicator that the pathologic basis of age-related hearing loss is fundamentally different from the pathologic basis of most forms of noise-induced or drug-induced hearing loss.

Otoacoustic emissions, both transient evoked and distortion product, are nonlinear phenomena that are assumed to reflect the integrity of sensory cells, especially outer hair cells. Given this assumption, one would expect to find very high correlations between loss of outer hair cells and changes in otoacoustic emissions; however, inconsistent relations among distortion products, threshold measures, and sensory cell pathology have been reported from widely different types of experiments. Indeed, there are reports of normal emissions in the presence of missing outer hair cells as well as reduced emissions in the presence of a complete complement of outer hair cells. In the aging ear of experimental animals with a minimal, if any, loss of outer hair cells, distortion-product emissions are reduced somewhat in amplitude but are clearly present and robust. In aging human ears, transient emissions are present in about 80% of persons with a PTA hearing level better than 10 dB, present in about 50% with PTA of 11 to 26 dB, and absent in about 80% with a PTA greater than 26 dB. Thus, the presence of a transient otoacoustic emission suggests excellent hearing levels for most persons, whereas its absence reveals very little. Indeed, the major application of otoacoustic emissions may be in hearing screening of infants.

A recent development is the association of mitochondrial deoxyribonucleic acid (mtDNA) deletions with aging in general and with SNHL and age-related hearing loss. Ueda and colleagues, using DNA specimens extracted from peripheral blood leukocytes, found a higher rate of mtDNA deletions in patients with SNHL than in controls. Seidman, in a rat study, tied mtDNA deletions to presbycusis and mtDNA deletions to reactive oxygen metabolites (ROMs). These are highly toxic molecules that can damage mitochondrial DNA, resulting in the production of specific mtDNA deletions. Thus, compounds that block or scavenge ROMs should attenuate age-related hearing loss. Rats were assigned to treatment groups including controls, caloric restriction, and treatment with several antioxidants, including vitamins E and C, and were allowed to age in a controlled environment. The calorie-restricted groups maintained the best hearing, the lowest quantity of mtDNA deletions in brain and ear tissues, and the least amount of outer hair cell loss. The antioxidant-treated subjects had better hearing than the controls and a slight trend for fewer mtDNA deletions. The controls had the poorest hearing, the most mtDNA deletions, and the most outer hair cell loss. These data suggest that nutritional and pharmacologic strategies may prove to be an effective treatment that would limit age-related increases in ROM production, reduce mtDNA deletions, and thus reduce age-related hearing loss. ROMs (or reactive oxygen species) and oxidative stress have also been implicated in noise-induced hearing loss, ototoxic hearing loss, and cumulative injury that presents as age-related hearing loss. It is speculated that there is a genetic impairment of antioxidant protections that leads to the production of both age-related and noise-induced hearing loss by placing the cochlea in a state of vulnerability. Although an age-related hearing loss gene has been identified, the murine A 4.3 the discovery of the molecular/genetic basis of presbycusis and SNHL in general are just beginning.

In summary, animal experiments conducted under strict conditions show age-related declines in auditory function that indicate a “pure” aging hearing loss. Most of the pathologic anatomy associated with this “pure” aging hearing loss is in the cochlea, where the dominant pathology is degeneration of the stria vascularis. In experimental animals, most of the hearing loss can be accounted for by anatomic, physiologic, and biochemical changes in the auditory periphery. Indeed, there is no need to include the auditory CNS in an explanation of age-related hearing loss, even when the criterion measure of age-related hearing loss is derived from potentials arising from the auditory brainstem.

Explanations of age-related changes in auditory brainstem potentials in terms of alterations in the auditory periphery run counter to the current dogma that there is a significant, perhaps dominant, component of presbycusis that involves degeneration of the auditory CNS. Indeed, there are significant, age-related changes in the auditory CNS involving subtle to gross changes in anatomy and neurochemistry. One prominent change is a reduction in γ-amino-butyric acid (GABA) affecting neural inhibition. Another is increases in the release of aspartate in the cochlear nucleus following cochlear injury and leads to increased excitatory neurotransmission. The role of the CNS in age-related hearing loss is almost surely substantial; however, the focus here is on the auditory periphery. Nearly all changes observed in auditory brainstem potentials can be explained by alterations in the auditory periphery.

PERCEPTION OF AUDITORY SIGNALS AND SPEECH

In addition to age-related declines in auditory sensitivity, there are age-related declines in differential sensitivity for intensity, frequency, and time. Until recently, these age-related declines in the basic properties of the ear and hearing were almost always measured in older persons with significant hearing losses. Thus, it was nearly impossible to separate the effects of a hearing loss from the effects of aging. Recently, however, both discrimination in intensity and discrimination in
frequency have been shown to decline with age only at low frequencies and independently of any hearing loss. These results are important because they are negative effects measured in the presence of normal hearing and may very well represent age-related declines in information processing capability. It remains unclear whether these age-related declines represent age-related effects of the auditory periphery or CNS.

The term “phonemic regression” was coined to describe a disproportionate difficulty in speech perception relative to the magnitude of hearing loss of older persons. Later, many studies of speech discrimination and other complex listening tasks showed results with older subjects that were difficult to explain solely on the basis of the audiogram alone. With the ready availability of many published articles showing degenerative changes in the auditory brainstem and cortex of older persons, there evolved a viewpoint that a significant component of age-related hearing loss is attributable to the decline of the auditory CNS. Of course, the auditory CNS is involved in age-related hearing loss; however, the extent of the involvement of the CNS in presbyacusis is currently receiving much debate.

Perhaps the largest qualitative/quantitative description of speech discrimination as a function of age and hearing loss is provided by Jerger from the clinical records of 2,162 patients. Figure 5 shows percent correct on phonetically balanced (PB) words as a function of chronologic age. The parameter on the figure is the PTA of 0.5, 1, and 2 kHz. Figure 5 shows that speech discrimination declines systematically as a function of chronologic age; however, the decline with age is dramatically dependent on hearing loss. That is, for subjects with very little hearing loss (less than 30 dB), the decline with age is measurable but small through age 70. On the other hand, for subjects with moderate-to-severe hearing losses, the decline with age is noteworthy, particularly for persons between the ages of 45 and 85 with hearing losses of 40 to 49 dB, 50 to 59 dB, and 60 to 69 dB. In other words, when hearing loss as indicated by the PTA is held constant, speech discrimination scores decreased between the ages of 50 and 80 for moderate (greater than 40 dB) to severe (60 dB) hearing losses. In contrast, age had very little effect as long as the PTA is less than about 30 to 39 dB. A remarkable and perhaps the most noteworthy feature of Figure 5 is that persons over the age range of 50 to 80 perform as well as 25 year olds as long as their average hearing loss at 0.5, 1, and 2 kHz is less than 35 dB.

Performance on tests of speech discrimination by older persons is shown (Figure 6) for PB words. 3 versions of the Speech Perception in Noise (SPIN) test, and synthetic sentence identification (SSI). Subjects in whom hearing levels were nearly identical (±3 dB) were placed into 3 age groups over the range from 55 to 84 years. Statistical analysis of the speech discrimination data showed that performance on all tests was not affected by age. That is, when hearing levels were equated, there were no age-related declines in performance on tests of speech discrimination in persons over the age range of 55 to 84 years.

Performance on tests of speech discrimination was overestimated. In other words, word recognition in adults 75 years and older decreased significantly and nonpredictably from audometric measures. Moreover, the decline in word recognition occurred at a constant, linear rate of 0.8% per year. It is important to note that these data are from well-trained older persons who have been participating in auditory listening experiments for up to 20 years. It is also the case that a significant history of noise exposure was not a factor as the results from noise exposed and nonnoise exposed were virtually identical.

In addition to the results observed for 75 year and older subjects described above, there are many age-related declines in auditory behavior that are not strongly associated with auditory thresholds. This is most evident using binaural (dichotic) listening tasks and right ear versus left ear performance under poor signal-to-noise conditions. In many of these binaural experiments using older subjects, age-related declines are observed that are clearly independent of peripheral hearing loss, and individual differences between subjects are sometimes dramatic.

**AUDITORY EVOKED POTENTIALS**

With the development of straightforward techniques to measure evoked potentials arising from the auditory nerve, brainstem, and auditory cortex, there has been significant progress in evaluating the aging auditory nervous system of human subjects. In regard to the ABRs, most studies show age-related declines in the amplitude of wave V, which should be interpreted to reflect peripheral hearing loss rather than changes in the brainstem. Even in older persons with excellent hearing levels, ABR waveforms are of “poor quality” and reduced amplitude, probably reflecting pathology of the cochlea and auditory nerve as well as a reduction in synchronized neural activity. For young subjects with normal and abnormal hearing, auditory thresholds measured behaviorally are about 10 dB better than auditory thresholds estimated from the ABR. For aging subjects, this behavioral/ABR disparity is 20 dB, reflecting the poor quality/low amplitude of the ABR. Other evoked potentials show inconsistent results. The P300 arising from the auditory cortex shows age-related declines, whereas the amplitude-modulated following response may remain unaffected by aging. In contrast, the frequency-modulated following response may be enhanced in older subjects, perhaps reflecting the
An important study by Engstrom and colleagues
in elderly monkeys and humans sheds a great
deal of light on the neuroepithelial consequences
of aging.53 Hair cell loss was found to be reduced
by as much as 40% in the epithelium of the cris-
tae and 20% on the maculae using transmission
electron microscopy. Type I hair cells were more
susceptible than Type II hair cells and as the for-
mer is more abundant at the top of cristae, it gives
the light-microscopic appearance of neuroepithe-
リアル thinning. Concurrent with the death of hair
cells are those of supporting cells which develop
fibrillotubular and vesicular structures before death.
Even surviving sensory and supporting cells
appear to have irregularities which appear as
abnormal intracellular laminated structures at
the level of the basement membrane. Other signs
of damage to sensory cells identified by this study
include intracellular vesicles and irregular patchy
changes in the synaptic membranes of type I cells
and their afferent calyces. The number of cell bodies
within the hair cell show the tendency for
accumulation of lipofuscin inclusions in sensory
cells and supporting cells, but also disarrange-
ment of cilia, increased fragility of cilia, and
the formation of giant cilia are noted consequences
of aging.54 Similarly, intraneuropil cysts have been
shown in the maculae and cristae of elderly subjects which appear either as pale blue
inclusions in near-normal sized cells or larger
eccentrically placed structures.55,56 Quantitative
studies have been recently more feasible using
differential interference contrast microscopy and
have allowed for unambiguous identification of
hair cells in the vestibular system. Merchant and
colleagues performed serial section counting of
hair cells in normal temporal bones that ranged in
age from birth to 100 years of age.57 At birth the
ratio of type I to type II hair cells in the cristae
was 2.4:1 and in the maculae it was 1:3:1. They
found a highly significant age-related decline in
cellular bodies; however, they showed that the
cristae lost type I cells with advancing age at a
significantly greater rate than the maculae.

Otoconia
Otoconia are normally cylindrical calcite rods
with a tripartite flat endplate at each pole and vary
regularly in size. Ross and colleagues showed
that aging is associated with a decrease in the
number of otoconia, especially in the saccule.58
They were shown to degenerate in a posteroan-
terior direction across the macula and take on a
fibrous, hollowed-out appearance. During the
sixth decade of life, the furrows become deep-
ened with a loss of the original surface and pits of
degeneration appear toward the middle of the rod.
As normal crystalline substance is reabsorbed,
some rods are cleaved in half.59 A recent animal
study in aged rats revealed similar findings with
pitted, fissured, and broken otoconia with preser-
vation of terminal facets.60 The clinical relevance
of these observations may be reflected in data
that shows BPPV increases in incidence expo-
nentially as a function of age.61 There does not
appear to be any evidence, however, that standard
repositioning maneuvers have any less efficacy in
this age group.62

Vestibular Ganglia
An integral part of the vestibular system are
the bipolar neurons that relay information from
the sensory neuroepithelium to the vestibular
nerve and the central vestibular nuclei and evi-
dence exists that this anatomical component of
the system, like all others, appears to undergo
deterioration which contributes to the overall
problem of disequilibrium. Park and colleagues
utilized assumption free stereotone techniques in
the study of 20 serially sectioned archival human
temporal bones specimens with no his-
tory of vestibular pathology from donors aged
2 to 88 years.63 They were able to show that in
youth, the human has a roughly constant number
of cells at about 28,952. However, from ages 30
to 60 a decline begins such that patients older
than 60 level off at approximately 23,349 cells
which remains stable and demonstrates another
anatomical basis for age-related imbalance.62 A
similar study confirmed that total ganglion cell
count declines as a function of age at an aver-
age rate of 57 cells per year with a decline that
appears to be significantly greater in the superior
division compared to the inferior division.63

Primary Afferent Axons and Dendrites
Bergstrom studied freshly dissected human ves-
tibular nerves from humans of varying ages and
noted a reduction in fiber density beginning at age
40. Myelinated thick fibers from the cristae dem-
strated the greatest loss.64 This correlated well
with the 40% hair cell loss noted in the cristae
by Engstrom and colleagues53 and another study
by Richter which noted a dramatic reduction in
the number of neuronal cell bodies in Scarpa
ganglia noted to occur after age 50.65 A myloid

---

**Figure 7** (A) Mean observed word-
recognition scores (filled) and mean
predicted scores (open) obtained
during 13 consecutive laboratory
visits plotted against mean subject
age during those visits. Observed
scores appear to be declining with age. Scores predicted by an
audibility-based model, the articu-
lation index, are also declining, as
predicted from changes in speech
audibility over time, independent of
age. (B) Mean differences between
observed and predicted scores. Scores at
younger ages are better than predicted and scores at older
ages, for example, >75 years, are
worse than predicted. The observed-
predicted difference function (solid
line) has a negative slope, so that as
subjects age, their observed scores
deviate increasingly from predicted
scores at a rate of 0.8% per year.
The linear fit of these data suggests
that this decline does not accelerate
with age. Thus, word recognition
in quiet declines significantly with
age more than would be predicted by
declines in pure-tone thresholds.
(A adapted from reference 50.)
deposits, associated with degeneration of nerve cells are insoluble deposits that stain with amyloid and are associated with nerve degeneration. Fuji and colleagues sectioned the vestibulocochlear nerve at various points and found that in the aging human, amyloid bodies are concentrated in the limiting glial portion of the nerve and become increasingly larger in the sixth, seventh, and eighth decades of life.66

Central Nervous System

In an attempt to correlate central neurologic pathology with presbyastasis, Lopez and colleagues utilized computer-based microscopy to determine neuronal counts, nuclear volume, and neuronal density in postmortem specimens of the human vestibular nuclear complex (VNC) as a function of age.67 Using 15 subjects aged 40 to 90 years of age the 4 vestibular nuclei were studied and a linear model revealed approximately a 3% neuronal loss per decade. Interestingly, neuronal loss as a percentage of the total number of neurons was greatest in the superior vestibular nucleus and least in the medial vestibular nucleus. There was a corresponding increase in giant neurons, which were felt to be due an accumulation of lipofuscin deposits in the cell somata. This was an important finding as studies of other brainstem nuclei had failed to show an age-related neuronal loss.67 Whitman and colleagues compared postmortem brain specimens from 6 patients with disequilibrium of aging and 4 control subjects. In comparison with controls, the study group had prominent atrophy and ventriculomegaly, but lacked any difference in other gross pathology such as infarcts or areas of necrosis.68 Histologically the frontal lobes had markedly reactive astrocytes and increased arteriolar wall thickness (sclerosis index) in those with presbyastasis. This study furthered interest into the concept that atherosclerosis of aging and 4 control subjects. In comparison to the two groups.68 Those predisposed to falls had a significantly higher frequency of postheadshake nystagmus and a corresponding significant increase in postural sway and hence problems with balance and stability.66 This may be due to earlier research that shows that unilateral vestibular hypofunction has deleterious consequences to postural sway due to dysregulation of the vestibulospinal reflex (VSR).69 The authors postulate that vestibular asymmetry, while easily compensated for by central mechanisms in the young and healthy are more disturbing to balance and gait in those with decreased ability for central compensation such as age-related disorders of the proprioceptive and visual systems. Indeed this was confirmed in a recent study of "multisensory decay" in 40 elderly patients with imbalance in which 85% were found to have marked impairment of the somatosensory system and 40% had visual problems.70 The vestibulocollie reflex (VCR) has also shown deterioration in aged patients. Welgampola and Colebatch measured the VCR in 70 healthy adults aged 25 to 85 using 100 dB clicks, forehead taps, and galvanic stimulation. Beginning at age 60, average click evoked response amplitudes decrease with age at 25 to 30% per decade with the most marked effects noted using click and galvanic stimulation, a likely correlate of known hair cell decline associated with aging.68

Influence of Age on Vestibular Function Testing

The accumulation of anatomical deficits, which clearly characterize degeneration of the peripheral and central vestibular system and the associated CNS have a myriad of effects on balance and function. Some of these are measurable with objective testing, while other aspects of this decline are not. Electronystagmography (ENG) and videonystagmography (VNG) are the most commonly used tests of vestibular function and visual tracking. Some reports indicate age-related changes beginning after age 50 in saccadic, pursuit, and optokinetic studies to the point at which saccade latency and velocity thresholds deviate by 10 to 20 ms and 10° to 20° per second, respectively, for each decade over 50.69-71 The vestibulo-ocular response (VOR) was carefully measured in a larger study comparing aging effects on auditory and vestibular responses. The study revealed a significant amplitude-dependent decrease in gain and increase in phase lead of the VOR and a significant decrease in the gain of vestibular responses at low frequency sinusoidal stimulation over a 5-year longitudinal study.72 A nother study of the VOR using head autorotation testing revealed abnormalities in 86% of elderly volunteers.73 However, caloric response as a function of age has been harder to characterize. In a study of caloric tests in 102 healthy subjects between ages 11 and 70, M ulch and Petermann showed that although the absolute values of nystagmus parameters are dependent upon age, there is no decrease in the intensity of the reaction with age.74 A more recent study has confirmed and extended these findings and showed that the slow phase velocity of caloric responses does not decline with age and does not parallel the age-related physiological decline of the vestibular system as a whole.75 However, asymmetric vestibular decline may play a role in postural control. In a study of elderly fall-related hip fracture patients compared to age-matched controls, postheadshake nystagmus (indicative of vestibular asymmetry) measured by VNG was compared between the two groups.76 Those predisposed to falls had a significantly higher frequency of postheadshake nystagmus and a corresponding significant increase in postural sway and hence problems with balance and stability.76 This may be due to earlier research that shows that unilateral vestibular hypofunction has deleterious consequences to postural sway due to dysregulation of the vestibulospinal reflex (VSR).77 The authors postulate that vestibular asymmetry, while easily compensated for by central mechanisms in the young and healthy are more disturbing to balance and gait in those with decreased ability for central compensation such as age-related disorders of the proprioceptive and visual systems. Indeed this was confirmed in a recent study of "multisensory decay" in 40 elderly patients with imbalance in which 85% were found to have marked impairment of the somatosensory system and 40% had visual problems.70 The vestibulocollie reflex (VCR) has also shown deterioration in aged patients. Welgampola and Colebatch measured the VCR in 70 healthy adults aged 25 to 85 using 100 dB clicks, forehead taps, and galvanic stimulation. Beginning at age 60, average click evoked response amplitudes decrease with age at 25 to 30% per decade with the most marked effects noted using click and galvanic stimulation, a likely correlate of known hair cell decline associated with aging.68

Presbyacusis: Alleviation/Treatment

Assuming that any problems with the external and middle ear are diagnosed and treated, that other medical issues are under control, and a diagnosis of presbyacusis in the general sense, the best treatment currently available is a hearing aid. The successful use of hearing aids by older persons and the hearing impaired in general is mixed. There is a literature of substantial magnitude that reports on the successful or unsuccessful use of hearing aids by the elderly. Many older persons who would clearly benefit from an aid do not use one. The reasons for not using an aid or being a dissatisfied user include cost, stigma of a
hearing handicap and of being old, difficulty in manipulating controls, and too little benefit, particularly in the presence of background noise.

In a large group of older persons (N = 516) who are participants in a longitudinal study of age-related hearing loss, 53% (n = 272) are candidates for a hearing aid. CANDIDATE by very conservative audiologic criteria is a speech reception threshold greater than 30 dB in the better ear or hearing level greater than 40 dB at 3 and 4 kHz in the better ear. Using these criteria, nearly half (n = 131 of 272) of those who are considered to be excellent candidates have never tried a hearing aid, and only 38% (n = 104 of 272) of candidates were successful hearing aid users. Thirty-seven persons (~10%), for one or several reasons, were dissatisfied hearing aid users. Of those who did not meet the conservative criteria for a hearing aid (n = 244), our clinical judgment suggested that at least 40 to 50% of these persons would benefit from an aid. Clearly, the older persons in our longitudinal study were uninformed about hearing aids, poorly served, or underserved. Our experience is confirmed. Indeed, it is our opinion that as a result of excellent advances in hearing aid technology in combination with improved fitting techniques, nearly every older hearing-impaired person should be considered a potential candidate for a hearing aid.

In the case of bilateral severe hearing loss not helped significantly by hearing aids, cochlear implants are indicated regardless of age. Current cochlear implant technology, the majority of patients experience excellent speech understanding in quiet. Speech discrimination in a noisy background as well as the appreciation of music remains problematic. An area of active interest to address these current limitations involves electroacoustic stimulation, that is, the combination of a shorter electrode (20 mm or less) with a hearing aid in the same ear. This paradigm is considered for individuals with residual low frequency hearing (rehabilitated with acoustical speech processing) and severe high frequency SNHL (rehabilitated with the electrical speech processing). The ability to preserve low frequency hearing after short electrode insertion and enhanced speech recognition in noise have been demonstrated in a small group of patients.

PRESBYASTASIS: ALLEVIATION/TREATMENT

The first objective when faced with an elderly patient who describes disequilibrium issues with or without vertigo is to assess the immediate risk of danger to the patient by virtue of a fall. Simple neurootologic, Romberg, and gait testing can give a reliable picture as to whether immediate referral to rehabilitation is needed for assistive gait strategies such as the use of a cane, walker, or wheelchair. Once this has been determined, a detailed historic review is needed to evaluate the presence of neurologic or other medical problems that may be affecting coordination, muscle strength, and balance. Cardiovascular issues are reviewed including blood pressure stability during orthostatic challenge. The potential for advanced cerebrovascular disease or transient ischemic attacks (TIAs) is investigated by review of imaging and carotid duplex studies. Vision status should then be reviewed along with a close review of medications, which the patient may be taking. An effort to remove unnecessary vestibular suppressants will often yield immediate benefits to the patient. Orthopedic issues, such as knee, hip, or spine arthritis should be accounted for as these contribute to a decline in proprioceptive function and muscle strength. Specific questions directed at determining the presence of vertigo should ensue in an effort to rule out more acute treatable issues such as BPPV, Meniere disease, and perilymphatic fistula. This is coupled with an oto-neurologic examination that includes positional testing and an audiometric evaluation. Once this is complete, specific vestibular testing can be obtained including VNG and posturography. Typically at this time, in the absence of a particular system issue that warrants immediate intervention, the presbyastasis patient is best served by vestibular rehabilitation therapy. Referral to a physical therapy group that has experience with specific protocols for balance retraining in the elderly patient will likely reduce the risk of falls and improve mobility, confidence, and quality of life.

REFERENCES

The concept of vestibular rehabilitation, that is, providing exercises for patients with dizziness and balance disorders, was first documented in the literature in the 1940s when Cooksey and Cawthorne worked together to develop an exercise program that was useful for patients with dizziness.\(^1\)\(^2\) They suggested that the exercises were very effective in ameliorating dizziness symptoms and employed physical and mental exercise plus occupational therapy.\(^1\)\(^2\) Their exercises included many different forms of eye–head coordination movements while incorporating balance activities. Approximately 40 years later, Norre and de Weerdt suggested that exercise, in the form of repeating the dizziness provoking movements (habituation training) could decrease symptoms.\(^3\) Shepard and Telian\(^4\) and Horak\(^5\) in the early 1990s provided evidence that vestibular rehabilitation was effective in patients with vestibular disorders. More recently, evidence suggests that various diagnostic groups may have different outcomes.\(^6\)\(^9\)

Vestibular rehabilitation is a generic term that is used by physical therapists and occupational therapists to describe exercises that are provided to enhance balance function and reduce dizziness. Physical therapists focus on exercises to enhance balance, increase strength and range of motion, and improve coordination and walking. Occupational therapists focus on activities of daily living, instrumental activities of daily living, and driving skills.

Most of the therapists who treat patients with balance and vestibular disorders have prior experience working with patients with nonvestibular neurologic disorders. An interest in learning and a desire to treat people with vestibular dysfunction is a necessity. The practitioners who perform vestibular rehabilitation should have an understanding of the underlying anatomy and physiology of the inner ear and brain. Patients with vestibular disorders require more time than typical patients seen in therapy because of their comorbid conditions. They are also more likely to fall than those in the general community, so heightened vigilance is required while they perform their exercise programs, often requiring close supervision for safety.

Generally, it is thought that patients adapt, habituate or use sensory substitution to recover from a vestibular insult. Fatigue, bed rest, fear, and anxiety have all been implicated in slow recovery after a vestibular insult, most likely related to decreased activity of the patient. Movement appears to be a key factor in recovery in both primates and humans. Vestibulo-ocular reflex (VOR) adaptation has been hypothesized to be potentiated by either retinal slip or a visual position error stimulus.\(^10\) Thus, many of the exercises employed by therapists (Table 1) attempt to stimulate retinal slip, to promote adaptation of the VOR. Since VOR efficiency decreases with unilateral hypofunction, a goal of vestibular rehabilitation is to increase the VOR gain, that is, the ratio of eye velocity to head velocity, to near unity. With the VOR gain closer to 1, vision improves and usually patients will report less dizziness. Figure 1A through C illustrates diagrammatically the process of recovering symmetric vestibulo-ocular signals following a unilateral peripheral vestibular injury.

Although there is no convincing evidence in the literature that habituation, through the use of repeated movements decreases dizziness, its use continues today because it seems to provide relief. For habituation to be successful, it appears to be very important to have patients focus on visual targets as they perform the exercises. Also patients should be exposed to more difficult visual conditions as they improve.

Sensory substitution is used for patients who either have minimal or no remaining vestibular function. The goal of sensory substitution is for the patient to use remaining senses, that is, somatosensory and visual signals, to help orient the body in space. These strategies are particularly helpful in patients with bilateral vestibular hypofunction and in those who have multisensory disequilibrium.

### Vestibular Disorders

#### Peripheral Vestibular Disorders

**Unilateral Vestibular Loss.** Patients with peripheral vestibular dysfunction, with the exclusion of those with bilateral vestibular loss, generally have better outcomes than those who have central vestibular dysfunction. Patients with benign paroxysmal positional vertigo (BPPV) have the best prognosis.

Unilateral peripheral loss is amenable to treatment with vestibular rehabilitation. Patients with unilateral loss who have minimal symptoms are usually considered to have compensated “well.” However, there is evidence that the compensation is not complete.\(^11\) Bowman reported that all patients with unilateral vestibular loss continue to have remaining complaints.\(^11\) Even those with minimal symptoms are not symptom free and continue to have permanent deficits in balance function.\(^12\)
Patients with unilateral vestibular loss who remain symptomatic note particular difficulty with strenuous activities, bright lights, noise, confined spaces, open spaces, and busy environments.11 Also, such patients are often concerned that they might be injured as the result of a fall. Patients with obsessive-compulsive tendencies also poorly compensate from vestibular insults.11

Even though it has been previously suggested that patients with peripheral vestibular disorders make a full recovery, there is emerging evidence that this is not true. Vestibular neuritis, labyrinthitis, and vestibular ablative procedures all appear to result in some functional deficits, even after vestibular rehabilitation.14 Patients should be advised that they may continue to have some functional limitations even after “successful” vestibular rehabilitation.

Bilateral Vestibular Loss. Patients with bilateral vestibular loss exhibit significant functional impairments as a result of their disorder. Unlike many people with unilateral vestibular loss, patients with bilateral loss may be unable to stand or ambulate on uneven surfaces, often require an assistive device for ambulation and usually cannot walk in dimly lit or darkened environments without being very unstable or falling. The amount of improvement that can be expected from vestibular rehabilitation is dependent upon the amount of residual vestibular function. Those people with greater remaining vestibular function have the best prognosis. Patients with little to no vestibular function fall frequently and have significant complaints of oscillopsia, gait ataxia, and often require an assistive device during ambulation.

Recent avenues of research in vestibular rehabilitation for patients with bilateral vestibular loss include the vibrotactile vest,15 the vestibular implant (similar to the cochlear implant which is being developed in primates),16 and the Brainport device.17 These devices are designed to provide a postural control signal that the brain can utilize in lieu of the damaged labyrinth(s).

Exercise programs for patients with bilateral vestibular loss typically focus on substituting for the loss of vestibular function by increasing reliance on either the visual or the somatosensory systems. If there is any indication that there is remaining VOR function, VOR exercises are initiated (Figure 2). Also, head-eye coordination exercises are prescribed to activate the

Figure 1. When a peripheral vestibular injury is chronic, in this case on the right, the CNS is able, through vestibular compensation, to restore partially the lost resting activity within the deafferented vestibular nucleus, and thus reduce the asymmetry of neural activity between the vestibular nuclei at rest (A) and partially restore the function of the vestibulo-ocular reflex (VOR). (B) Movement toward the intact ear. (C) Movement toward the lesioned ear. (Republished with permission of reference 13.)

Figure 2. The patient is focusing on a target and moving his head to the right and left while keeping the object in focus. (A) Note the plain background to initiate the exercise. (B) Note that the background has high contrast. Patients are progressed from performing the exercise from a blank background (A) to a high contrast background (B) as their symptoms improve.
vestibular clinics is between 7 and 45%, \(^4,19,20\) is approximately 40%. Reports of people with vestibular disorders is in the literature. From Central Vestibular Disorders sensory disorders.

Chronic disequilibrium in patients with comorbid diseases such as intratympanic gentamicin injection vestibular loss alone, vestibular ablative procedures such as intratympanic gentamicin injections should be considered more likely to produce chronic disequilibrium in patients with comorbid sensory disorders.

Central Vestibular Disorders

It is not evident what the frequency of central vestibular disorders is in the literature. From our tertiary vestibular clinic, the percentage of patients with central vestibular dysfunction that present to our vestibular physical therapy clinic is approximately 40%. Reports of people with central vestibular dysfunction in tertiary balance and vestibular clinics is between 7 and 45%, \(^4,19,20\) yet little is known about the effect of physical rehabilitation on their outcomes. There are no randomized controlled trials to support the use of vestibular rehabilitation for patients with central vestibular dysfunction. However, recent evidence suggests that changes occur with gait, dizziness, and balance after rehabilitation. \(^4,6,19,21\)

Central vestibular disorders include damage to the vestibular nuclei, vestibulocerebellum, perihypoglossal nuclei, or to the vestibulospinal, vestibulocollateral, vestibulo-autonomic, and vestibule-cerebral pathways. \(^22\) The vestibular nuclei are major sensory processing centers that receive input not only from the peripheral vestibular system, but also from the visual and somatosensory systems. If there is damage to the vestibular nuclear complex, postural control, eye movement, and orientation of the body in space may be compromised.

Damage to the cerebellum, especially the flocculonodular lobe, will impede the ability of the brain to adapt/compensate for either a central or a peripheral vestibular insult. If there is damage to the vestibular-cerebellar loop, recovery is impaired even in patients with peripheral vestibular damage \(^23\) and their functional outcomes will be adversely affected. Patients with central vestibular diagnoses that have improved following vestibular rehabilitation include those with migraine dizziness, head trauma, cervical vertigo, anxiety-related dizziness, and cerebellar stroke.

The most common central vestibular disorder is migraine dizziness, which is also known as migraine-associated dizziness, or vestibular migraine. Migraine dizziness occurs with a prevalence of approximately 6.5% \(^24\) and sometimes presents as migraine without headache. Migraine dizziness is a diagnosis of exclusion. Specific criteria have been developed to help guide the clinician in making the diagnosis of migraine dizziness. \(^25\) A sensation of vertigo, head pressure, and situational dizziness are all common characteristics of patients with migraine dizziness with or without headache. Duration of symptoms in patients with migraine dizziness is variable. \(^26\) Rehabilitation for patients with migraine dizziness must be done with great care, as these patients best optimize their progress with a combination of medication and exercise. \(^27\) If patients with migraine are pushed to perform eye–head exercises without the benefit of medication, they often experience a worsening of symptoms and therapy may fail.

People with migraine dizziness have poorer emotional outcome scores on the Dizziness Handicap Inventory (DHI) than age-matched subjects with vestibular disorders, but no migraine. \(^8\) Patients with migraine dizziness continue to experience emotional complaints from their migrainous disorder, even as their physical function improves. Even having a remote history of migraine appears to affect adversely vestibular rehabilitation outcome, \(^8\) suggesting that it is important to determine if a patient has had migraines in the past when evaluating a patient.

Patients with migraine dizziness often complain of having an increase in symptoms in wide, open spaces, in large grocery stores with many products, and around crowds of people. Exposure to complex visual environments is often part of the therapy program, yet often patients cannot tolerate these complex environments without medication to help to control their symptoms. Gradual exposure to complex visual environments is a key principle leading to recovery. A physician/therapist team helps to optimize recovery.

Approximately 30% of patients with head trauma experience dizziness. \(^28\) The dizziness complaints may be of short or long duration (seconds to years), depending on the cause. Symptoms may be perceived as dizziness, lightheadedness, or a sensation of spinning and even complaints of intense head pressure. After head trauma, people may experience dizziness from cervical injuries, damage to the peripheral labyrinth (unilateral dysfunction, BPPV, perilymphatic fistula, and posttraumatic endolymphatic hydrops), damage to the central vestibular structures (vestibular nuclei, cerebellum, and other structures), or damage to both peripheral and central structures. Preexisting central or peripheral dysfunction impedes functional recovery after vestibular insults from head injury.

Patients who have experienced head trauma are often difficult to rehabilitate because of their comorbid impairments. The International Classification of Diseases of the World Health Organization—10 or the ICD-10 diagnostic criteria for postconcussion syndrome describe a history of head trauma with loss of consciousness preceding symptom onset by a maximum of 4 weeks. Patients must have 3 of the following: headache, dizziness, malaise, fatigue, noise intolerance, irritability, depression, anxiety, or emotional lability. In addition, they must also have a minimum of 3 symptoms from these categories: (1) subjective concentration, memory, or intellectual difficulties without neuropsychological evidence of marked impairment; (2) insomnia, reduced alcohol tolerance, or preoccupation with above symptoms; and (3) fear of brain damage with hypochondriacal concern and adoption of a sick role. Patients with postconcussion disorder are more challenging rehabilitation candidates because of the above.

Patients with posttraumatic dizziness often have difficulty remembering the exercises provided, making compliance difficult. Any of the above symptoms have the potential to slow recovery that could occur with a vestibular rehabilitation program. A supportive family is needed for optimal functional recovery, as the patient often does not remember nor are they motivated to perform exercises that might make them dizzy because of their head injury.

Cervical vertigo has been discussed in the literature for over 100 years, yet the diagnostic criteria for cervical vertigo are not well-established. Whiplash injuries may result in cervical vertigo, with or without associated head injury. Furman and Cass \(^29\) have defined cervical vertigo as “A nonspecific sensation of altered orientation in space and disequilibrium originating from abnormal afferent activity from the neck.”

The cervical receptors provide inputs to the vestibulospinal track that travel to the vestibular nuclei, resulting in an accurate representation of the neck in space. The cervico-ocular reflex is not always used in humans, \(^30\) but it has been suggested that it is helpful in the rehabilitation of patients with unilateral and bilateral vestibular loss with its ability to provide information of neck positioning. Disruption of cervical afferents

Figure 3 The patient is asked to focus on a target. Then the patient is asked to move the eyes to the target in the left hand, followed by head movement so that the patient is directly looking directly at the target. The patient is then asked to repeat the same eye movement to the object held in the right hand followed by the head movement back to the right target.
has resulted in changes in postural stability, mild ataxia, visual disturbance, and dizziness that can last minutes to hours usually associated with a change of head position. It has been reported that decreasing neck pain and increasing neck range of motion decreases dizziness in patients experiencing cervical dizziness or vertigo.31

There is no definitive test to make the diagnosis of cervical vertigo, and the diagnosis of cervical vertigo is controversial. There are 2 tests suggested as helping to make the diagnosis of cervical vertigo: the head-fixed-body-turned maneuver and the smooth pursuit neck torsion test. The head-fixed-body-turned maneuver stimulates the neck without stimulating the labyrinth and may result in nystagmus and dizziness.32 The smooth pursuit neck torsion test has recently been used to assess patients with whiplash injury.3 The patient is placed in the neutral neck starting position and then is turned 45° to the right and left. Pursuit gain is calculated and compared between neutral and 45° of rotation with a sensitivity of 90% and a specificity of 91% in patients with dizziness.33

Vertigo can sometimes be elicited by extension and rotation of the cervical spine. However, without a history of trauma, it is not likely to be cervical vertigo. Eno and colleagues suggest that hyperextension combined with rotation of the cervical spine may result in a cerebellar infarction or vertebrobasilar insufficiency.34 A though rare, vertigo, or dizziness associated with extension and rotation of the neck and accompanied by neurologic signs and symptoms should be carefully examined. Therapists must report neurologic signs and symptoms to the referring physician immediately and discontinue treatment until the cause of the symptoms has been investigated.

Patients with central vestibular disorders often improve with vestibular rehabilitation, but there is less improvement than in patients with peripheral vestibular disorders.35 Patients with a central disorder diagnosis demonstrate better outcomes than patients with both central and peripheral vestibular disorders.35 The length of treatment time is generally longer in patients with central vestibular disorders compared to those with peripheral disorders.36 Medication that decreases dizziness or pain may be necessary for patients with severe complaints to comply with an exercise program. Space and motion symptoms experienced with migraine or a vestibular disorder may need to be controlled pharmacologically for rehabilitation to progress. Communication among the patient, physician, and physical therapist appears to provide optimal recovery of function in this complex group of patients.

Central and Peripheral Vestibular Disorders

Many studies have combined results from people with peripheral vestibular disorders with results from people with central vestibular disorders, making it difficult to determine outcomes in either group.4,14,15,17 Meli and colleagues recently reported on a group of people with either peripheral or central vestibular disorders and suggested that patients improved an average of 15 points on the DHI after rehabilitation and improved to a mean score of 22 (another decrease in score of 3 points) 6 months postrehabilitation.14 Jacobson and Newman reported that a clinically significant change score on the DHI was 18 points, suggesting that 6 months postrehabilitation the average DHI score change was 18 points.38 Seventy percent of the patients in Meli and colleagues study14 had a DHI score between 0 and 30 at the conclusion of their rehabilitation program, which Whitney and colleagues have reported as being “mildly” impaired. Scores between 0 and 10 would be considered normal, so even 6 months postrehabilitation, patients had not returned to baseline “normal.”

Space and Motion Symptoms

One can almost always improve a patient’s balance, which is less true for their dizziness. Patients with dizziness who have “space and motion” complaints or visual vertigo are more difficult to treat. Patients with space and motion symptoms often complain of having difficulty walking in “busy” visual environments and may even start to avoid life situations that provoke their dizziness symptoms, such as refusing to go to a shopping mall or to ride a bus or train.

Space and motion symptoms are often associated with patients with panic/anxiety disorders and those with migraine, but the same complaints can also occur with unilateral hypofunction. There are patients who have space and motion symptoms who are incapacitated by the symptoms, yet they have no history of either panic/anxiety or migraine. Many patients with uncompensated peripheral vestibular dysfunction have space and motion discomfort, leaving them to feel disabled. They may become symptomatic during typical daily activities such as going to the grocery store, to visit family, or to a shopping mall. Even if their balance improves, these patients continue to feel limited because they are not comfortable in large groups or in situations where there is a lot of background motion. Empirically, it appears that those who complain of space and motion discomfort have a poorer recovery, yet Pavlou and colleagues39 reported that there were improvements in space and motion discomfort after simulator-based therapy, which provides the patient with desensitization exposure through visual motion during exercises, in a group of people with chronic unilateral hypofunction.

Rehabilitation Concepts

The sooner rehabilitative movement is begun following a vestibular insult, the quicker the functional recovery.41 Patients with vestibular disorders have a tendency not to move, as moving increases their symptoms. Logically, one would stop or decrease head and body movements to decrease symptoms. The strategy of decreasing movement to feel better is not a good one and may actually delay recovery. Patients with vestibular disorders must be encouraged to move early and move a lot to stimulate recovery.

Care and experience must be utilized in constructing an exercise program for patients with vestibular dysfunction. For example, people with central vestibular impairments often complain of more constant symptoms that may or may not be related to changes of head position. They may have constant, intense symptoms of vertigo, nausea, and/or dizziness and may complain of difficulty with their vision. Head pain and head pressure are common complaints. The use of medication in conjunction with physical therapy is effective.38 Decreasing the severe symptoms is often necessary to begin the rehabilitation program, as movement increases some patients’ complaints of dizziness and vertigo.

Once some of the symptoms are managed medically, the patient is able to begin and make use of the rehabilitative exercise program. Exercises must begin slowly, and later the speed of the exercise is increased. In patients with central vestibular dysfunction, the progression is often slower than in patients with peripheral vestibular disorders. Bright lights, visually complex stimuli, and noise often bother people with vestibular dysfunction, so methods to decrease external stimuli while performing the exercises are employed as part of the exercise prescription.

Referral Patterns

People with various vestibular disorders appear to improve with rehabilitation (Table 2). Patients with vestibular disorders should be referred to a physical or occupational therapist who is knowledgeable about the management and care of patients with balance and vestibular disorders.14 Experience with patients with balance and vestibular disorders most likely changes the rehabilitation outcome, as the entire patient must be treated for optimal results. Both physical and psychological well-being are important variables in the outcome of patients with balance and vestibular dysfunction.42

Finding a therapist who is interested in treating patients with balance and vestibular dysfunction can sometimes be a daunting task. We typically quiz therapists about their knowledge and interest in treating our patients prior to referral. Other methods sometimes employed include checking web sites that list therapists who are interested in the treatment of patients with balance and vestibular disorders. The web site method does not insure that the person is an expert but is more effective than sending the patient to the local therapy office without any assurance of quality.

Most therapists who have expertise in the treatment of people with balance and vestibular dysfunction have some long-term rehabilitation experience. In addition, some of the physical therapists may be board certified neurologic clinical
sensory, and vestibular) are impaired, recovery is compromised. A history of a childhood strabismus or ocular misalignment is often overlooked until the person experiences a vestibular insult. The visual impairments, often forgotten from childhood, appear to make compensation from a vestibular injury more difficult.

There is insufficient evidence to state that patients with certain diagnoses should not have a trial of physical or occupational therapy. Improvements are noted in patients who demonstrate poor prognostic signs, yet their improvement is often lesser than what is usually expected. Being reasonable when explaining potential outcomes is important so that the patient does not feel like a treatment failure. Compliance with all exercises and instructions, with any of the conditions listed in Table 3, may still result in a rehabilitation disappointment for the patient and the family.

**Presenting Complaints**

Some patients complain of a balance problem or dizziness, and others will have both dizziness and balance complaints. Patients who are only dizzy are usually provided with exercises that promote VOR adaptation in various situations, both in static and more dynamic positions. Those who complain of having balance problems alone are often asked to perform exercises in more difficult positions and postures, but are usually not routinely asked to perform VOR exercises.

Patients who have both vestibular and balance complaints will be treated with both eye–head adaptation exercises and balance exercises in increasingly more difficult situations. One must use care with patients with both dizziness and a balance problem, as they may be at a higher risk for falling.

**Exercise Progression**

Typically, the progression of positions and mobility during exercises is as follows: supine (if the patient is grossly unstable or fearful), sitting, standing, to more difficult standing positions (Romberg, semitandem, and then tandem Romberg), and lastly during gait. Exercises are performed with eyes open and sometimes with eyes closed, depending on the capabilities of the patient. Walking programs and specific actions during walking (turning, stepping over and around objects, bending over while walking, or even looking up or down) are incorporated into the exercise program as the patient improves. Head movements progress from slow to fast, and the distance of targets while performing exercises is varied from close to far.

It appears optimal to begin the exercise program at the highest level of difficulty that the patient can tolerate, rather than go through a specific exercise progression from supine to walking. Typically, the physical therapist will customize the exercise program to target the specific patient deficits identified in the physical therapy examination. Shepard and Telian reported more effective results with a customized versus a generic exercise program. Horak and colleagues have also reported that customized balance exercises were more effective than a generic exercise program or medication in patients with peripheral vestibular dysfunction.

Whether they have 1 or more presenting problems (balance, dizziness, or both), patients will still receive some benefit from performing the prescribed exercises. A patient who refuses to perform any exercise will not improve with rehabilitation. Primates who moved little after surgery did not improve until they were permitted to move about their cages. Movement is critical to a positive rehabilitation outcome.

**VESTIBULAR REHABILITATION ASSESSMENT AND TREATMENT**

People referred to physical therapy for vestibular disorders are usually seen one-on-one by physical therapists. The physical therapy assessment generally requires 1 hour or more during which subjective and objective testing is necessary to evaluate a patient with balance and/or vestibular dysfunction adequately.

The subjective history is very important to a physical therapist, as the patient’s story will often dictate treatment and will also provide direction as to which clinical tests are necessary. Key questions are asked during the subjective history related to movements or situations that increase or decrease dizziness symptoms. Physical therapists develop a physical therapy diagnosis by the end of the assessment. Often the medical diagnosis and the physical therapy diagnosis will match, but not always. Physical therapists are concerned about functional limitations and how well patients are able to participate in their community and within their home environment.
Typically, the questions asked during the subjective history include the intensity and duration of the symptoms and whether the symptoms are episodic or constant. Associated symptoms (nausea, vomiting) with their dizziness or vertigo are also determined. Questions such as does your dizziness increase with rolling over, moving from supine to sitting, moving from sitting to standing, walking in a grocery store, reading, and walking while moving the head are typically asked to determine what increases symptoms and to develop a treatment plan.

Key aspects of the subjective history include determining the intensity and duration of the symptoms and whether the symptoms are episodic or constant. Associated symptoms (nausea, vomiting) with their dizziness or vertigo are also determined. Questions such as does your dizziness increase with rolling over, moving from supine to sitting, moving from sitting to standing, walking in a grocery store, reading, and walking while moving the head are typically asked to determine what increases symptoms and to develop a treatment plan.

Duration, frequency, latency, and fatigability are all factors that are considered during the collection of the subjective history. Often patients are asked to rate their dizziness symptoms at rest and indicate what is the “best” and “worst” dizziness rating within the last 24 hours on a perceived dizziness scale (0 to 10 or 0 to 100). The dizziness rating provides an indication as to whether the patient has constant symptoms or if they are episodic and also provides information related to the magnitude of the perceived dizziness. Very high scores are often associated with severe dysfunction, possibly of central origin or of comorbid psychiatric dysfunction.

Information about vision, ear status (tinnitus, aural fullness, and pain), past and present medical history, past fall incidents, motions that provoke symptoms, and medication use are all helpful in guiding the physical therapy intervention. The use of bifocals or trifocals makes a person at higher risk for falling, due to impaired depth perception. Similarly, a unilateral cataract or poor unilateral outcome is more difficult for the patient to determine what increases symptoms and to develop a treatment plan.

Exercises and treatment interventions will be employed depending on the presenting diagnosis. Communication of physician findings to the therapist will only enhance the care of the patient and allow the therapist to develop a more effective and customized exercise program.

Vestibular Rehabilitation Therapy Outcome Measures

Several common outcome measures are available to assess the benefit of rehabilitation. The DHI has been used extensively to help quantify changes in perceived disability from dizziness.

Patients answer 25 questions that require them to decide whether they are always, sometimes, or never bothered by dizziness during the 25 activities or circumstances included as part of the questionnaire.

The DHI scale (scores range from 0 to 100) is easy to interpret, with lower scores indicating less dysfunction. Scores between 0 and 30 denote mild disability, 31 to 60 moderate, and >60 severe handicap. The DHI is a helpful tool to determine if the patient’s perceived disability has changed over the course of treatment. In addition to a total score, the DHI provides 3 subscores: emotional, functional, and physical. A score of the DHI decreases over time, the expectation would be that the patient’s function is also improving. Very high DHI scores (>80) may be indicative of the need for a psychologic or psychiatric consultation. Scores >80 indicate that almost everything bothers the patient, suggesting that motion-provoked dizziness is only one of their problems.

The Activities-specific Balance Confidence (ABC) scale was initially developed to grade subjectively graded fear of falling. The ABC scale consists of 16 questions that the patient rates on a 0 to 100% scale in increments of 10. Higher scores indicate greater confidence. Scores <57 have been related to high fall risks and scores >50 have been related to older adults who are homebound or significantly functionally impaired.

The total score is calculated by adding up all of the percentage scores and dividing by 1,600. Changes in the ABC score have been noted after vestibular rehabilitation, suggesting that patients feel more confident with their balance. A positive change of 10 or more has been suggested to be clinically significant in patients with vestibular disorders.

Gait speed and the Timed “Up & Go” test are both powerful measures of gait performance that help gauge recovery. In older adults, changes of 0.1 m/s in gait speed are considered to be clinically significant. Both measures are easy to collect and provide quantifiable evidence of change over time from the physical therapy intervention.
The four-item DGI is helpful in identifying impaired gait during dynamic activities.43

**Exercise Program**

The frequency of physical therapy intervention visits ranges from 2 to 3 times a week to weekly and in some institutions the visits occur once every 2 weeks. Optimal frequency of visits is unknown. It has been suggested that patients who are older and/or fearful are less likely to follow though with the home exercise program and, therefore, should be seen more frequently face-to-face. Repeat visits are required to ensure that the patients are performing the exercises correctly. Patients can be performing the exercises incorrectly, as they do not always remember what they were instructed to do, even when they were provided with a written exercise prescription. Many of the eye-head exercises are complex and may require repetition for the patient to perform them correctly.

The exercises are done both in the physical therapy clinic and at home. The home exercises are essential for recovery, as the frequency of visits to the clinic is probably not adequate to cause changes in function. Figure 4 demonstrates a typical exercise that a patient might be asked to perform at home. Safety is always emphasized with the exercise prescription. Customized exercises have been shown to be better than a list of generic exercises. Most therapists suggest that patients perform the exercises 2 to 3 times per day.

If the patient is continuing to work, 3 exercise sessions a day is usually unreasonable. Often the dose of the exercise must be adapted based on the patient’s tolerance. The patient may need to spread out the exercise session over several hours to be able to tolerate the exercise without too much residual dizziness. Generally, most patients are told to use an analog scale (with some maximum score negotiated between the therapist and the patient). The patient is instructed to modify how they are doing the exercises if their symptoms remain 20 to 30 minutes after completion. If they become significantly symptomatic, the patient should be encouraged to contact the therapist, and the exercise program will most likely be modified over the telephone or they will be told to stop the exercise until the next session if they are particularly symptomatic.

Most patients with peripheral vestibular disorders are treated over a 2- to 3-month period or less. However, patients with central vestibular disorders or with bilateral hypofunction should be treated for longer periods of time. It is important that the patient continues to make positive functional changes through the treatment period, otherwise therapy is not considered helpful. Occasionally, if the patient becomes too symptomatic while performing the exercises, the therapist will contact the physician to see if a CNS or vestibular suppressant is necessary to assure exercise compliance, with the goal of decreasing or eliminating the use of the medication over time.53

**Improvements Noted after Vestibular Physical Therapy**

Patients undergoing vestibular physical therapy often demonstrate improvements in postural control, as measured via computerized dynamic posturography, gait tasks, gait speed, a negative Dix-Hallpike test, dizziness rating, quality of life, or even timed standing tasks. The DHI is used to determine if there are positive changes in the patients perceived handicap after the rehabilitation process. The A B C is used to determine if the patient’s confidence related to fall risk has improved over the course of rehabilitation. Baseline dizziness at discharge is also compared to baseline dizziness symptoms to determine if the patient has improved.

Not all patients return to “normal” on the above tasks, but generally there are documentable improvements in performance on balance tasks. Changes in time to perform a task or enhanced stability during standing and walking tasks are most commonly recorded as outcome measures. Changes in postural control have been documented in patients with peripheral and/or central vestibular disorders.4,5,6,21,38

The DHI has been used to quantify change in dizziness over time. Not all patients improve by a clinically significant amount of 10 or more points on the DHI. Few patients get worse with rehabilitation, yet there are some who do not change even after having diligently performing their exercises. At this time, it is impossible to predict who will improve and who will not after a course of rehabilitation.
Tinnitus and Decreased Sound Tolerance

Margaret M. Jastreboff, PhD

Pawel J. Jastreboff, PhD, ScD, MBA

Definitions

Writings about tinnitus can be found in ancient documentation of Babylonian, Egyptian, Greek, Indian, and Assyrian medicine. Throughout the world, a variety of terms have been used to describe a ringing, tinkling (Latin, tinnire), buzzing, whistling, or unpleasant sound (French, acouphènes) in the ears or in the head, leaving us with the two most commonly used terms, tinnitus (in English) and acufenos (in Spanish). The historical review of tinnitus may be found in a number of publications, particularly those by Stephens.14-16

There is no precise, short, and distinctive definition of tinnitus. Today, commonly used definitions of tinnitus focus on different characteristics. Definitions that are based on patients’ experiences describe tinnitus as: ringing, buzzing, the sound of escaping steam, hissing, humming, cricket-like, or noise in the ears.1-3 Tinnitus as “a phantom auditory perception” represents a physiologic definition of tinnitus pointing out a lack of a physical acoustic stimulus related to tinnitus.17,18 There is also the definition proposed by the Committee on Hearing, Bioacoustics and Biomechanics of the US National Research Council: “a conscious experience of sound that originates in the head” of its owner.1

Etiology, Prevalence, and Epidemiology

The results of studies conducted in numerous places around the world have shown a significant variability in the estimation of tinnitus prevalence in the general population.3-5,19-22 Recent epidemiological data confirmed previous findings, pointing to even higher prevalence of bothersome tinnitus in the United States of about 8% compared with the 4% previously reported.2 A total of 6 to 17% of the general population experience tinnitus lasting for a period of at least 5 minutes. A bout 3 to 7% of the general population seek help for their tinnitus, and 0.5 to 2.5% report that tinnitus has severe effect upon their life.1,3,5-23 The prevalence of tinnitus in adults with hearing problems is high (59 to 86%), and it is estimated that tinnitus is present in 50% of patients with sudden hearing loss, 70% with presbyacusis, and 50 to 90% with noise-induced hearing loss.2,24

The prevalence of tinnitus increases significantly with aging, except in the highest age group when it declines,2 but people of all ages experience tinnitus.23,25 Although frequently not reported, children are also affected by tinnitus, and the estimated prevalence is similar to that reported in adults. Nodar, in a sample of 2,000 children, reported the average prevalence of 15%, with 13.3% for children with normal hearing and 58.6% with hearing loss.26 Similar data were reported by others with a general prevalence in the range of 15 to 29% in healthy children and approximately 50% in children with otologic problems or hearing loss.27,28 A significant proportion of children reported having problems with tinnitus including: sleep disturbance (42%), problems with concentration (47%), and sensitivity to sound (33%).29 In younger healthy children (age 5 to 16 years), 29% have tinnitus and 9.6% reported their tinnitus as troublesome.27 Recent data from a survey performed in Turkey on school children revealed that 15.1% of children had tinnitus, which was typically high pitched, of soft loudness, and described as ringing.30 A study performed in Italy showed that out of 1,100 children, 34% of them had tinnitus and 6.5% complained about it,31 and a study from Sweden showed 8.7% self-reported tinnitus and 17.1% self-reported decreased sound tolerance.32

Extensive studies have been performed in an attempt to link various factors with tinnitus prevalence.1-3,10,19 Hearing loss, specifically the extent of high frequency impairment in the worse ear, is one of the main predicting factors for tinnitus.3 Conductive hearing loss seems to be a separate factor,29 and noise exposure has been correlated with tinnitus as well.19 Tinnitus is also experienced by those with normal hearing; 18% of tinnitus patients were reported to have normal hearing.33

Other factors do not appear to be correlated with tinnitus. Pregnancy has been shown to increase significantly the probability of tinnitus.34 Neither smoking, coffee, nor alcohol has been shown to increase tinnitus prevalence directly.35,36 Severity of tinnitus is associated with severity of anxiety and depression,38 and tinnitus seems to affect patients’ cognitive abilities.39,40 The main risk factors associated with the presence of tinnitus are age, male sex, lower level of education, lower annual income, being a military service veteran, poor general health status, being obese, significant hearing loss, exposure at work.
for more than 15 hours per week to loud sound, exposure to impulse noise, and daily smoking cigarettes. Interestingly, being in the managerial or administrative or technical sales occupational group as well as moderate alcohol consumption were associated with reduced risk for tinnitus.

**Mechanisms and Models**

Our knowledge of the mechanisms of tinnitus is still limited and based more on theoretical speculations than on strong research data or stringent clinical studies. Past models were focused on peripheral mechanisms in the auditory system, whereas recent models tend to involve or even focus on processing information within the central auditory pathways and central nervous system. Although the molecular and genetic basis for tinnitus is not known, brain-derived neurotrophic factor (BDNF) and the activity-dependent cytoskeletal protein (Arq3.1/arc) have been found to be potentially related with acoustic trauma induced tinnitus at both peripheral and central levels. The neurophysiologic model of tinnitus combines all levels and differentiates between the perception of tinnitus versus tinnitus-induced activation of nonauditory structures in the brain. The discordant damage/disfunction theory of the generation of the tinnitus signal postulates that the tinnitus signal is generated at the level of dorsal cochlear nucleus as a result of imbalanced activation coming from outer and inner hair cells. Specifically, when outer hair cells are dysfunctional at a certain region of the basilar membrane and inner hair cells in the same region are still working, this yields disinhibition in the dorsal cochlear nucleus and thereby generation of the tinnitus signal. This theory explains many tinnitus conundrums and is accumulating support from experimental data. Table 1 summarizes the approaches to the mechanisms of tinnitus.

**Tinnitus as a Symptom of Medically Treatable Diseases**

Tinnitus may also be a part of more complex medical conditions, and some of these are identified in Table 2.

**DECREASED SOUND TOLERANCE**

Tinnitus is frequently accompanied by decreased sound tolerance, that is, oversensitivity to sound, which, in many cases, is a sum of hyperacusis and misophonia.

**Definitions**

There is no generally accepted definition for decreased sound tolerance to suprathreshold sounds although a variety of terms have been proposed, with hyperacusis used most frequently. According to Stedman’s Medical Dictionary, hyperacusis is defined as “Abnormal acuteness of hearing due to increased irritability of the sensory neural mechanism. Syn: auditory hyperesthesia.”

With hyperacusis defined as “A normal acuteness of sensitivity to touch, pain, or other sensory stimuli” or, according to American Heritage Dictionary, as “An abnormal or pathological increase in sensitivity to sensory stimuli, as of the skin to touch or the ear to sound.” It has been recognized that decreased sound tolerance might reflect physical discomfort or be related to a fear of sound.

We proposed the approach to decreased sound tolerance based on neurophysiology, recognizing the systems that can be involved: the auditory system, both peripheral and central parts, and the limbic and autonomic nervous systems and consequently propose the following definitions. Hyperacusis is defined as abnormally strong reactions to sound occurring within the auditory pathways. At the behavioral level, it is manifested by a subject experiencing physical discomfort as a result of exposure to moderate/weak sound that would not evoke such reaction in the average population. The strength of a reaction is linked to the physical characterization of a sound, for example, its spectrum and intensity. Misophonia is defined as abnormally strong reactions of the autonomic and limbic systems without abnormally high activation of the auditory system, resulting from enhanced connections between the auditory and limbic systems. At the behavioral level, patients have a generally negative attitude toward sound (misophonia, from Greek: miso meaning strong dislike, hate) or could specifically be afraid of sound (phonophobia; phobia, fear). In this classification, phonophobia is a specific case of misophonia. The strength of a reaction will be only partially determined by the physical characterization of a sound and will depend on the patient’s previous evaluation of a sound, for example, potential threat, beliefs that it can be harmful, the patient’s psychological profile, and the context in which the sound is presented.

Note that neither hyperacusis nor misophonia have any relation to the threshold of hearing, which can be normal or can reflect hearing loss. Most frequently, decreased sound tolerance results from a combination of hyperacusis and misophonia. It is important to assess the presence and the extent of both phenomena in a patient as each needs to be treated using different methods. Terms used in the literature do not differentiate these problems; and, since the reported decreased sound tolerance is typically dominated by hyperacusis, we will use the term hyperacusis in describing reports in the literature.
Additionally, note that the term recruitment is not related to a decreased sound tolerance or hyperacusis. Recruitment refers to unusually rapid growth of loudness as the level of a tone is increased, occurs in association with hearing loss, and is purely a cochlear phenomenon. It might coexist with hyperacusis, but there is no functional link between these two phenomena.

**Prevalence and Epidemiology of Decreased Sound Tolerance**

There are limited data available on the prevalence of hyperacusis. Questionnaires provide an assessment of hyperacusis prevalence in the general population. Recent data gathered from 10,349 randomly selected subjects showed that 15.3% reported hyperacusis. Patients being evaluated for other otologic problems frequently undergo audiologic evaluation, which involves assessment of speech discomfort level and puretone LDLs. There are no good normative data. Several studies indicated that in the normal population, LDLs are in the range of 90 to 110 dB SPL, with varied results depending on the specific method used, for example, stimuli: pure tone, warble tone, noise: presentation: free field, insert earphones, headphones; and instructions given to patients. Moreover, these measurements are not part of a routine audiological evaluation. The results tend to cluster within 95 to 110 dB sound pressure level (SPL) for frequencies from 500 to 8,000 Hz, which correspond to approximately 90 to 100 dB hearing level (HL).

Hyperacusis and tinnitus frequently coexist, and it has been postulated that in some patients, hyperacusis might actually be a pre-tinnitus state. Approximately 60% of tinnitus patients exhibit decreased sound tolerance, with about 30% requiring specific treatment for hyperacusis. Conversely, study of 100 patients with hypersensitivity to sound showed that 86% of them suffered from tinnitus. Considering the clinical observation that approximately 30% of tinnitus patients require treatment for hyperacusis and 86% of hyperacusis patients reported tinnitus and accepting that about 4 to 5% of the general population have clinically significant tinnitus, it is possible to estimate that significant hyperacusis exists in approximately 1 to 1.5% of the general population. An even larger proportion has some hyperacusis that, although detectable in questionnaires, is not sufficiently strong to initiate intervention.

**EVALUATION OF TINNITUS**

We do not have any objective method to detect and measure tinnitus. Therefore, interview and psychoacoustic characterization are typical approaches in clinical practice, sometimes expanding into the direction of physiologic testing. New advances in research offer the possibility to detect tinnitus in an objective manner using imaging techniques or magnetoencephalography. These techniques are promising but cannot yet be implemented into clinical practice owing to their complexity and cost. Table 3 lists the methods used for evaluation of tinnitus.

**Problems Evoked by Tinnitus**

As tinnitus can present as part of a complex medical condition, a complete medical evaluation is needed to exclude all medically treatable problems that can be linked to tinnitus. Even though tinnitus is classified as a symptom and not a disease, it does require treatment as it can cause significant emotional and somatic distress and can significantly influence patients’ quality of life, particularly if allowed to become a chronic problem. The list of reported associated complaints is long and includes emotional problems, such as irritation, annoyance, anxiety, stress and depression; hearing problems such as difficulty with speech comprehension; and somatic problems such as headache, neck pain, and jaw pain. Tinnitus can be intrusive and may cause difficulty with sleep and concentration and a decreased ability to participate in everyday activities and social events; it may also create problems in relationships. A detailed interview, aimed at characterizing the specifics and degree of tinnitus impact on the patient’s life, coupled with an otolaryngologic evaluation, provides the most thorough assessment and allows the practitioner to address all of the issues that need to be considered, including potential intervention of a psychologist or psychiatrist to accompany the commencement of a specific tinnitus oriented treatment.

**Hyperacusis and Misophonia as a Problem**

Decreased sound tolerance can have an extremely strong effect on patients’ lives and can be more debilitating than tinnitus. Whereas tinnitus may affect attention, sleep, work, and life enjoyment and make social contact less rewarding, hyperacusis can prevent people from exposing themselves to louder environments and therefore prevent them from working and interacting socially; it can also control a patient’s life. In extreme cases, patients do not leave their homes, and their lives and the lives of their families are controlled by the issue of avoidance of sound. Misophonia can have similar effects; and, since it is inevitable in all cases with significant hyperacusis, misophonia further enhances the effects of hyperacusis.

**Decreased Sound Tolerance as a Symptom of Medical Conditions**

Hyperacusis has been linked to a number of medical conditions (Table 4).

**Etiology and Potential Mechanisms of Decreased Sound Tolerance**

In the majority of cases, the cause of hyperacusis is unknown. Hyperacusis has been linked to sound exposure (particularly short, impulse noise), head injury, stress, medications, and some medical conditions. The lack of strong epidemiologic data and animal models of hyperacusis prevents proving the validity of any potential mechanism responsible for hyperacusis.

At the peripheral level, it is possible to speculate that the abnormal enhancement of vibratory signals within the cochlea by the outer hair cells might result in overstimulation of the inner hair cells and subsequently results in hyperacusis. Indeed, in some cases, it is possible to observe high amplitude distortion product otoacoustic emissions and distortion products evoked by low level primaries. The presence of asymmetric hyperacusis might indicate a peripheral mechanism since central mechanisms would more likely act similarly on both sides.

Laboratory research has shown that damage to the cochlea or a decrease in the auditory input results in a decrease of the threshold of response in a significant proportion of neurons in the ventral cochlear nucleus and inferior colliculus. Studies with evoked potentials indicated abnormal increase of the gain in the auditory pathways after such manipulations. Some of the medical conditions listed in Table 4 can be linked to the central processing of signals and modification of the level of neuromodulators as possible sources.
factors inducing or enhancing hyperacusis. Moreover, serotonin has been implicated in hyperacusis,127 and a case report indicated that serotonin reuptake inhibitors might be helpful for hyperacusis.128

Mechanisms of misophonia could involve enhancement of the functional links between the auditory and limbic systems, both at the cognitive and subconscious levels.17 Alternatively, a tonic high level of activation of the limbic and autonomic nervous systems may result in strong behavioral reactions to moderate sounds.54,128

Methods of Evaluation of Decreased Sound Tolerance

Whereas there is no one clearly accepted method for the evaluation of decreased sound tolerance, hyperacusis, and misophonia, there is a general agreement that LDLs provide a good estimation of the problem. There are several variants of the protocols of LDL evaluation with various features, for example, continuous, pulsed, or beeps of sound; pure tone; narrow-band noise.89,129,130
The approach we are pursuing incorporates modifications of the standard procedure aimed at obtaining results dominated by hyperacusis by decreasing the effects of the misophonic component to a minimum. To achieve this, a situation is created during testing in which patients have the feeling of full control over the maximal sound level to which they will be exposed.80 A detailed interview is needed with each patient to determine the relative contribution of hyperacusis and misophonia to decreased sound tolerance, reflected in decreased values of LDLs. As normative data are not uniform and there is substantial individual variability (even while using one method) in measuring LDL,89 it is advisable to pay attention to the potential presence of hyperacusis when average across the frequencies LDL values are lower than 95 to 100 dB HL.

REVIEW OF TREATMENTS

The list of approaches and techniques attempted to help with patients tinnitus is long. Table 5 lists the most commonly used of these treatments.

Antireassurance

Over the years, the most common advice given to tinnitus patients has been, “Nothing can be done—go home and learn to live with it.”9,82 This is actually a powerful form of negative counseling, sufficient on many occasions to convert a person who just experiences tinnitus to a patient who suffers from it.17,81,85

Pharmacotherapy

Many pharmacologic agents have been considered for tinnitus treatment (Table 6) but no single, effective, specific, secure, and reliable drug has yet to be identified.57,136–142 In this respect, strong consideration must be given to the side effects of pharmacologic treatments, such as tolerance, dependence, and withdrawal effects. Recent reviews of randomized clinical trials of drugs for tinnitus have shown that all studied drugs have failed to prove their efficacy, as compared with a placebo.133,143 Future double-blind randomized studies, with proper outcome measurements and adequate sample size, might identify some promising pharmacologic agents.144–147

Surgery

Surgery can offer help to some patients with somatosound, conductive hearing loss, and Meniere disease.8 However, there is no specific surgical procedure shown to be consistently effective for tinnitus that does not have a clear surgically treatable cause. Neither transection nor microvascular decompression of the auditory nerve, promoted in the past,148,149 has proven to be effective.7,150,151

Sound Therapies

A wide variety of therapies focused on sound is used, for example, music therapies, auditory discrimination therapy, pink noise therapy, desensitization, dynamic tinnitus mitigation system, phase shift tinnitus reduction, auditory integration training, masking relief therapy, neuromonics, and tinnitus retainer therapy (TRT).13,152–155 They are based on various presumed mechanisms of sound action on tinnitus and implement different sounds and counseling. Sound modifications may involve varying intensity within a short time, different intensities for specific stages of treatment, phase modifications, or complex processing of the sound. It is not clear which type of sound processing and protocol of sound use are optimal. For the majority of methods, results were not published in peer-reviewed journals and there are not sufficiently strong data from systematic studies to determine which of these methods might be effective in alleviating tinnitus.

Specific sound therapy is used as an integral part of TRT to achieve consistent and prolonged weakening of tinnitus signal and desensitization of the auditory system, with type and protocol of the sound used based on the neurophysiologic model of tinnitus.12 According to the neurophysiologic model of tinnitus, any sound is better than silence, as long as it does not annoy, create discomfort, or damage hearing. Counseling appropriate to a given implementation of sound therapy is important as well.

Electrical Suppression

Electrical suppression of tinnitus was first reported in 1855.156 Over the years, many different approaches have been attempted, and methods based on electrical stimulation are still of interest (Table 7).156,157 Three new variants of electrical stimulation for tinnitus have been introduced over the last several years. The first involves deep brain stimulation, sometimes performed for movement disorder and chronic pain.158 Anecdotal reports of patients receiving deep brain stimulation initiated an investigation that demonstrated that, indeed, some patients experienced a decrease in their tinnitus with deep brain stimulation.159 A second approach involves high frequency electrical stimulation of the cochlea performed by placing an electrode on the promontory or via a cochlear implant.160 A third approach involves direct electrical stimulation of the auditory cortex via electrodes placed on the auditory cortex.161

All these approaches are at an early stage of investigation. Only intracochlear or promontory stimulation has shown consistent and positive results in approximately 50% of patients.127,162,163 Other approaches were less effective.164 Although
positive direct/pulsed current can provide tinnitus suppression, and it has no clinical application as it would damage the cochlea if used for a prolonged period of time.

Transcranial Magnetic Stimulation (TMS)

TMS uses short pulses of a powerful magnetic field to stimulate the brain cortex. The method, primarily used for psychiatric disorders (but not approved by the United States Food and Drug Administration [FDA]), has recently been investigated for tinnitus. The magnetic field easily crosses the skull and induces a strong electrical field, perpendicular to the magnetic field, which in turn activates neurons in the cortex. As such, the final effect is electrical stimulation of the cortex. The relative position of the axons and dendrites of neurons to the evoked electrical field is crucial and depending on this relationship one group of neurons can be activated while another in the same area will not be activated. Consequently, changing the angle of the magnetic coil will modify which neurons are going to be stimulated within the active area, which is about 1 inch in diameter. Moreover, as the cortex is highly convoluted, only some parts will be activated. All these factors, combined with the fact that the auditory cortex is in deeper part of a sulcus, create a challenge to achieve repetitive, stable results while using this method for tinnitus.

In addition to immediate effects longer lasting consequences are of clinical interest. There are two types of TMS differentiated by the frequency of stimulation. When higher frequency is used, TMS has an inhibitory effect on cortical activity reflected in immediate attenuation of tinnitus perception, which lasts only for a limited period of time. When low frequency (1 Hz) stimulation is used over a period of days, this presumably evokes plastic changes in the cortical areas and a decrease in the negative impact of tinnitus. The initial effect might be absence of tinnitus or the tinnitus might even increase; but, over a period of time, the tinnitus is attenuated and its effects may last for some time.

The strong positive aspect of TMS is that it does not require opening the skull and can be done on conscious subjects easily, which have a high level of anxiety, and psychosomatic problems, indicated that the limbic and autonomic nervous systems are crucial in individuals with clinically relevant tinnitus. It was postulated that the sustained activation of the limbic and autonomic nervous systems is essential in creating distress and, therefore, clinically relevant tinnitus.

Psychological management of chronic tinnitus can be helpful for some patients. A tinnitus affects patients’ well-being, the application of cognitive behavioral therapies may have a positive impact on the quality of life by improving their ability to cope with tinnitus. Cognitive therapies, behavioral modifications, coping strategies, cognitive distraction, and minimizing distress are examples of the psychological approach. Of particular interest seems to be methods of cognitive behavioral therapy (CBT). Recent meta-analysis of all controlled, randomized clinical trials listed in the Cochrane ENT Group Trials Register, the Cochrane Central Register of Controlled Trials, MEDLINE and EMBASE identified six trials involving 285 patients and showed that while there were no effect of CBT on the subjective loudness of tinnitus or on depression, but cognitive behavioral therapy improved significantly quality of life. Prospective study of 434 patients treated with integrative behavioral medicine treatment show significant improvement as well.

NEUROPHYSIOLOGIC MODEL OF TINNITUS AND TINNITUS RETRAINING THERAPY

More than a decade and half has passed since the introduction of the neurophysiologic model of tinnitus and, based on it, treatment, which is known as TRT. Several observations led to the neurophysiologic model of tinnitus and hyperacusis. It is known that tinnitus induces distress in only about 20% of those who perceive it. There is no correlation among the psychoacoustic characterization of tinnitus, tinnitus-induced distress, and the treatment outcome. The experiment by Heller and Bergman showed that the perception of tinnitus cannot be pathologic since essentially everyone experiences it when put in a sufficiently quiet environment as evidenced by the emergence of tinnitus in 94% of people without prior tinnitus when isolated for several minutes in an anechoic chamber. This phenomenon has been recently confirmed. These observations strongly argue that the auditory system plays a secondary role, and other systems in the brain are dominant in clinically relevant tinnitus, that is, tinnitus that creates discomfort and annoyance and requires intervention.

A review of the problems reported by tinnitus patients, who exhibit a strong emotional reaction to its presence, a high level of anxiety, and psychosomatic problems, indicated that the limbic and autonomic nervous systems are crucial in individuals with clinically relevant tinnitus. It was postulated that the sustained activation of the limbic and autonomic nervous systems is essential in creating distress and, therefore, clinically relevant tinnitus. Tinnitus-related neuronal activity is processed by the parts of the central nervous system involved in memory and attention. It is possible to distinguish several feedback loops, with two major categories: loops involving the conscious perception of tinnitus and those that act at a subconscious level (Figure 1), with the subconscious loop dominant in most patients. It is further suggested that the activation of the limbic and autonomic nervous systems by tinnitus-related neuronal activity follows the principles of conditioned reflexes.

The processing of tinnitus-related neuronal activity occurs in a dynamic balance scenario, with continuous modification of the weight of synaptic connections. Both learning and memory have a physiologic basis in the modification of the strength of synaptic connections. A continuous presence of tinnitus, combined with attention given to it, results in plastic modifications of synaptic connections, yielding the modification of receptive fields corresponding to the tinnitus signal and its subsequent enhancement. This postulate has been proven using magnetoencephalography.

Whereas the initial signal provided by the auditory system is needed to start the cascade of events, its strength is irrelevant, as the extent of activation of the limbic and autonomic nervous systems depends on the strength of negative associations linked to tinnitus and the susceptibility of the feedback loops to modification. It appears that tinnitus-related neuronal activity may result from compensatory processes that occur within the cochlea and the auditory pathways to minor dysfunction at the periphery.

Notably, once plasticity-related modifications of neuronal connections occur, the peripheral signal itself may become of little importance, as is similarly observed in chronic pain. Indeed, there are clear similarities between tinnitus and chronic pain, including the phenomenon of prolonged exacerbation of tinnitus as a result of exposure to sound, which is observed in some patients.
The neurophysiologic model includes several systems of the brain involved in analysis of clinically relevant tinnitus. All levels of the auditory pathways, starting from the cochlea through the subcortical centers and ending at the auditory cortex, are essential in creating the perception of tinnitus. When subjects are not bothered or annoyed by tinnitus, auditory pathways are the only pathways involved, and tinnitus-related neuronal activity is constrained within the auditory system. Therefore, although subjects are perceiving tinnitus, they are not disturbed by it.

In approximately 20% of those with tinnitus, strong negative emotions are induced, which, in turn, evoke a variety of physiological defense mechanisms of the brain. The limbic and autonomic nervous systems play a crucial role, and improper activation of these systems by tinnitus-related neuronal activity results at the behavioral level in the problems described by patients. The connections between the auditory, limbic, and autonomic systems with various cortical areas, as proposed in the neurophysiological model of tinnitus, are outlined in Figure 1.

The model points out that the sustained activation of the limbic and autonomic nervous systems is responsible for the distress induced by clinically relevant tinnitus. Activation of both systems can be achieved through two routes branching at the level of thalamus (medial geniculate body). The first includes stimulation of the autonomic and limbic systems from higher level cortical areas, which are involved in our awareness, verbalization, and beliefs, called high, conscious or cortical in the neurophysiologic model of tinnitus. The second route is through the subconscious level. If the stimulus is new and does not require any association, or if there are no high-level processes, the subconscious system screens and categorizes all stimuli at the subconscious level. If the stimulus is important, it is transmitted to the subconscious level, called low subconscious or subcortical in the model, and provides stimulation from the lower level auditory centers, specifically linking directly the medial geniculate body with the amygdala and involves the extralemniscal auditory pathways. These two paths are called the “high road” and the “low road.”

At the early stage of tinnitus, the high loop is dominant, and activation of the limbic and autonomic nervous systems are due to cognitive processing of the information and thinking about tinnitus. Later this loop and corticothalamic and corticolimbic interaction might still play a role in activation of the limbic and autonomic nervous systems. This postulate is supported by the findings of studies on patients, which revealed enhancement of gamma band activity in the auditory cortex and allows prediction of the laterality of tinnitus perception as well as by other studies assessing function of the limbic system in patients with tinnitus and an animal model.

Once negative associations with tinnitus are initiated, the low loop is automatically created and becomes dominant. The low loop does not involve cognition and is controlled by principles governing conditioned reflexes. Consequently, it is fast and activates the limbic and autonomic nervous systems before the higher loop may potentially modify reactions. Furthermore, conditioned reflexes cannot be modified by conscious thinking. Therefore, even though the patient may be totally convinced that tinnitus is benign, the negative reactions to the tinnitus signal will still occur.

The activation going through these two routes changes the strength of synaptic connections, enhancing the stimulation of the limbic and autonomic nervous systems by the tinnitus-related neuronal activity during the process of the development of tinnitus as a clinical problem. The question of how the neutral signal of tinnitus can evoke persistent strong distress can be answered by the principles of conditioned reflexes. It is necessary, to create a conditional reflex, the temporal coincidence of sensory stimuli with negative (or positive) reinforcement is sufficient. Habituation is defined as “disappearance of a reaction to a neutral stimulus due to its repetitive appearance without reinforcement.” The second, habituation of perception, occurs when awareness of this particular stimulus disappears.

Habitation of reaction and perception are natural processes. Habituation is a crucial characteristic of brain function necessitated by the brain’s inability to perform two tasks requiring complete attention simultaneously.

When forced to carry out two tasks concurrently that require full consciousness, the brain uses its function of task switching by actually devoting consciousness to only one task at a time. The brain areas involved in task switching have been indicated by a functional magnetic resonance imaging study. If forced to monitor all of the incoming sensory stimuli, our brain would not be able to perform any tasks, except that of monitoring, ultimately paralyzing us in our actions.

To solve this problem, the central nervous system screens and categorizes all stimuli at the subconscious level. If the stimulus is new and unknown, it is passed to a higher cortical level where it is perceived and evaluated. However, in the case of a stimulus to which we have previously been exposed, the stimulus is compared with patterns stored in memory. If the stimulus was classified as unimportant and does not require action, it is blocked at the subconscious level of the auditory pathways and does not produce any reactions or reach the level of awareness. The reaction to this stimulus and its perception is habituated. In everyday life, habituation occurs to the majority of sensory stimuli surrounding us.

However, if a specific stimulus was once classified as important and, on the basis of comparison with the patterns stored in memory, was linked to something unpleasant or dangerous, this stimulus is perceived and attracts attention. Furthermore, the sympathetic part of the autonomic nervous system reduces or inhibits responsiveness during repeated stimulation.

Habituation of perception of this stimulus will follow in the same manner as for all unimportant stimuli.
nervous system is activated, inducing reaction to this stimulus (frequently of the “fight or flight” category), which further reinforces memory patterns associated with this stimulus. Consequently, if the previous assessment of the importance of a stimulus has been confirmed, this specific stimulus becomes even more important; and its next appearance will result in faster identification, even in the presence of other competing stimuli, preventing the habituation of this stimulus. In the case of auditory stimuli, our auditory system becomes tuned to recognizing specific patterns of sound that have negative links. Under such conditions, the natural habituation of the tinnitus signal becomes impossible. In everyday life, this results in people having problems with their work, concentration, and sleep.

A simplistic description of the above process can be outlined to a patient as increased concern for tinnitus results in an increase of its significance, which ultimately increases the amount of time a person pays attention to it. This is a classic feedback loop or the “vicious circle” scenario, which increases patients’ level of distress up to the limit of mental and physical endurance. At this stage, the patient will move from acute tinnitus, which can be easily relieved by proper counseling, into a chronic stage, which is much more difficult to deal with.

In the case of tinnitus, it is impossible to remove the reactions induced by the excitation of the sympathetic autonomic nervous system or even change them in a substantial manner. The solution to achieve the passive extinction of the conditioned reflex, in which both stimulus (tinnitus) and negative reinforcement are continuously present, is to decrease the magnitude of this negative reinforcement over a period of time. This will result in partial weakening of the reflex, but has to be applied consistently to yield positive effects. Moreover, it is fundamental that patients understand these principles so that the enhancement of this reflex by inducing too much verbal thinking and beliefs can be minimized.

Once activation of the autonomic nervous system is lowered, this decreases negative reinforcement to a signal that is continuously present and gradually decreases the strength of the conditioned reflex. This causes further decreases in the reaction. Once tinnitus has achieved a neutral status, its habituation is inevitable as the brain is continuously habituating to all types of stimuli, providing that they are not significant.

Consequently, retraining counseling (the first component of TRT) is oriented toward reclassification of tinnitus into a category of neutral stimuli and removal of the patient’s negative associations with tinnitus. This is accomplished by educating the patients that their tinnitus results from a normal compensatory mechanism, which occurs in the auditory system, to typically minor changes in the cochlea. As part of counseling, it is also important to demystify the mechanisms through which tinnitus may affect a patient’s life. Counseling in TRT is a teaching session aimed at providing patients with a new frame of reference by explaining potential mechanisms of tinnitus generation, neurophysiologic mechanisms through which tinnitus is influencing various aspects of their lives, and that by activating a naturally occurring mechanism of brain function (habituation and the plasticity underlying it), it is possible to achieve primarily habituation of the tinnitus-induced reaction of the brain and the body and secondarily habituation of the tinnitus perception. The clear goal of achieving an active and selective block of tinnitus-induced reactions is set for the patients.

The second component of TRT is sound therapy aimed at decreasing the strength of tinnitus signal in a systematic manner over the period of time of the treatment. It is based on the following feature of brain function. All our senses are working on the principle of differences of the stimuli from the background, and the perceived strength of a signal is not linked directly to the physical strength of a stimulus. Presently, we cannot easily suppress tinnitus-related neuronal activity, but by increasing background neuronal activity, we are effectively decreasing the strength of this signal, which activates the limbic and autonomic nervous systems and which is being processed in all of the centers of retraining; (4) partial suppression (“partial masking”), which does not prevent retraining but does make it more difficult as the training is performed on a different stimulus than the original; and (5) activation of limbic and autonomic nervous systems by too loud or unpleasant sounds, yielding an increase in tinnitus and contracting habituation.

It is intuitive that if the sound level is significantly below the threshold level of detection, there is no basis to believe that it asserts any effect on the auditory system and tinnitus. On the other hand, when external sound becomes strong enough to suppress detection of tinnitus-related neuronal activity, by definition, any kind of retraining (including habituation) is prevented because the brain cannot change reactions to a stimulus it cannot detect.

When the sound level is still below but close to the threshold of detection, the phenomenon of stochastic resonance, that is, addition of a low level of noise can decrease the threshold of detection of the stimulus and enhance it when the stimulus is weak and close to the threshold of detection, comes into play. The presence of stochastic resonance has been shown at the level of hair cells and the auditory nerve, and preliminary data indicate its effect on the loudness of tinnitus. The effective sound level inducing stochastic resonance covers a range of about 15 dB, beginning from about -9 dB below the threshold of detection of the additional noise. Thus, owing to stochastic resonance, by adding low level external noise, for example, by using sound generators set at the threshold of hearing,
paradoxical enhancement of the tinnitus signal may occur. This will, in turn, make habituation more difficult. The results of a study in which a comparison was performed among groups with counseling only (including advice on using environmental sounds), counseling combined with sound generators set at the threshold of hearing, and counseling combined with sound generators set close to the “mixing point” fully support the prediction of the importance of stochastic resonance. The group that performed the worst was the one with the sound level set close to the threshold of hearing, whereas the group that performed the best was the one with the sound level set at the “mixing point,” with the counseling-only group in the middle.202

When sound level is increased further, the mechanism involving the decreased difference between the tinnitus signals and background neuronal activity becomes the dominant factor. As with all perception, the difference between signal and background plays a dominant role. By decreasing the difference between the tinnitus-related neuronal activity and the background ongoing neuronal activity, the effective strength of the tinnitus signal decreases, and this weaker signal is passed to the higher level cortical areas and, most importantly, to the limbic and autonomic nervous systems. This helps in initiating and sustaining the process of passive extinction of conditioned reflexes that link tinnitus to negative reactions.54,183 As the background activity is the sum of spontaneous and evoked activities, a decrease in the difference between the tinnitus signal and the background neuronal activity can be achieved by exposing patients to additional external sound.

This principle, if working alone, would imply that we should use a sound that is as intense as possible. Two other factors (3 and 4), however, become dominant. First, once the tinnitus signal is suppressed, by definition habituation will not occur owing to the lack of a signal to habituate (principle 3). Second, when the sound level surpasses the threshold of partial tinnitus suppression (“partial masking”), it will modify not only the intensity but also the quality (spectrum) of the tinnitus signal. Then retraining of neuronal networks will occur to the modified tinnitus signal and not to the original one. Owing to the generalization principle, that is, reaction can be induced to stimuli similar to the original, with the strength depending on the difference between the original and the modified signals, some habituation may still occur. The higher the external sound is above the threshold of partial masking, the smaller its contribution to habitation. Finally, once a level of total suppression is reached, the effectiveness of habituation is decreased to zero as the brain is unable to retrain to an undetectable signal.

The optimal setting of the sound level is different when hyperacusis is the dominant or the only problem. In this situation, the effect of stochastic resonance is of secondary importance to the primary need not to stimulate the auditory system sufficiently. Patients start with a sound level closer to their threshold but as high as their sound sensitivity allows, with the aim to be above the range of stochastic resonance. Once a partial reversal of hyperacusis is achieved, the sound level can be increased rapidly to address tinnitus directly. At this point, the rules previously outlined for patients with tinnitus should be followed.

Beneficial effects of the use of sound have been recently supported by results of experiments in which animals were exposed to a damaging sound level, which caused hearing loss and presumably tinnitus. Three groups of animals were studied: control, which were exposed to standard low level laboratory sound background, and two groups, which were subsequently exposed for several weeks to continuous broad-band, low, or high frequency sound. Control animals and animals exposed to low frequency continuous sound exhibited modification of the spontaneous activity recorded from the auditory cortex linked to tinnitus.203 Neuronal activity recorded from animals exposed to continuous high frequency sound was, however, similar to activity recorded from animals which were not exposed to damaging sound and which did not have tinnitus.46,92 These data support a postulate that continuous broad-band sound may reverse tinnitus-related changes in the neuronal activity of the auditory cortex.

The need to preserve stimulation in the low frequency range yields a strong recommendation for people who have relatively normal low frequency hearing to be provided with devices or hearing aids with fittings as open as possible. It is not sufficiently appreciated that in the normal acoustic environment there is a high proportion of low frequency sounds, below 200 Hz, which provide constant stimulation of the auditory pathways. Since the majority of patients have relatively normal hearing in this frequency range, they benefit from this stimulation. Consequently, blocking the ear canal with closed ear molds decreases the auditory input, and many patients experience enhancement of tinnitus when their ears are blocked.

Note that even the best hearing aids act as noise generators set at the threshold of hearing, totally remove hyperacusis.214 These data support a postulate that continuous broadband sound may reverse tinnitus-related changes in the neuronal activity of the auditory cortex.

TREATMENTS FOR HYPERACUSIS

Treatments for hyperacusis go into two contrary directions. First, the most common approach is to advise patients to avoid sound and use ear protection. This is based on reasoning that because patients became sensitive to sound, this may indicate that they are more susceptible to sound exposure and consequently need extra protection. Patients easily embrace this philosophy and start to protect their ears, even to the extent of using earplugs in quiet environments. Unfortunately, this approach actually makes the auditory system even more sensitive and further exacerbates hyperacusis.214

The second approach involves the desensitization of patients by exposure to a variety of sounds. The desensitization approach has been promoted for some time with a variety of protocols and types of sounds used, such as the recommendation of using sound with certain frequencies removed, short exposures to moderately loud sound, or prolonged exposures to low level sounds.84,85,215 A study of the neurophysiologic model of tinnitus, the latter approach is recommended and is used as part of TRT. Note that the misophonic component cannot be removed by desensitization, and a separate approach needs to be implemented.

Tinnitus Retraining Therapy for Decreased Sound Tolerance

TRT can help patients with both tinnitus and hyperacusis, and the presence of hyperacusis is one of the crucial factors in categorization of the patients (Table 8) and determining the optimal protocol for their treatment. It is recommended that if hyperacusis is present, it has to be treated first. Although TRT offers only a treatment for tinnitus rather than a cure, it can, in some patients with decreased sound tolerance, totally remove hyperacusis and misophonia, thus providing a cure for these conditions.92,93,184

In some patients, tinnitus and hyperacusis are two manifestations of the same internal mechanisms of increased gain within the auditory system.

questions remain unanswered. Mechanisms of tinnitus and hyperacusis are still challenging. Following a specific protocol, such as actively listening to music, is fundamental and that are pleasant, systematically in activities involving sound as in practice by instructing patients to engage.

The setting of sound generators for hyperacusis is more complex than for tinnitus treatment. There might be a need for a low setting of initial sound level, which might bring patients to the range of effects of stochastic resonance. A abbreviations: Impact on life—the extent tinnitus and/or hyperacusis influence patient’s life; Prolonged sound-induced exacerbation of tinnitus/hyperacusis—when the effects persists to the following day or longer; Significant hearing loss—having a significant impact on patient’s life; SG = sound generators; Combi = combination instruments; HA = hearing aids. Common treatment for each category involves counseling and the use of enriched auditory background. Sound used in sound therapy is always set below annoyance level. Note that the presence of misophonia, which is treated concurrently, does not affect categorization. A adapted from reference 204. Details of Tinnitus Retraining Therapy implementation are presented elsewhere. 

CONCLUSIONS

Tinnitus and hyperacusis are still challenging topics to study and symptoms to treat. Many questions remain unanswered. Mechanisms of tinnitus and hyperacusis are speculative and not yet proven. We do not yet have objective methods for detection and evaluation of tinnitus. We believe that the neurophysiologic model of tinnitus and TRT provide a promising approach that may ultimately result in a better understanding of tinnitus and in providing greater help to patients with tinnitus and hyperacusis.

The development and improvement of cochlear auditory prostheses have radically improved the management of children and adults with profound hearing loss. Rapid evolution in the candidacy criteria and the technology itself has resulted in large numbers of individuals who have benefited from implantation. Likewise, the introduction of three device manufacturers into the United States marketplace has accelerated the research and development of these auditory prostheses. In this chapter, the evaluation and expectations for both children and adults will be presented, as will the similarities and differences between all three available devices in the United States. The Advanced Bionics Corporation’s (Sylmar, CA) Hi-Resolution Bionic Ear (HiRes 90K) device, Cochlear Corporation’s (Englewood, CO) Nucleus Freedom device with the Contour electrode (CI24RE (CA)), and the Med-El Corporation’s (Durham, NC) Pulsar100 and Sonata100 devices, as well as various electrode options and external hardware, will be discussed. Surgical techniques and frontiers with applications with auditory prostheses, such as combined electroacoustic stimulation, rehabilitation of asymmetric hearing loss, bilateral cochlear implantation, and auditory brainstem implantation will be analyzed.

GENERAL BACKGROUND

Cochlear implants are auditory prostheses designed to link an internal device with the auditory nerve to an external device that uses a specific speech coding strategy to translate acoustic information into electrical stimulation. For the majority of causes of deafness, the auditory hair cells are lost or dysfunctional. The bipolar spiral ganglion neurons and their primary afferent dendrites remain intact, to varying degrees based on etiology, and are available for direct electrical stimulation by the cochlear implant. The tonotopic organization of the cochlea is emulated by orienting the electrode contacts toward the modiolus within the scala tympani and assigning frequencies to specific electrodes along the length of the electrode array such that electrical stimulation corresponding to the highest pitches are delivered within the apical region of the cochlea. The electrical impulses directly depolarize the primary afferent neurons, effectively bypassing the dysfunctional hair cells. All 3 device manufacturers use an external processor that encodes speech based on the features that are critical for word understanding in normal listeners, and these features are discussed in Chapter 33, “Cochlear Implant Coding Strategies and Device Programming.” There have been over 70,000 individuals who have received cochlear implants and these devices are now reliably enabling speech comprehension in the vast majority of appropriate cochlear implant recipients.

Prelingually deafened children acquire speech and language through central plasticity resulting from stimulation by auditory prostheses. Some prelingually deafened adults are appropriate cochlear implant recipients, but have more limited central plasticity that is required for auditory pathway development and processing. Postlingually deafened children and adults, as well as those with severe to profound hearing loss, who derive marginal benefit from hearing aids, are appropriate cochlear implant candidates. Detailed review of the current candidacy criteria for children and adults will follow.

PATIENT EVALUATION

There are several issues that can be generalized to both children and adults, and others that are specific to each of these groups. In this section we will address the common issues, followed by the specific adult and pediatric issues.

Otolologic/Medical Evaluation and Imaging

The medical evaluation begins with a detailed collection of the patient’s history, followed by physical examination. The otologic history includes age of onset, progression, bilaterality of the hearing loss; risk factors for hearing loss (eg, noise exposure, ototoxicity, trauma), and ear infection and surgery. History of possible vestibular dysfunction includes delayed walking, difficulty in riding a bicycle, or difficulty maintaining balance while walking with eyes closed or in the dark. A thorough family history is important, including the age of onset, severity and rate of progression of any hearing loss.

Genetic Hearing Loss. The etiology of the hearing loss is an important consideration. Profound hearing loss and deafness, while clear symptoms, have a heterogeneous group of causes. Of the genetic causes, over 400 forms of syndromic hearing loss have been described, and the list of nonsyndromic loci now exceeds 80; many of which are discussed in Chapter 26, “Hereditary Hearing Impairment.”

Congenital deafness occurs in approximately one in every 1,000 children, and at least 60% of these children have hereditary causes of the deafness. It is estimated that 70% of all hereditary hearing losses are nonsyndromic; nearly 80% of which are inherited in an autosomal recessive fashion. To date, 54 autosomal recessive, 24 autosomal dominant, and 8 X-linked loci have been characterized for nonsyndromic sensorineural hearing loss (NSHL). Several mitochondrial DNA variants have also been implicated. Studies indicate that up to 50% of all NSHL cases are due to a mutation in a single gene encoding connexin 26 (Cx26). The gene coding for Cx26 (gap junction protein beta 2 or GJB2) is located at locus DFNB1 on human chromosome 13q12. The coding sequence of the protein is contained in a single exon that can be easily analyzed using sequencing methods.

Gap junctions facilitate communication between adjacent cells by providing a channel for diffusion of ions, second messengers, and metabolites. Gap junctions are composed of an integral membrane protein called connexin, which can oligomerize to form single-membrane channels called connexons. Each connexon is composed of 6 connexin subunits arranged radially around a central opening, and in some cases can be composed of multiple types of connexins (heteromeric). Cx26 and connexin 30 (Cx30) are examples of different connexins that are capable of forming functional heteromeric connexon channels. Connexins are members of a multigene family composed of 20 different connexins with distinct tissue-specific distributions. Cx26 and Cx30 are coexpressed in many tissues including the cochlea where they are thought to provide a means of returning K+ ions to the endolymph after hair cell stimulation. A single genetic mutation, the deletion of a guanine within a stretch of six guanines at nucleic acid position 35 (35delG) resulting in premature...
The previous 4 syndromic disorders are not readily diagnosed at birth by history and physical examination. The most common dominant syndromes resulting in deafness are Stickler syndrome, branchio-oto-renal syndrome, and Waardenburg syndrome. When physical examination or history suggests a syndromic hearing loss, online resources have been developed to help the physician during the evaluation process.24

**Auditory Neuropathy/Auditory Dysynchrony.** Over several years evidence has gradually emerged regarding the existence of a hearing disorder that does not fit into the standard conductive, mixed, or sensorineural hearing loss categories. Relatively recently, the diagnosis of auditory neuropathy/auditory dys-synchrony (A/N/AD) has been specified as a hearing disorder in which outer hair cell function is normal in conjunction with absent or abnormal auditory neural responses, which is indicative of poor neural synchrony.25 Reports on the incidence of A/N/AD symptoms range from 0.5% to 1.3%17 of the population suspect for hearing loss and 15% of those with absent auditory brainstem responses,26 who are otherwise consistent with those with severe-to-profound sensorineural hearing losses. Behavioral audiometric thresholds may or may not be within normal limits and can fluctuate over time, and speech perception in patients with A/N/AD is often much poorer than the behavioral thresholds would predict. There are many possible reasons for poor auditory neural synchrony, including, but not limited to, dysfunction of inner hair cells, of the inner hair cell-spiral ganglion neuron synapse, or of the auditory nerve itself.

The variety of etiologies in A/N/AD results in a heterogeneous population. Starr and colleagues reported the diagnoses from 70 patients with A/N/AD as fitting into the following categories: 40% hereditary, often associated with Charcot-Marie-Tooth disease; 20% with a mix of causes including toxic-metabolic (ie, anoxia, hyperbilirubinemia), immune, and infectious; and 40% idiopathic.28 Recent investigations have examined the genetic aspects of nonsyndromic A/N/AD. Nonsyndromic A/N/AD heritability has been documented as X-linked,29 autosomal dominant,30 autosomal recessive,39,33,37,38 M itochondrial mutations with A/N/AD have also been reported.34 In a large family of European descent, a gene responsible for late-onset, progressive, autosomal dominant A/N/AD (Locus AUNA1) has been mapped to chromosome 2q12–23,35 the locus of which was named DFN B9.35–37 DFN B9 has been identified as an autosomal recessive locus associated with sensorineural hearing loss35–39 and more recently with A/N/AD.32,34 Y asunaga and colleagues identified the causative gene for DFN B9 which they termed otolfin (OTOF) due to the sequence and structural homology OTOF shared with the spermatogenesis factor Fer-1 in C. elegans.38 In the 4 unrelated Lebanese families with DFN B9, a nonsense mutation in OTOF was found which was homozygous in all affected individuals and heterozygous in their parents, consistent with a recessive inheritance pattern. Such a mutation was not found in 106 unrelated, unaffected Lebanese individuals. Recent investigations of families of Spanish,33,35,41 European,32,33,41,42 and Turkish35 origin have determined that mutations in the OTOF gene are associated with clinical findings of A/N/AD. The OTOF gene has 48 exons, or coding regions, and has both short and long isoforms in humans.44 There are 6 and three C2 domains on the long and short OTOF isoforms, respectively, and it is hypothesized that these C2 domains are instrumental in binding calcium and subsequent synaptic vesicle docking.45,46 Strong otolfin expression in mouse tissue samples has been found in cochlear inner hair cells, vestibular type I sensory cells, and brain tissue, while no or little otolfin expression has been observed in the outer hair cells, supporting cells, and spiral ganglion cells.46 Due to the potential for synaptic involvement and the inner hair cell expression findings, OTOF is considered an excellent candidate for underlying some cases of recessive A/N/AD. To date, there have been 23 coding variants (affecting 16 exons) identified in OTOF which are considered to be pathologic.28,29

Audiologic findings for patients identified with DFN B9 commonly present with prelingual onset, severe-to-profound hearing loss29,35,37,38,40–43; however, there are instances of OTOF mutations associated with moderate-to-severe hearing loss and even with temperature-sensitive A/N/AD that leads to exacerbation of hearing loss when febrile.40,45 While the spectrum of OTOF mutations and associated phenotypes are emerging, there have been reports of intervention outcomes for individuals with OTOF mutations. In the few cases available, hearing aid use has not demonstrated benefit whereas cochlear implantation has been considered successful.32,42,44 In general, fitting A/N/AD patients with hearing aids may not provide sufficient benefit for amplification, as amplification provides increased sound intensity but does not have the capability to contribute to improved neural synchrony. After careful evaluation and
when recommended, electrical stimulation with cochlear implants holds promise as a treatment option for individuals who are severely hearing impaired from AN/A.45,46 and has been successful in our clinical experience. However, cochlear implantation may be contraindicated in individuals in whom neural function is compromised.

Acquired Deafness. In young children, many acquired forms of deafness cannot be easily differentiated from genetic deafness. Prenatal infection with TORCH microorganisms (toxoplasmosis, syphilis, rubella, cytomegalovirus (CMV), and herpes) is commonly associated with deafness. This spectrum of infections can result in reduced ganglion cell counts, cognitive dysfunction and abnormal position of the facial nerve, all issues limiting the effectiveness of cochlear implants or increasing the risk of cochlear implant surgery. Prematurity and low birth weight, low Apgar scores, and hyperbilirubinemia can all be associated with deafness and, because of the central auditory processing abnormalities associated with these conditions, expectations for performance outcome following cochlear implantation should be tempered. Similarly, there can be rehabilitation needs and problems with these multiply disabled children.

Autoimmune inner ear disease, first described by McCabe in 1979, is typically rapidly progressive in nature and is often associated with some of the best possible outcomes in postlingual patients receiving cochlear implants, largely due to the well-preserved primary afferent neuron population and the short duration of deafness. While it is unusual that patients with bilateral Meniere disease lose enough hearing to require cochlear implantation, these patients typically perform at excellent levels with an implant, likely due to the relatively high level of residual hearing.

There are many inherited or acquired diseases affecting the temporal bone that can produce severe to profound hearing loss requiring cochlear implantation. Examples of these disease processes include: otosclerosis, Paget disease, Camurati–Engelmann disease,49 and meningitis with secondary labyrinthitis ossificans. Aside from the potential difficulty in electrode insertion, the reduction in bone density often leads to unwanted sequelae such as facial nerve stimulation due to current spread outside of the cochlea. These challenges impact the postoperative programming of the device.

Although rare, bilateral temporal bone fractures resulting in deafness can be rehabilitated with cochlear implants. Early implantation should be performed to avoid cochlear fibrosis. If imaging studies suggest trauma to the auditory nerve, it is important to determine if the auditory nerve is functional using promontory electrical stimulation while recording electrically evoked auditory brainstem responses (ABR). The use of auditory brainstem implantation in this clinical setting has been reported in Europe50; however, the first such application of this technology in the United States occurred recently as will be discussed later.

Physical Examination. All adults or children with profound hearing loss should have a complete physical examination. This should include features commonly associated with syndromic deafness. Important features include branchial cleft pits, cysts or fistulae, preauricular pits, telecanthus, heterochromia, white forelock, pigmentary retinopathy, goiter, and craniofacial abnormalities. It is also important to keep in mind that each of these genetic features can have variable expressivity, thereby limiting the specific phenotype.

Chronic Suppurative Otitis Media. Cochlear implantation was initially viewed as contraindicated in young children with chronic suppurrative otitis media (CSOM) because of the potential risk of infection.33 However, selective retrospective studies have shown that the prevalence and severity of OM does not increase following implantation,52,53 leading surgeons to advocate cochlear implantation if the ear is dry at the time of implantation.

At present, there is no general consensus regarding the management of patients with CSOM with severe to profound hearing loss requiring cochlear implantation. Some surgeons advocate a two-stage operative approach: the first operation involves a radical mastoidectomy (if not already performed), eustachian tube obliteration, and mastoid cavity obliteration with oversewing of the ear canal. Cochlear implantation is performed at a later time, usually 2 to 6 months postobliteration.54 The major risk of mastoid obliteration is the formation of cholesteatoma, which must be carefully monitored on a long-term basis. Other authors advocate an individualized management strategy: (1) patients with a dry tympanic membrane perforation receive a first-stage myringoplasty followed by implantation in 3 months; (2) patients with cholesteatoma or an unstable mastoid cavity receive a radical mastoidectomy and obliteration followed months later by a second-stage cochlear implantation; (3) patients with a stable cavity receive one-stage cavity obliteration and electrode implantation.55 Finally, some practitioners advocate treating radical mastoid cavities with a one-stage operative approach that includes overseeing the external auditory canal and cochlear implantation without obliteration or reduction of the cavity.56,57 Luntz and colleagues have described a treatment algorithm with multiple steps aimed at resolving the draining ear.58 Using this strategy, cochlear implantation is performed at the completion of any step if the ear is dry. The existence of multiple protocols for managing cochlear implant candidates with CSOM reflects the problematic nature of this disease process. Regardless of the management protocol, all patients currently receive selected antimicrobial prophylaxis immediately prior to implantation.59

Microbial biofilms are a common if not normal phenomena in nature; however, in the clinical arena biofilm formation is associated with increased morbidity and mortality.59,60 Biofilms are characterized by a complex 3-dimensional architecture with a network of adherent cells connected by water channels and encapsulated within an extracellular matrix.61 Biofilms are recalcitrant to antibiotics, antiseptics, and industrial biocides. Possible mechanisms include (1) restricted penetration of drugs through the matrix; (2) phenotypic changes resulting from a decreased growth rate or nutrient limitation; and (3) surface-induced expression of resistance genes. While there is an extensive literature on bacterial biofilms, little attention has been paid to medically relevant fungal biofilms, despite the fact that yeasts are the third leading cause of catheter-related infections, with the second highest colonization to infection rate and the highest crude mortality. Transplantation procedures, immunsuppression, use of chronic indwelling catheters, and prolonged intensive care unit stays are salient risk factors for fungal disease.62 Biomedical devices including: stents, shunts, and prostheses (voice, heart valve, knee, etc); implants (breast, lens, dentures, etc); endotracheal tubes; pacemakers; and various types of catheters have been shown to support colonization and biofilm formation by Candida.63 A fibrin graft alone has been shown to be insufficient for cure, requiring removal of the biomedical device.62

Since the advent of antibiotics in the 1940s, many authors have reported fungal overgrowth following antibacterial therapy.65 Although bacteria usually cause CSOM, fungal infection or overgrowth is surprisingly common. One prospective study in CSOM patients reported growth of Candida species in 10% of ears with purulent otorrhea and in 35% of ears treated for purulence with topical ciprofloxacin for 3 weeks.66 Furthermore, another study in which cultures were obtained from ears with ventilation tubes and otorrhea before and after a 10-day course of topical ofloxacin ear drops (Floxin) or oral amoxicillin/clavulanate demonstrated a 5% incidence of Candida superinfections in the amoxicillin/clavulanate group but negligible incidence in the ofloxacin group.67,68 These results confirm the findings of an earlier study in which the incidence of Candida was significantly greater for patients treated with amoxicillin/clavulanate compared to a group treated with topical ofloxacin. We have had 1 case of fungal colonization of a cochlear implant with Candida albicans.69 No guidelines have been proposed for dealing with episodes of otitis media in the early postoperative period. During this time interval, the physical barrier created by the fibrous sealing of the cochleostomy is in the process of being laid down; and, thus, the electrode array provides direct access to the inner ear. An infection of the middle ear during this period may easily extend along the electrode array, induce damage to the auditory nerve, and possibly lead to biofilm formation, requiring immediate removal of the implant. In addition, this puts the patient at higher risk for further spread of infection into the intracranial space and subsequent meningitis.70 The high prevalence of bacterial biofilms in chronic otitis media have been recently demonstrated,71 and bacterial biofilms have also...
been demonstrated in cases of infected cochlear implants that required explantation.14 Biofilms are discussed in Chapter 71, “Biofilms.”

Imaging. Preoperative high-resolution temporal bone computed tomography (CT) scans, without contrast, should be performed on all cochlear implant candidates. Determination of intact internal auditory canals (IACs), normalcy of the cochlea, primary or secondary bone diseases affecting the cochlea, and presence of a wide vestibular aqueduct represents an important data set to complete. Many children with congenital deafness will be found to have an associated cochlear malformation, typically dilated vestibule, wide vestibular aqueduct, cochlear hypoplasia or a common cavity.15 When congenital or acquired narrow IACs are identified on preoperative CT scanning, primary afferent innervation may be lacking and cochlear implantation is therefore contraindicated (Figures 1 and 2).49,74 Another important finding to identify is a wide vestibular aqueduct which when present is an indication to perform preoperative magnetic resonance imaging (MRI) (Figure 3). This is an important preoperative consideration since this abnormality is associated with an abnormal communication between the cerebrospinal fluid (CSF) space and the cochlea. Clinically, this is often associated with a “perilymph gusher,” and sealing of the cochleostomy with pericranium or fascia is particularly important to avoid meningitis following acute suppurative otitis media. Hypoplastic cochleas are associated with shorter length and range in character from a common cavity to an incomplete partition at the apical region of the cochlea (Figure 4). In children with auditory neuropathy/auditory dysynchrony, MRI should be performed since up to 18% of these children can have small or absent cochlear nerves despite normal IAC size as demonstrated with CT.15 Other anomalies such as the abnormal course or position of the facial nerve and round window niche occur. With the exception of an absent auditory nerve or IAC, most malformed cochleas can be implanted with a sufficient number of electrodes to provide open-set (unlimited word or sentence possibilities) speech perception.

**Labyrinthitis ossificans** can occur after meningitis, particularly when Streptococcus pneumoniae is the infecting microorganism.16 Whereas temporal bone CT can show complete ossification well (Figure 5), MRI can provide complementary information when partial ossification has occurred (Figure 6). T2-weighted MRI sequences are particularly useful in determining whether a scala tympani with partial ossification or fibrosis contains perilymph (Figure 6).

High-resolution temporal bone CT scanning can also be helpful in sorting out issues related to device dysfunction or when unexpectedly poor outcome occurs. Figure 7 shows the temporal bone containing a Med-El C40+ device in a patient who has otosclerosis and the new onset of facial nerve stimulation. The reduced bone density and lucency seen around the otic capsule resulting from her advanced cochlear otosclerosis allowed current to spread from the cochlea to the facial nerve. Figure 8 shows the temporal bone of a young child whose performance was unexpectedly low and who was also noted to have facial nerve stimulation with cochlear implant use. After his referral to our center for evaluation, a high-resolution temporal bone CT was obtained. The CT scan showed a malformed cochlea with an incomplete partition at the apex and the electrode tip leaving the cochlea and extending into the IAC. This type of cochlear malformations is typically associated with a thin partition between the modiolus and the IAC.

**EVALUATION OF ADULT COCHLEAR IMPLANT CANDIDATES**

The benefits of cochlear implantation have increased substantially over the last quarter century due to changes in technology and expanded candidate criteria. Consideration for cochlear implantation in adults still requires careful assessment to (1) determine preimplant hearing aid fitting and performance, (2) compare a candidate’s preimplant performance with that of current implant recipients, (3) provide a recommendation for or against cochlear implantation, (4) select an ear for implantation, and (5) determine appropriate expectations that will guide the counseling of prospective patients, which is critical for user satisfaction.
Current Adult Selection Criteria

Food and Drug Administration (FDA) approved guidelines for cochlear implantation vary slightly with different clinical trials depending on the manufacturer's submission and labeling aims. Guidelines also change over time, in part, due to findings that cochlear implant recipients' average scores are higher than individuals with better hearing or word recognition. Current adult selection criteria in the most recent clinical trials include (1) severe or profound hearing loss with a pure-tone average (PTA) of 70 dB HL, (2) use of appropriately-fit hearing aids or a trial with amplification, (3) aided scores on open-set sentence tests of <50%, (4) no evidence of central auditory lesions or lack of an auditory nerve, and (5) no evidence of contraindications for surgery in general or cochlear implant surgery in particular. Additionally, cochlear implant centers generally recommend at least 1 to 3 months of hearing aid use, realistic expectations by the patient and family members, and willingness to comply with follow-up procedures as defined by the center.

The goal of the evaluation process is to determine whether an individual would perform as well with appropriately-fit hearing aids as with a cochlear implant. In addition to comparing the candidate's performance with average cochlear implant users, it is important to compare the candidate with cochlear implant users who are matched for such factors as length of profound hearing loss or useable residual hearing, which are known factors that contribute to the variance in patient performance. In other words, if a candidate has had recent onset of profound hearing loss, it is more appropriate to compare him or her to the top 25% of cochlear implant users. Likewise, if a candidate has had no hearing aid use for 20 years and long-term deafness, it is more appropriate to compare that individual to the lower 25% of implant recipients' performance. However, even with the most educated guess of cochlear implant outcome for a given individual and the knowledge that detection levels can be improved, specific postimplant results cannot be guaranteed, and this principle must be effectively communicated to potential candidates.

Adult Audiologic Protocol. For adults, sound detection and speech perception abilities are assessed to determine candidacy. Preoperatively, patients are evaluated with a battery of measures while using hearing aids, and the results are compared to the most recent average and range of cochlear implant performance. Preoperative measures are also repeated postimplant for longitudinal monitoring of patient performance. Single-subject research designs are often implemented in clinical trials in which each patient serves as his or her control, primarily due to the large variability within the population of cochlear implant candidates and users. The selection of preoperative test measures, therefore, should also take into consideration comparative postimplant measures.

Preimplant audiologic tests include unaided and aided detection thresholds for pure-tone and word-tone stimuli, respectively. Unaided thresholds are obtained in each ear individually, and aided detection thresholds may be obtained monaurally as well as binaurally. Although there are no aided detection level criteria, it is helpful to determine aided levels as one aspect of appropriate hearing aid fitting and for comparison to expected postimplant sound-field detection thresholds. For some patients, aided testing can also reveal recruitment, that is, unusual sensitivity to loud sounds, that may limit benefit from amplification due to the inability to incorporate needed hearing aid gain.

Aided speech perception abilities are often assessed in both monaural and binaural conditions, depending on the use of amplification in each ear. Speech perception measures are conducted in the sound field, typically at a presentation level of 60 dB SPL and include open-set recorded
Word and sentence recognition tests included in the Minimum Speech Test Battery (MSTB) for Adult Cochlear Implant Users are assessed at many cochlear implant centers to assess performance. The MSTB is a set of compact disc recordings designed to provide word and sentence tests for the pre- and postimplant evaluation of speech recognition, regardless of implant device. The Consonant-Nucleus-Consonant (CNC) Monosyllabic Word Test\(^{27}\) assesses single-syllable word recognition. One CNC list contains 50 monosyllabic words presented in an open-set format. The CNC Words were among the original set of words from which the Northwestern University Auditory Test 6 (NU6) Monosyllabic Word Test\(^{28}\) were taken.

The presentation of auditory-only sentence lists from the Hearing in Noise Test (HINT)\(^{19}\) evaluates each patient's ability to understand sentence material in quiet or in the presence of background noise. Each HINT list is phonemically balanced and contains 10 sentences recorded by a male speaker that are equivalent in the features of length, intelligibility, and naturalness. When the sentences are presented in noise, the signal-to-noise (S/N) ratio typically used is +10 dB, although this ratio can be adjusted to make the test condition more or less difficult. For patients with some open-set speech recognition for words and/or sentences preoperatively, the Bamford-K 

\[\text{Figure 7} \quad \text{High-resolution temporal bone axial CT scan using a bone window algorithm shows a right ear with a well-positioned electrode array (Med-El C40+) within a cochlea affected by otosclerosis. Note the reduced density of the otic capsule bone and the lucency surrounding the otic capsule (center, top right). This patient was experiencing facial nerve stimulation problems. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)}\]

\[\text{Figure 8} \quad \text{High-resolution temporal bone axial CT scan using a bone window algorithm shows a right ear with a cochlear implant electrode array that has broken through the cochlea/modiolar wall to enter the internal auditory canal (CII Bionic Ear with HiFocus 1j electrode). The implanting surgeon, at another institution, did not recognize that the child had an incomplete partition at the apex of the cochlea. This malformation can be associated with a thin bony wall between the cochlea and the modiolus. This child was performing at a level lower than expected with his cochlear implant and had facial nerve activation with implant use, which led to the CT scan to evaluate the electrode position. The child's second side was implanted with a HiRes 90K device, and the initial device was removed and replaced with a HiRes 90K device, resolving his facial nerve stimulation problem. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)}\]
These modifications include: controlled opening and specific surgical techniques designed to make the Med-El device, and 10 mm for the Nucleus inserted in the cochlea (Figure 9). This is obtained must be preserved when the electrode array is inserted. To use EAS, the low-frequency residual hearing cal signals that are complemented by acoustic sig-nals that are important to the basolateral direction, allowing the ear with the basolateral hearing to be better. In addition, some patients have considerable residual hearing in the lower frequencies (ie, 250 and 500 Hz), but little measurable hearing for frequencies at 1,000 Hz and above. In these patients, it is difficult to obtain good aided benefit in the high frequencies with a hearing aid while maintaining appropriate gain in the lower frequencies where little, if any, amplification is needed. The ability to understand speech is consequently compromised by the inability to detect and/or discriminate important high-frequency sounds. Also, low-frequency sounds may be masked or distorted by the power needed in the high frequencies. These findings have led to the investigation of combined electrical and acoustic stimulation (EAS), such that the basal end of the cochlea receives electrical signals that are complemented by acoustic signals received at the apical portion of the cochlea. To use EAS, the low-frequency residual hearing must be preserved when the electrode array is inserted in the cochlea (Figure 9). This is obtained by using shortened electrode arrays (20 mm for the Med-EI device, and 10 mm for the Nucleus Hybrid device) inserted into the scala tympani and specific surgical techniques designed to make the electrode insertion asatraumatic as possible. These modifications include: controlled opening and no direct suctioning of perilymph from the scala tympani; avoidance of perilymph contamination by blood and debris; use of nonototoxic topical antibiotics, corticosteroids, and lubricant (hyaluronic acid) during insertion; and immediate sealing of the cochleostomy after insertion using fascia. Speech perception findings reported thus far suggest improved performance in the combined EAS condition compared to either stimulation condition alone and compared to preimplant performance. Traditionally, individuals have received cochlear implants in 1 ear only. With the implementation of clinical trials with bilateral implantation and the benefits of binaural implantation being realized, current candidacy decisions now include whether to receive 2 implants rather than 1. Outcomes data regarding the benefits of binaural implantation continue to emerge, and clear benefits in sound localization and listening in noise have been published. Specifically, studies have shown that binaural implants provide a “head shadow” effect for listening to speech in the presence of other noise or competing speakers. This occurs because 1 ear is “shadowed” from the noise source when speech and noise come from different directions, allowing the ear with the better S/N ratio to do the listening. Other binaural advantages occur when information from both ears is combined to improve listening. Binaural summation effects have been reported whereby performance is improved in the binaural condition compared to either monaural condition when speech and noise are in the front. Binaural squelch effects have been reported less frequently to date, but in some cases, improvement in performance has been shown by adding the ear near the noise source. Both binaural summation and binaural squelch effects rely on successful bilateral interaction of the brainstem and central auditory system nuclei, whereas the head shadow effect is simply a physical phenomenon created by the listener’s head. We have found that presentation of more difficult auditory stimuli helps to demonstrate the improved benefit obtained by patients tested in the binaural condition compared to that with their better performing cochlear implant.

Binaural implantation in adults recently completed clinical trials at a number of centers and with each of the cochlear implant manufacturers in the United States. It has now become the norm for patients to inquire about the possibility of bilateral implantation and receive bilateral cochlear implants if they so desire. Because results have been generally positive and the majority of bilateral recipients indicate a strong preference for bilateral over unilateral implant use, it is now the case that binaural implantation has become a part of the candidacy decision.

Factors that Affect Adult Cochlear Implant Performance

The most common preimplant factors that affect performance for adults include hearing experience (eg, amount of residual hearing, length of profound hearing loss, and hearing history for each ear), age at onset of profound hearing loss (particularly if prior to age 3 years), age at implant (particularly if prior to age 3 years), cognitive/central abilities, and motivation to hear. Postimplant factors that contribute to performance levels may include length of cochlear implant use, stability of threshold and comfort levels used for device programming, and lifestyle. The need for auditory skills and social interaction in the environment can be a greater issue for those who are not in the workforce or who live alone (often the elderly) since they have less practice listening.

Ear Selection in Adult Unilateral Cochlear Implant Candidates

Cochlear implant teams have different philosophies about the selection of the ear for implantation. Some believe that the poorer ear should be chosen for implantation while others consistently choose the better ear. Generally speaking, with a normally developed cochlea, we expect the ear with the shortest length of deafness, better acoustic detection thresholds, acoustic hearing at more frequencies, and better word recognition, to be the better ear for cochlear implantation. At our center, 74% of adults have a cause that includes progressive hearing loss compared to 18% with
sudden bilateral hearing loss and 8% with congenital bilateral hearing loss. Although at times there is no ear difference, given the complexities in hearing history and ear asymmetry that can exist with progressive hearing loss, it can be difficult to know which ear is the better to select for unilateral implantation. If there has never been a response to acoustic stimulation in one ear, we select the other ear for implantation. Given that there is no medical reason to do otherwise, if either ear is a reasonable choice for implantation, we typically determine whether a hearing aid on the contralateral ear would be beneficial in conjunction with the cochlear implant. If so, we recommend implantation of the poorer ear with hearing aid use on the other side. If neither ear can continue to use a hearing aid, then we generally implant the better ear. If either ear can continue to use a hearing aid equally well, we choose the ear to implant based on handedness, patient preference, or other nonotologic reasons.

**Recommendations for Referral for Adult Cochlear Implant Evaluation**

At our center, we suggest the following referral criteria for cochlear implant evaluation for adults. Referral to a cochlear implant center does not mean that the individual is necessarily going to receive a cochlear implant, but that an evaluation is recommended to determine whether a cochlear implant would be beneficial. If the individual meets the following criteria, an evaluation is suggested. The criteria are (1) unaided thresholds of 70 dB HL or poorer at 1,000 Hz and above in the better ear, even if hearing levels at 250 and 500 Hz are better; (2) unaided word discrimination <70%; and (3) frustration on the part of the patient due to communication difficulties, even with appropriate hearing aid use.

**EVALUATION OF PEDIATRIC COCHLEAR IMPLANT CANDIDATES**

Cochlear implants have been available for children ages 2 to 17 years since 1990. Originally, children who were candidates for cochlear implantation typically had profound bilateral sensorineural hearing loss with PTA thresholds of 100 dB HL or greater, often with corner audiograms. These children also displayed aided sound-field thresholds well below the range of average conversational speech and typical speech detection thresholds at and above 60 dB HL. During early clinical trials, pediatric candidates were not able to understand words when using their hearing alone, even with high-gain hearing aids and well-fitted earmolds. Since then, candidacy criteria have changed and technology has improved, both of which have influenced benefit. As with adults, consideration for cochlear implantation still requires careful assessment to (1) determine preimplant fitting of hearing aids and baseline performance, (2) compare a candidate’s preimplant performance with that of current implant users, (3) provide a recommendation for or against cochlear implantation, (4) select an ear for implantation, and (5) determine appropriate expectations that will guide the counseling of prospective families.

**Current Pediatric Selection Criteria**

The selection criteria for children vary slightly depending on the respective FDA approved clinical trial and/or criteria recommended by the cochlear implant center. Generally speaking, the subject selection criteria include the following: (1) 12 months through 17 years of age; (2) profound sensorineural hearing loss (unaided PTA thresholds of 90 dB HL or greater); (3) minimal benefit from hearing aids, defined as <20 to 30% on single-syllable word tests, or for younger children, lack of developmentally appropriate auditory milestones measured using parent report scales; (4) no evidence of central auditory lesions or lack of an auditory nerve; and (5) no evidence of contraindications for surgery in general or cochlear implant surgery in particular. Additionally, cochlear implant centers generally recommend at least 3 to 6 months of hearing aid use, unless cochlear ossification is noted or anticipated; realistic expectations by family members; enrollment in a postoperative rehabilitation program that supports the use of cochlear implants and the development of auditory skills; and willingness on the part of the family to comply with follow-up procedures as defined by the center.

**Pediatric Audiologic Protocol**

As with adults, children are assessed preoperatively with a battery of sound detection and speech perception measures while using hearing aids, and this baseline is compared to the most recent average and range of cochlear implant performance. For children, speech perception measures assess a wide range of auditory skills from sound detection to recognition of words and sentences. Measures are selected that are developmentally appropriate for the child’s age, language level, and auditory ability. Although the audiologic assessment will play a key role in candidacy, with children other factors may influence the candidacy decision and/or postimplant outcome, and therefore a multidisciplinary team approach is advised.

Prior to cochlear implant evaluation, most children will have an ABR test as an objective measure of the status of the peripheral and brainstem auditory system. With an ABR, acoustic click stimuli are presented to assess auditory sensitivity to each ear. Children who are implant candidates typically have no response to acoustic stimuli at the limits of the testing equipment, suggesting with reasonable accuracy hearing loss in the profound range. Another group of children that can display absent or abnormal ABR findings are those with auditory neuropathy. In these cases of absent or abnormal ABR, comparison of positive (condensation) and negative (rarefaction) polarity stimuli will show an inversion of the peaks of the cochlear microphonic. The cochlear microphonic appears as an early latency response on the ABR waveform and is indicative of outer hair cell function. Otoacoustic emission testing can also be used as a measure of outer hair cell function. Due to the prevalence of children diagnosed with AN/A/D, and the number of these children who have received cochlear implants, our current protocols for electrophysiologic assessment include otoacoustic emission and ABR testing, since these measures are sensitive to cochlear and auditory nerve function, respectively. The diagnosis of auditory neuropathy does not necessarily preclude a child from cochlear implant candidacy.

Unaided detection thresholds for pure-tone stimuli are obtained in individual ears using standard clinical procedures. Aided thresholds are obtained in the binaural condition, and if possible, the monaural conditions. For young children who are unable to participate in speech perception tasks, both unaided threshold testing and electrophysiologic measures become important criteria for cochlear implantation. Since we know the limitations of hearing aids, if we are confident in the reliability of the unaided threshold levels, we can predict with some certainty the eventual aided benefit. Using hearing aids, the measurement of sound detection levels, and with possible, speech perception abilities, can provide confirmation of the unaided thresholds. Although 1 criterion for pediatric candidacy is profound hearing loss, published reports and clinical experience both indicate that adults with severe hearing losses perform well with cochlear implants, therefore we might expect the same outcome for children with similar severe hearing losses. With respect to children with AN/A/D, unaided detection levels vary considerably and may not be predictive of aided levels or speech perception abilities.

Tests of speech perception assess a range of skills depending on the child’s auditory abilities and language level. Closed-set measures include a small number of choices that are provided to the child either as objects or pictures (eg, Early Speech Perception Test or ESP). M onosyllable, nonsense words are spoken with audition alone (no visual cues), and the child is asked to select the object or picture that represents the stimulus. With open-set measures of word and sentence recognition, no choices are provided. The child repeats the words or sentences presented in quiet or in the presence of background noise. For example, using the Lexical Neighborhood Test (LNT), 50 monosyllabic words are presented that are either “easy,” occurring with high frequency in the English language and having few lexical neighbors, or “hard,” occurring less frequently and with many lexical neighbors. For children with vocabulary levels that approximate a 5-year-old, the Phonetically Balanced Kindergarten (PBK) Test can be administered which includes 50 words, and has been in clinical use for many years. Recordings of the BKB Sentences and the HINT-C Sentences are typically used in the evaluation process for children who have some language and auditory experience. For children who are too young to
participate in speech perception measures, parent interview scales are administered. The Meaningful Auditory Integration Scale (MAIS) \(^4\) asks questions of parents or family members related to the child’s spontaneous awareness of sound and use of audition in a meaningful way at home, school, or other natural environments.

Other Evaluations for Pediatric Cochlear Implant Candidates. For children, the results of speech production assessments are good indicators of hearing history and whether the child has learned to use his or her residual hearing. Language evaluations are also important since the ultimate goal of cochlear implantation is effective communication. Neither of these areas of assessment dictates candidacy, but they contribute to the confirmation of hearing levels and expected preimplant communication coincident with auditory experience. Results also are used to monitor either pre- or postimplant performance over time and to develop rehabilitation goals for educators, clinicians and parents.

A psychological evaluation is obtained to assess the child’s verbal and nonverbal intelligence, attention and memory skills, and visual-motor integration. When considering a child for a cochlear implant, counseling the family pre-implant, and planning for possible rehabilitative needs postimplant, it is important to know the cognitive abilities of the child. If the child is gifted, for example, then expecting average cochlear implant performance may be an underestimation. Likewise, if the child has a developmental delay, this will affect rate and eventual level of performance with the implant; and counseling may be directed toward more conservative expectations. Differentiating the influence of deafness and cochlear implantation from other disabilities or diagnoses, such as developmental delay, autism, attention deficit disorder, or learning disabilities can be difficult. These issues are addressed in the psychological evaluation preimplant and influence the recommendation for or against cochlear implantation, provide guidance for counseling families, and assist in rehabilitative planning.

Success with a cochlear implant can be influenced by the collaboration of individuals working with the child (parents, educators, and therapists). A team effort is best initiated during the preimplant process and sets the stage for later communication between the individuals on the implant team and the child’s educators and family. Early cultivation of communication is important for a variety of reasons, including confirmation of the child’s test results and use of residual hearing, discussion of areas of concern, sharing effective test-taking and rehabilitative strategies, setting expectations, and identification of postimplant rehabilitation resources and goals.

Outcome Expectations for Children. Auditory detection levels with a cochlear implant are expected to be similar to those for adults, which are approximately 25 dB HL for frequencies 250 through 4,000 Hz. These detection levels allow access to information that is important for the development of auditory skills and communication. As with adults, when determining expectations, it is important to stay informed of the average and range of pediatric cochlear implant performance.

In a publication by Geers and colleagues, \(^5\) the results of 81 prelingual deaf children, implanted prior to age 5 years who had used their cochlear implants for an average of 5 years, were reported for the outcome areas of speech perception, speech production, spoken language, total language, and reading. The average scores reported for several measures are as follows: ESP-spondee 85%, ESP-mono-syllable 79%, LNT-easy 48%, LNT-hard 44%, and BKB sentences 57%. Children who were good speech perceivers were also the children who exhibited superior performance for measures of speech intelligibility, language, and reading. Half of the children were enrolled in oral communication programs and the other half were enrolled in programs using total communication. Those children enrolled in educational environments that emphasized auditory and spoken language development had the highest scores on speech perception, speech production, and language measures. In this study, subjects were implanted between 1992 and 1994, mostly using the Nucleus 22 and SPEAK coding strategy; therefore, the most recent cochlear implant technology and candidacy criteria were not represented.

Studies conducted with children indicate that earlier implantation is associated with higher performance for a given time period postimplant, \(^6\) that preimplant unaided residual hearing influences performance and the development of speech perception skills postimplant, \(^7\) and that there is a steady increase in performance over time that does not plateau during the first 3 to 5 years of implant use. \(^8\)

Based on research studies and clinical experience, we describe below general expectations for children with onset of deafness of less than 1 year based on their age at implantation. Expectations for children implanted at age 2 years and before include the potential for communication skill development at rates similar to normal-hearing peers, potential for speech to be easily understood by strangers, reduced or possible elimination of language delay, attendance at a neighborhood school with minimal support services by kindergarten or first grade, and increased likelihood of becoming an auditory/oral communicator. Expectations for children implanted before the age of 4 years include substantial improvement in speech perception, increased vocalizations/verbalizations at early stages postimplant, auditory behaviors evident before they can be formally measured, speech production skills reflective of auditory abilities, and language delays that are reduced. For children implanted between 4 and 5 years, expectations include improvement in speech perception with excellent closed-set performance and varied open-set abilities, improvements in speech production, use of hearing to support improvements in language, and reduced dependence on visual cues for communication.

For children implanted at or after age 6 years, we expect improved auditory detection abilities, improvements in speech perception that entail good closed-set abilities but limited open-set skills, possible improvements in speech production, and continued dependence on visual cues for communication. Generally, children implanted at an older age require more time to reach their potential with the device than those implanted at younger ages.

In addition, for children with progressive or sudden onset of hearing loss, we expect excellent progress with cochlear implantation and achievement of these skills with a shorter duration of cochlear implant use. Likewise, for children with some residual hearing preimplant, we also expect higher levels of performance in relatively shorter periods of time. As discussed regarding adults, it is important to match expectations with reasonable appropriate outcomes for children based on their hearing history, age at implantation, and nonaudiologic factors.

Current Trends that Affect Pediatric Cochlear Implant Candidacy

Binaural Cochlear Implants. Far beyond what has been experienced with adult patients, the majority of major cochlear implant centers are now performing bilateral cochlear implantation of children in the majority of children. Reports in children have followed similar trends as those for adults, with improvements in the ability to recognize speech in noise and to localize a sound source. The ability to follow large spatial changes in speaker location is a critical skill for academic learning in the classroom setting, as is the ability to follow rapid changes between speakers in a smaller space, such as in a small group setting at school or during a conversation with multiple speakers at home. Bilateral implantation is desirable for young children during the critical period for the development of spoken communication. To study the observed clinical benefits reported by parents and teachers and observed by clinicians caring for these children, there are several multicenter investigations of bilateral cochlear implantation in children currently underway in North America and Europe. Due to the longer periods required for speech language development in young children, these trials are designed to extend a minimum of 5 years. Based on the findings in these trials, the circumstances for which we would recommend bilateral implants for children will be evident.

Factors that Affect Pediatric Cochlear Implant Performance

The most common preimplant factors that affect performance for children include age at implantation, hearing experience (age at onset of profound hearing loss, amount of residual hearing, progressive nature of the hearing loss, aided levels, and consistency of hearing aid use), training with amplification (in the case of some residual hearing), presence of other disabilities, and parent and family support. Postimplant factors that
contribute to performance levels include length of cochlear implant use, rehabilitative training, and family support. Communication mode is also a documented variable that affects postimplant outcome, where children in programs and homes that focus on the development of spoken language perform higher than children in programs without this emphasis.97 Children using total communication at school and home can achieve substantial levels of performance; however, this achievement will be less likely if an emphasis on auditory skill development and spoken communication is not included with the use of sign language.

Ear Selection in Pediatric Cochlear Implant Candidates

For children whose parents elect for their child to receive a single cochlear implant, the selection of the ear for unilateral implantation follows the same logic as discussed earlier for adults. At our center, the pediatric population differs from the adults in that fewer children have an etiology of progressive hearing loss (22%), compared to those with congenital bilateral hearing loss (65%), or sudden onset of bilateral hearing loss (13%). In general, this results in fewer children having ear asymmetries or patterns of change in hearing over time; therefore, there are fewer children with ear differences. Since we encourage the use of a contralateral hearing aid postimplant if at all possible, we select the ear for implantation that is least likely to benefit from amplification. All things being equal, we select the right ear to capture the possible advantage of contralateral, left hemisphere specialization for speech recognition.103

Recommendations for Referral for Pediatric Cochlear Implant Evaluation

At our center, we suggest the following referral criteria for cochlear implant evaluation for children. As mentioned previously with adults, referral to a cochlear implant center does not mean that a child is necessarily going to receive a cochlear implant, but that an evaluation is recommended to determine whether a cochlear implant would be beneficial. If the child meets 1 or more of the following criteria, an evaluation is suggested. The criteria are (1) unaided thresholds of 90 dB HL or poorer at 2,000 Hz and above in the better ear, even if hearing levels at 250 and 500 Hz are better; (2) aided levels in the better ear poorer than 35 dB HL, especially at 4,000 Hz; (3) no response for ABR testing in both ears or no response for 1 ear and responses at elevated levels in the other ear; (4) parents are frustrated with their child’s development of auditory and/or communication skills; (5) progressive hearing loss with detection levels at or near the profound range at 2,000 Hz and above; or (6) evidence of severely impairing auditory neuropathy/dys-synchrony. There is no lower age limit for evaluation; age at implantation is a critical factor that influences postplant performance, and children who may be too young for the operation are not too young for evaluation.

DEVICE SELECTION

All cochlear implant systems include external and internal hardware. The external equipment includes a microphone, a speech processor, and a transmission system. The internal device includes a receiver/stimulator and electrode array.

In general, an external microphone picks up sound and speech in the environment and sends the information to a speech processor, either the body-worn (BW) or ear-level type. The speech processor converts the sounds into electrical signals, which are sent across the skin via radio frequency transmission to the internal receiver/stimulator. The transmission of the signal occurs when there is successful alignment of the external magnet housed in the transmitter with the internal magnet housed in the receiver/stimulator. The receiver/stimulator decodes the signals and delivers them to the electrodes positioned within the cochlea. The electrodes stimulate the auditory nerve, and the signal is sent along the auditory pathway to the auditory cortex. A description of the most recent available equipment for each cochlear implant manufacturer used by patients in the United States is provided below.

Figure 10 General appearance of the Nucleus Freedom device with the Contour Advance electrode. Note the receiver/stimulator, removable magnet, loop antenna, separate ground electrode, and electrode array. (Published with permission, copyright © 2007 Cochlear Americas.)
The Nucleus device also has a second electrode design, a double electrode array to be used for implantation of severely ossified cochleas (Figure 12). The configuration for this includes two electrode arrays, each with 11 contacts within a length of 8.5 mm. A depth gauge is used to determine whether the standard or double array is appropriate.

**HiRes 90K.** The Advanced Bionics Corporation system includes the HiRes 90K receiver/stimulator (Figure 13) and a choice of 2 electrodes; the HiFocus 1j array or the Helix array. The receiver/stimulator uses a flexible silicone housing surrounding a titanium case, the overall dimensions are 28 x 56 mm, and the thickest point is 5.5 mm where the electronics are encased in titanium; however, the portion designed to remain on the surface of the skull is only 2.5 mm thick. The HiRes 90K system has a removable magnet that has been approved by the FDA to allow for an MRI with a field strength of up to 1.5 T, providing that the magnet has been removed. The HiFocus 1j electrode system is shown in Figure 14. This electrode is “banana-shaped” and curved toward the modiolus, consisting of 16 contacts, spaced every 1.1 mm over 17 mm. The diameter of the intracochlear portion ranges from 0.6 to 0.8 mm. The length of the electrode array inserted into the cochlea is 23 mm. The electrodes face the modiolus with a width of 0.4 mm and length of 0.5 mm. The HiFocus 1j electrode system utilizes an insertion tube through which the insertion tool allows advancement of the electrode array. Both a metal (outer diameter of 1.5 mm) insertion tube and a Teflon (outer diameter of 2 mm) insertion tube are included, and selection is based on surgeon preference; however, the metal tube provides greater stability. Gentle pressure along a thumb-driven advancement mechanism is required to insert the electrode. Should errors occur during electrode insertion, the electrode is easily reloaded into the insertion tube, and additional electrode insertion attempts can be completed until the electrode insertion has been achieved.

The HiFocus Helix electrode system is shown in Figure 14. This electrode is designed to be perimodiolar in location after insertion. The array consisting of 16 contacts spaced every 0.85 mm over 13 mm. The diameter of the intracochlear portion ranges from 0.6 to 1.1 mm. The length of the electrode array inserted into the cochlea is 24.5 mm. The electrodes face the modiolus with a width of 0.4 and length of 0.5 mm. The HiFocus Helix electrode system utilizes a preloaded styllet assembly by which the electrode array is advanced. Should errors occur during electrode insertion, the electrode is easily reloaded into the insertion styllet assembly, and additional electrode insertion attempts can be completed until the electrode insertion has been achieved. This is in contrast to the Nucleus Contour Advance perimodiolar electrode that cannot be reloaded after removal of the styllet.

**Med-El PulsarCI** and **Sonata100.** The Med-El PulsarCI device uses a receiver/stimulator that is housed in a ceramic case that is 26.5 mm at the base, 23.7 mm at the end, and 4 mm thick (Figure 15). The PulsarCI device has FDA approval for use with MRI at 0.2 T causing no additional risk to the patient or significant impact on the device or image quality, except for the magnet-induced artifact surrounding the internal magnet. In Europe, many patients with Med-El implants have safely undergone MRI studies with 1.0 and 1.5 T scanners. The Med-El system has 6 separate electrode designs (Figures 16 and 17). The standard electrode is the longest electrode available in the marketplace and is tapered in design. Twelve pairs of electrode bands are distributed over the 31.5 mm electrode array length. The contacts are spaced over 26.4 mm with 2.4 mm between each contact. There is also a FLEX eas array (20.9 mm) available for applications such as EAS; for cochleas that are partially ossified, a compressed electrode is available; and
for severely ossified cochleas, a split electrode array is available. In July 2007, FDA approval was granted for the Med-El Sonata™100 internal device (Figure 15). The Sonata™100 Cochlear Implant contains the same 150 electronics as the PulsarCI100 device, but the electronics are encased in a titanium housing that is smaller and thinner than the PulsarCI100 ceramic casing. All Med-El electrode arrays are compatible with the Sonata™100. The receiver coil and internal magnet are positioned outside of the electronics package in flexible silicone, although the magnet is not removable for MRI. The Sonata™100 is also MRI-compatible in the United States at 0.2 T without magnet removal.

If ossification of the cochlea is encountered during the opening of the cochleostomy, the use of the Med-El Insertion Test Device (ITD) can be helpful to determine which of their various electrode options should be used. If the ITD can be inserted to the small flanges present 17.8 mm from the tip, the standard array should be used; if less than that, the medium or compressed array should be used. The medium electrode array (PulsarCI100M) has all 12 pairs of electrodes distributed over 21 mm-spaced 1.9 mm apart. The PulsarCI100 compressed electrode (PulsarCI100S) is designed with the same number of electrode contacts (n = 12 pairs) but arranged closer together on the apical end of the array and spaced over 12.1 mm. With ossification present, the ITD is advanced through the cochleostomy and the depth of insertion is determined. If it is apparent that insertion of the standard electrode array would result in electrodes being extracochlear in location, the compressed or medium electrode array should be used and fully inserted.

External Speech Processors

Each manufacturer offers a BW and behind-the-ear (BTE) processor. The BW processors were the first wearable devices for each implant type, followed by the introduction of BTE processors, which are generally preferred by adults and some children/parents. Both BW and BTE processors have program switches, volume and/or sensitivity controls, batteries (rechargeable or alkaline), and accessories. External processor wear options vary from one device to another, but may include, for example, a remote battery pack worn off the ear or a rechargeable battery pack worn on the processor at the ear. A variety of mechanisms exist (eg, earhooks, indicator lights) that perform functions such as alerting parents to a low battery or a disconnected headpiece. External auditory input sources can be connected to the processors, such as auxiliary microphones, telephone adaptors, tape recorders, television audio amplifiers,
or FM systems. Other cosmetic considerations include a variety of processor and transmission coil colors, decorative caps, processor belt clips and harnesses, or hip packs for daily wear. Since the external equipment changes regularly, the specifics for each manufacturer are reviewed at the time of device discussion and selection, which occurs once cochlear implantation has been recommended.

Current Speech Processing Strategies

Specific aspects of current speech processing strategies are discussed in Chapter 33, “Cochlear Implant Coding Strategies and Device Programming,” and the purpose of this section is to present the relevance of speech processing strategies to device selection.

Speech processing strategies used in auditory prostheses have evolved over the years to enhance presentation of the acoustic signal by electric stimulation. Early on, the primary goal for cochlear implant signal processing was to maximize encoding of the speech signal, which was a prudent and necessary starting place since the devices were designed to restore aural communication abilities to otherwise deaf individuals. The subsequent strides in development of speech processing strategies and the changes in cochlear implant candidacy have raised the bar beyond encoding speech in quiet to now including goals for understanding speech in noise and for appreciation of nonspeech acoustic stimuli such as music.

In general, signal processing improvements across all devices have addressed issues with electrical field interaction, extraction of temporal and spectral characteristics, and stimulation rate. Current strategies available tend to have faster sampling and stimulation rates, and new strategies are being developed to increase the number of perceived stimulus delivery channels, all of which allow for a higher resolution representation of an acoustic signal. Regardless of how ideal a signal processing strategy may be, however, there are always patient-based limitations due to physiologic or anatomic issues that affect the accurate neural encoding of the electrical signal. Many investigations are currently being undertaken to address both stimulation and patient-based limitations.

With respect to device selection, all devices offer several different speech processing strategies, with some strategies potentially more appropriate for an individual patient than others. For example, a person who has a relatively short-term hearing loss of cochlear origin likely have a large number of auditory nerve fibers available for stimulation.13  A high-resolution strategy would likely be appropriate for this individual, and this would be particularly desirable if the listening needs included various challenging listening environments and music appreciation. In some cases, however, it may be beneficial to employ a low-rate strategy, particularly in cases of reduced neural integrity such as demyelination or other neuropathies in which rapid stimulation of nerve fibers can result in slowing or even blockage of action potential conduction along the nerve.101-106. Although these are general guidelines, care must be taken to avoid underestimating a cochlear implant user’s potential based on these factors alone.

Regardless of device choice, it is common clinical practice to allow patients to try various signal processing strategies or different parameter settings within a strategy (ie, pulse width, pulse rate, and paired versus simultaneous stimulation) in different listening situations and determine which results in the best speech perception performance and sound quality. Therefore, implementation of a speech processing strategy requires consideration of the cochlear implant user’s cause of hearing loss, interests, performance, subjective judgments, and communication and listening needs.

Factors that Affect Device Choice

In our center, we currently implant over 100 patients per year. We approach device choice as a personal decision that the patient or the child’s parents should make. Extensive counseling and education regarding the devices, operation and rehabilitation, which are important aspects of caring for patients with profound hearing loss who choose to receive a cochlear implant, help to prepare patients or a child’s parents to make an informed decision. Below we have outlined several factors that are important for consideration preoperatively.

Need for Special Electrode Arrays. When individuals have hearing loss that is appropriate for cochlear implantation, it is possible that the cochlea may be malformed, depending on the etiology of the hearing loss. This includes varying degrees of Mondini malformation, in which there may be fewer cochlear turns or dehiscent cochleae. The cochlea may be ossified, to varying degrees, which may occur with meningitis, Paget disease, or otosclerosis. In addition, there are types of hearing loss that may necessitate preservation of hearing with implantation. In any of these cases, it may be necessary to have special electrode arrays available, such as short, compressed, split or custom arrays, all of which were described earlier.

Technology Differences in Speech Coding Strategy and Electrode Configuration. Device selection is also influenced by changes in technology that may make one device more appealing than another for a given individual. For example, a speech coding strategy that emphasizes both temporal and spectral cues may be desirable for a patient who has a great love of music. Depending on an individual’s work or other daily life environment, certain noise reduction features may become relevant. As discussed previously, in some cases, a patient may be limited to selecting a given device based on his or her cochlear anatomy or hearing status that requires the use of a particular electrode array design.

Magnetic Resonance Imaging Compatibility. MRI is a powerful noninvasive diagnostic tool that uses magnetic fields and pulses of radio waves to generate images. The components of a MRI unit include: a static magnetic field (0.5 to 4 T), magnetic fields due to switched gradients (0 to 20 T/s at ~15 Hz); and radiofrequency energy (0 to 6 kW peak at 64 MHz [for 1.5 T]).107,108 It is an imaging modality with an already wide range of clinical applications that continues to expand. Ideally, this diagnostic tool should be available for the benefit of cochlear implant (CI) recipients. The Cochlear Corporation’s C124M, C124R (CA), and C124A B1 devices, as well as the Advanced Bionics Corporation’s HiRes 90K device were all designed so that the internal magnet can be removed and replaced to complete a MRI study.

Studies with the Med-El Combi 40/40+ and Clarion 1.2 (Advanced Bionics) cochlear implants have delineated many of the factors in CI/MRI interactions.109,110 The factors that have been studied include: demagnetization, artifacts, induced voltages, temperature increases, torque, and force. These investigations have utilized both the 0.3 and 1.5 T MRI units. The force and torque exerted by the MRI unit on the internal magnet of the cochlear implant receiver are of particular concern. The potential for a catastrophic force on the implant to fracture the inner table of skull and exert pressure on the brain demands full investigation of cochlear implant/MRI compatibility. Previous studies concluded that a 0.2 T MRI evaluation force and torque remained within “acceptable limits.”109,110 There have been several in vivo studies performed in Europe using 1.0 T MRI.107 In this largest series of 30 patients with Med-El cochlear implants who underwent 1.0 T MRI evaluations with a variety of MRI sequences, none suffered pain, burning, auditory sensation, deterioration of their auditory abilities, or other adverse sequelae. Presently patients with the Med-El C40+, PulsarCI, or Sonata, devices in place greater than 6 months are approved by the FDA to undergo MRI studies with a 0.2 T scanner provided the company approves the protocol for the radiologist.

We have completed studies to determine the magnitude of force required to fracture the floor of a cochlear implant receiver bed.111 The testing protocol was designed to create a physical worst-case scenario, yet approximate the in vivo condition. Several considerations went into attaining this dual goal. Each recessed cochlear implant bed was drilled to a maximum uniform thinness rather than drilling just deep enough to accommodate the cochlear implant. A stainless steel template was chosen for impacting the specimens because the arc of its edge would closely approximate that of the cochlear implant impacting the skull in vivo. In addition, a line load system more realistically approximated the in vivo condition than a point load system. The center of the specimen was chosen for contact with the template. This placement minimized the risk of the template touching any surface other than the floor of the recessed cochlear implant bed. It also
facilitated identical placement of the template for each specimen. Finally, this placement allowed the template to impact the specimen at its least reinforced site, thereby providing a worst-case scenario. Since the in vivo system had the thinned bone in continuity with the native skull and it is this region that receives the force vector during the cochlear implant magnet/MRI magnet interaction, it is anticipated that the biomechanical forces required to produce failure at this interface would be much greater than those measured in the study referenced above.112 In an earlier investigation of cochlear implant/MRI compatibility, 0.3 to 1.0 N was used as an acceptable level of force exerted on a cochlear implant during MRI evaluation.109 They recommended this range because it represents the magnitude of force that a cochlear implant may experience during a regular day in the life of a cochlear implant recipient. More specifically, this is the magnitude of the force exerted on the internal magnet of a cochlear implant when the external transmitter and magnet is removed. In these prior studies, the measured force vectors ranged from 0.17 to 0.42 N. Calculations using these measured forces vectors and appropriate geometry resulted in maximum forces of ~8 N exerted on the cochlear implant during 1.5 T MRI evaluation in a worst-case scenario. The results of our biophysics studies showed that the load carrying capacity of a recessed cochlear implant bed drilled into fresh frozen human calvaria specimens, with bone thickness of 0.3 to 0.6 mm (SD 0.11 mm), is more than an order of magnitude greater than this force (mean = 134.13 N).111 When a bone island with exposed dura is necessary to inset the internal device, titanium or resorbable mesh has been shown in vitro to provide even greater mechanical support beneath a cochlear implant and this approach also has the advantage of providing immediate support.112 Moreover, we have demonstrated that no demagnetization of the internal device magnet occurs after 15 successive MRI scans in a 1.5 T unit.113 Further studies in patients will be necessary to demonstrate the safety of this practice using cochlear implants with the internal magnet remaining in place. However, for all candidates, and particularly those who are in need of frequent MRI scans, the options and limitations of each device should be discussed so that the patient can make an informed decision.

External Speech Processor Size, Weight, and Aesthetics. Often, the design and esthetics of the external components, specifically the speech processor, has a great deal of influence on device selection (Figures 18 to 20). Individuals tend to prefer a BTE processor because it is lighter, smaller, and does not have a cord that runs down the back of the neck. For young children, it may be desirable to use a BW processor that can be worn on the child’s back and out of reach. In addition, some BTE processors may be too large or heavy to stay on a child’s ear. However, some manufacturers have introduced smaller, lighter BTE wear options designed specifically for children.

Patients with dexterity or vision problems often select a processor with larger, more accessible controls. Color choice of the external components is also relevant. Some prefer to match hair and/or skin tone, and others like interesting designs or colors they can change to match their clothing.

Batteries. The type, cost, and lifespan of batteries are important to some patients when choosing a device. BW speech processors can use either disposable alkaline or rechargeable batteries. BTE processors use either disposable high-power 675 hearing aid batteries or proprietary rechargeable batteries, depending on the manufacturer of the device. The specific processor, battery type, speech-coding strategy, and patient programming needs each affect battery life. However, the generally expected battery life and ease of changing the batteries may cause a patient or family to choose one implant design over another.

**OPERATIVE TECHNIQUES IN COCHLEAR IMPLANTATION**

The details of cochlear and brainstem implantation have recently been reviewed.114

**Figure 18** Ear-level and BW speech processors for the Nucleus Freedom System. (A) Freedom BTE speech processor. Multiple colors are also available. Disposable or rechargeable batteries are used. (B) Freedom BW speech processor. Note the ear hook, which contains the microphone and the magnet/transmitter coil. (Published with permission, copyright © 2007 Cochlear Americas.)

**Figure 19** Harmony ear-level speech processor. Multiple colors are available, lower right, and multiple colored accent strips are also available. A separate BW battery pack is also available for infants with cochlear implants. (Published with permission, copyright © 2007 Advanced Bionics Corporation.)

**Figure 20** Ear-level speech processors for the Med-El cochlear implant systems. The OPUS 1 has a modular design with 2 small switches, whereas the OPUS 2 has a more ergonomic switch-free design. Multiple colors are available. A separate BW battery pack is also available for infants with cochlear implants. (Published with permission, © 2007 Med-El Corporation.)

**Patient Positioning and Preparation**

For both children and adult patients, the standard otologic position is used, supine with the head placed on a foam doughnut and turned away from the operated ear. Surgical preparation should always include review of the CT and/or MRI to determine the cochlear anatomy and whether the cochlea is filled with fluid, fibrous tissue, or neo-ossification. With the wide array of available cochlear implant electrode designs, this is particularly important to be certain that the appropriate electrode array has been ordered and is available in the operating room.

**Soft Tissue Incisions and Approach**

Over the years, several variations of scalp and skin incisions have been utilized in cochlear
implant surgery. While several flaps have been utilized with consistently good results, 2 fundamental principles must be adhered to: first, the blood supply of the flap must be amply for survival of the flap; and second, the skin incisions must not overlie the cochlear implant itself. With this evolution in flap design have also come changes in philosophy regarding the amount of hair that must be shaved. Figure 21 shows the commonly utilized skin and scalp incision designs that are currently used by most cochlear implant surgeons. The only hair shaved is that necessary to allow draping of the field around the incisions. The postauricular incision is designed to be at the hairline and is thereby camouflaged. The posterior scalp extension length can be varied depending on the implant design. Because the internal magnet and receiving coil can be placed lateral to the skull for the Nucleus Freedom device (Cochlear), the HiRes 90K device (Advanced Bionics) and the SonataTI device (Med-El), shorter scalp incisions are required for these devices, thereby permitting a “minimally invasive” approach. A pocket can be developed beneath the existing scalp flap to receive these portions of the device. For the Pulsar, (Med-El) device the entire ceramic receiver portion of the device must be inset into the skull; and, therefore, the scalp incision must be somewhat longer. This issue is of no functional consequence and does not produce additional morbidity in patients. Moreover, this scalp incision is placed within the patient’s hair and is not seen once it is healed and the hair has regrown.

There are differences in the soft tissue approach between adults and children. For young children the incisions are carried through the skin, temporalis muscle and pericranium (periosteum), directly down to the bone. The soft tissue flaps are elevated en bloc, and subperiosteal elevation is completed to expose the sites of bone work necessary to accomplish cochlear implantation. An important point to consider and accomplish during this aspect of the operation is adequate exposure of the external auditory canal and zygomatic root. A ample elevation of the soft tissue necessary to protect the soft tissue from the surgical drill is also an important point.

With adults and older children, it is possible and desirable to develop 2 tissue planes. The first is in an avascular subgaleal plane lateral to the pericranium and temporalis fascia and mastoid periosteum superiorly and anteroinferiorly, respectively. Once these flaps are elevated, incisions through the peristeum are made first along the temporal line superiorly with a perpendicular extension down to the mastoid tip. The superior limb of this incision is carried posteriorly over the skull, and a periosteal flap is then elevated. These flaps are used to close the wound in 2 layers that further help in protecting the receiver portion of the cochlear implant and, thereby, minimize the risk of extrusion.

Several pieces of temporalis fascia or pericranium are harvested and kept sterile in the moist gauze sponge on the back table and are used for sealing the cochleostomy, for placing it between the facial nerve and electrode array, and in helping to retain the electrode array at the juncture of the trough housing the electrode array and the mastoid cavity. Once hemostasis has been achieved either with the bipolar or monopolar electrocautery, the monopolar cautery is taken off of the operative field and turned off. Once the cochlear implant has been opened and placed on the operative field, it is necessary to remove the monopolar cautery to prevent current-induced damage to the internal device.115

For both adults and children the elevated soft tissue flaps are protected with 1” x 3” cottonoids or moistened gauze sponges (Kendall Vistech sponges, TYCO Healthcare Group LP, Mansfield, MA) and retracted from the bone with dental fish hooks (DermaHooks, Weck Closure Systems, Research Triangle Park, NC) and rubber bands. Alternatively, after placement of the cottonoids and/or moist Vistech sponges, self-retaining retractors can be used.

**Receiver Bed and Electrode Array Trough**

Preparation of the receiver bed begins by selection and design of the placement. It is important to place the receiver bed posterior enough to accommodate the ear level hook or BTE speech processor. Placement of the receiver bed in a position that is too far anterior is a common mistake made by inexperienced cochlear implant surgeons. As is shown in Figure 22, the consequence of this is extrusion of the receiver following skin erosion due to the ear hook or BTE speech processor placing pressure on the skin overlying the receiver. A nother consideration in designing the position of the receiver bed is the anticipated position of a hat band, should the patient frequently wear hats or wish to wear hats. Each device manufacturer provides templates that are used in designing the shape of the receiver bed, and these accurately represent the size of the receiver. There are specific differences in how the receiver bed is designed and these will be described in separate subsections of this portion of the chapter; however, general techniques are described first (Figure 23). Whereas it is possible

![](image1.png) **Figure 21** Cochlear implant surgery skin incision designs. This style is commonly referred to as a lazy S or traditional postauricular and scalp skin incision (left). This style is used with the minimally invasive cochlear implant surgery technique (right). (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

![](image2.png) **Figure 22** Placement at another institution of this Nucleus CI24M device too close to the posterior aspect of the pinna resulted in skin erosion and device extrusion. Pressure from the behind-the-ear hook/microphone rubbing against the skin above the internal receiver/stimulator contributed to the skin breakdown and device extrusion. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

![](image3.png) **Figure 23** Cranietomy for placement of the internal receiver/stimulator using the bone island technique (left). A thin plate of bone together with the Med-El Pulsar, (Med-El) receiver/stimulator is displaced toward the brain. Tie-down sutures can be placed through channels created at an angle across the calvaria as shown or across the entire calvaria as shown in Figure 24. Cranietomy for placement of the Nucleus Freedom, HiRes 90K or SonataTI internal receiver/stimulator (right). With small children, the skull is too thin to accommodate the internal receiver/stimulator without performance of a craniotomy. In which case, a bone island technique is used with the remainder of the device remaining on the surface of the skull. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)
children a small cutting bur, usually 2.5 or 3 mm in diameter is used to remove the outer cortex and diploic layer while for older children and adults, a 6 mm cylinder bur is helpful because it allows perpendicular walls to be created around the receiver site while simultaneously, removing bone with the coarse diamond surface located on the tip of this type of bur. During the creation of the craniotomy and bone island necessary to accommodate the receiver-stimulator, inadvertent dural injury may occur. If this violation is small and fascia is placed through the opening, so that the fascia remains both medial to and lateral to the dura in a dumbbell-shaped manner the dura is easily sealed. It is also important to determine that no brain parenchymal injury has occurred.

Figure 24 shows the two methods available to create the tie-down suture holes through the bone, as well as the relative position of the internal device and the mastoidectomy. Two to four sites for suture tie-downs are created so that 3-0 nylon sutures can be used to secure the cochlear implant receiver.

Bone wax is useful for hemostasis; and, if there is epidural bleeding, strips of Surgicel (Ethicon, Inc., Somerville, NJ) are placed into the epidural space to achieve hemostasis and prevent postoperative epidural hematoma formation.

In the following subsections, specific details necessary to create the receiver beds for the currently available devices are described.

**Nucleus Freedom.** The Nucleus Contour device has two options regarding creation of the receiver bed. The first is to create the cylindrical well to receive the deepest portion of this cochlear implant. It is common in young children to require craniotomy down to dura and creation of the bony island as described above. For the majority of adults and older children, this is not necessary and a craniectomy is all that is required. The remainder portion of the internal device is placed lateral to the skull and in particular, the magnet and loop antenna have a low profile and are barely palpable beneath the scalp flap (see Figures 9 and 10). The remaining rectangular portion of the internal device/receiver is palpable; and, for this reason, it is especially important for this device to be placed well posterior to the position that will be occupied by the BTE speech processor. A nouter option for this device is to create a receiver bed that will accommodate most of the volume of the Nucleus Freedom receiver. This is done in the same manner as described above, and the advantage of this is that it allows a more integrated placement of the internal device but does require creation of a complex bony island and craniotomy, which requires additional surgical time.

The Nucleus Freedom device has a separate ground electrode that is placed beneath the temporalis muscle, which is located lateral to the principal electrode array. A trough is created between the internal receiver and the area of the mastoidectomy. A 2 mm cutting bur is used to create this trough, and an important point is that the dissection is completed so that one of the bony margins is cantilevered over the tract created in the bone. This further helps in securing and protecting the electrode array.

**HiRes 90K.** The HiRes 90K device has 2 ground electrodes, 1 built into the primary electrode array, just distal to the internal device, and the second built into the titanium internal case (see Figure 13). Therefore, a second electrode carrier containing the ground electrode is not used with these devices. The trough utilizes a cantilevered segment of the bone either on the superior or inferior aspect of this trough that is helpful in keeping the electrode array from becoming exteriorized on the lateral aspect of the skull (see Figure 24). The HiRes 90K Bionic Ear has a silastic carrier surrounding the components and has a position for a replaceable internal magnet within the center of the loop antenna (see Figure 13). The issues specific to the HiRes 90K receiver bed are similar to those described in the Nucleus Freedom device. The design of the HiRes 90K differs from the Nucleus Freedom device principally in the mid-portion of the internal device between the magnet and loop antenna and the electrode array. The design allows for a more tapered device that will theoretically result in less frequent problems with extrusion and skin erosion that experienced with the Nucleus devices. Thus, it is possible to create a small internal well to accommodate the most medial aspects of this device while allowing the remainder of the device to be positioned lateral to the skull. It is also possible to create a larger complex receiver bed that would accommodate this entire component as has been described in the Nucleus Freedom device subsection. The trough to accommodate the electrode array is the same as is necessary to accommodate any of the available electrode arrays.

**Med-El PulsarCI** and **SonataCI**. The biggest difference in the receiver bed for the Med-El PulsarCI is that the electrode array and ground electrode emanate from the side of the cochlear implant instead of from the proximal end of the cochlear implant, as is the case with the other available devices (see Figure 15). A accommodation for this design feature requires that the bony trough begins at the side of the implant internal device and must be positioned so that 1 of the holes necessary to secure the implant can be placed. This is shown in Figures 17 and 25 and illustrates the relative distance between the electrode trough and the internal device necessary to accommodate this specific tie-down hole.

Because the depth of the PulsarCI is approximately 4 mm (3.9 mm) some of the adult patients do not require a craniotomy down to the level of the dura and creation of a bone island. This however, is necessary in virtually all children and many adults. The same principles described in earlier sections apply with this device, both in terms of creation of the bony island and the trough necessary to accommodate the electrode array. The ground electrode is separate and is placed beneath the temporalis muscle, as is the case with the Nucleus Freedom device. Regarding the titanium and silicone Med-El SonataCI device, 1 design goal for this new housing is to allow a minimal incision and, therefore, faster recovery. The surgical approach recommended for the SonataCI is similar to that used for the Nucleus Freedom and HiRes 90K devices.

**Mastoidectomy, Facial Recess Approach, and Cochleostomy Techniques**

**Mastoidectomy.** The important point in considering the mastoidectomy for placement of a cochlear implant is that the defect is much smaller than that utilized for chronic otitis media (Figures 24 and 26). In contrast to the standard method of saucerizing the mastoid cavity, this is not performed in cochlear implant surgery. There are 2 areas that should be skeletonized, and the most important of these is the bony external auditory canal. If the bony external auditory canal is not thinned appropriately, the angle through the facial recess becomes more difficult to negotiate and the size of the posterior aspect of the mastoidectomy becomes much larger. It is important to skeletonize the bony external auditory canal but not to violate the integrity of this structure. Should this occur, the risk is that the electrode array can be extruded through the skin of the external auditory canal. Consequently, it is necessary to reinforce this area either with a graft comprised of thick AlloDerm (LifeCell Corporation, Branchburg, NJ) or a bone graft harvested from the cortex of the skull. The second area that needs to be skeletonized is that

Unlike an older child or an adult, it should be noted that the bony external auditory canal is extremely thin and the sigmoid sinus is dehiscent. Bony overhangs are designed to help retain the coiled electrode array. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

Figure 25 Six-month-old infant undergoing right cochlear implantation after completion of the craniotomy. The craniotomy and bone island were designed to conform to the receiver/stimulator device and allow the electrodes to remain in situ without compression. The bone island is inset approximately 4 mm for the Med-El C40+ receiver/stimulator to be placed so that the lateral aspect of the device is flush with the surface of the skull. Six holes were created through the skull to allow 3-0 nylon sutures to be used for securing the internal device. This was necessary due to the small head size, and this helps to avoid tilting or rolling of the device during healing and reformation of the bone beneath the receiver/stimulator. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

Of human temporal bones, the facial recess is of adult size by at least 2 weeks of age. Facial nerve electromyography is appropriate during this portion of the operation, and this cochlear implant surgeon always uses facial nerve electromyography during the dissection of the facial recess, creation of the cochleostomy, and insertion of the electrode array (NIM-2, Xomed, Jacksonville, FL). A general guideline for determining the position of the facial recess is a direct inferior extension of the short process of the incus. Because there is no mechanical function of the incus in an ear receiving a cochlear implant, there is no adverse consequence of removing the incus butress, which normally is preserved to maintain the suspensory ligament, attached to the incus. This has the advantage of delivering additional light into the middle ear and allows direct extension in an inferior direction below the short process of the incus. The vertical segment of the facial nerve is skeletonized, and a 1.5 mm diamond bur with a long shaft is helpful during this portion of the dissection. The dissection is carried inferiorly to the level of the chorda tympani nerve and in some of the patients undergoing cochlear implantation surgery, the chorda tympani nerve is divided to provide adequate access and visualization of the round window niche. Preoperative counseling of the parents or the patient is necessary so that they understand the consequences of dividing the chorda tympani nerve. The lateral limit of the facial recess is the tympanic annulus; and, for the majority of patients, this should be partially skeletonized to maximize the size of the facial recess.

While it is possible to create a small facial recess, most experienced cochlear implant surgeons do not do this and prefer opening the facial

Figure 26 Six-month-old infant undergoing right cochlear implantation with mastoidectomy completed. Unlike an older child or an adult, it should be noted that the bony external auditory canal is extremely thin and the sigmoid sinus is dehiscent. Bony overhangs are designed to help retain the coiled electrode array. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

For those individuals who have undergone a canal wall down mastoidectomy procedure in the past and require cochlear implantation, a two-stage procedure is required. First, mastoid obliteration with removal of all epithelium, overgrowing the external auditory canal, and filling the resulting dead space with abdominal fat is performed. Three to 6 months later, cochlear implantation can be undertaken. If no active disease is present, consideration of a one-stage procedure may be entertained; however, this is not recommended due to the risk of bacterial contamination.

Figure 27 Six-month-old infant undergoing right cochlear implantation with completion of the facial recess approach and cochleostomy. Note the size of the facial recess is no different than in an adult; however, increased precision in thinning the bony external auditory canal is required. The relationship between the short process of the incus and the facial recess is shown. The lateral semicircular canal, facial nerve and round window niche are seen. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

Facial Recess Approach. Once the mastoidectomy has been completed the facial recess dissection is performed (Figures 27 and 28). The size of the facial recess is the same for individuals of any age, and based on the anatomic measurements of the tegmen mastoideum. This allows greater ease in completing the facial recess and approach and developing the cochleosteomy. An additional advantage is providing better exposure and consequently better light delivery that results in better visualization within the facial recess and middle ear. It is also important to continue the skeletonization forward into the zygomatic root for the same reasons (Figures 27 and 28). In contrast, the posterior as well as inferior aspects of the mastoidectomy are not saucerized. It is also important to create bony overhangs in these posterior and inferior aspects of the mastoidectomy cavity that are helpful in retaining the electrode array, which is ultimately coiled into the mastoid cavity (Figure 29). These differences in the mastoidectomy technique also facilitate performance of cochlear implantation in children 6 to 12 months of age.

Figure 28 Facial recess approach to the round window niche and membrane, as viewed from the hypotympanic perspective (top). Bottom, round window niche as visualized through the facial recess. If the round window niche is divided into quadrants, the cochleostomy should be performed in the anterior inferior quadrant. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

Figure 29 Six-month-old infant undergoing right cochlear implantation. The separate ground electrode of the Med-El C40+ device can be seen passing upward across the skull and has been placed beneath the temporalis muscle (left center). Due to the relative size of the skull and the resulting shorter distance between the cochleosteomy and the internal receiver-stimulator, a larger amount of electrode array can be seen coiled within the mastoid cavity. Note the bony overhangs created by undercutting the mastoid cortex that were designed to facilitate retention of the electrode array. In this infant, a shallow trough was created because of her thin skull. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)
Cochleostomy. Placement of the electrode array within the scala tympani is accomplished through a cochleostomy. This cochleostomy is positioned relative to the round window membrane, and the most important factor in being able to place the electrode array within the scala tympani appropriately is visualization of the round window niche. The electrode inserted within the scala tympani is shown in Figure 30, and the specific electrode insertion techniques will be described later. This landmark is critical to determine the relative position of the basal portion of the scala tympani. In completing the facial recess approach, there is a temptation to begin preparing the cochleostomy when only the promontory is visualized. A cochleostomy into the scala vestibuli will likely result; however, this can also lead to the most common reason for failure to place the electrode array, which is the inadvertent opening into the hypotympanic air cell tract and the extracochlear insertion of the electrode array (Figure 31). If the drilling begins too inferiorly, dissection in this area can resemble an ossified basal turn of the cochlea. Often the hypotympanic air cell tract will appear like the open scala tympani following successful completion of a cochleostomy. The obvious result is an incomplete electrode insertion and ultimately no activation of the primary afferent neurons in the spiral ganglion. Another important anatomic landmark to keep in mind when experiencing difficulty in identifying the scala tympani is the position of the intratemporal internal carotid artery. With anterior dissection, when the scala tympani has not been adequately identified, the posterior aspect of the intratemporal carotid artery can be exposed and this is an especially important consideration when performing cochlear implant surgery in children between 6 and 12 months of age. A high index of suspicion must be maintained during the surgical dissection if the round window membrane and round window niche are not visualized at the beginning of the creation of the cochleostomy. This also underscores the importance of identifying this key landmark before beginning the cochleostomy. Those factors that help in the visualization of the round window niche include a wide facial recess and skeletonization of the bony external auditory canal.

Once the round window niche has been visualized, the use of a 1 mm diamond bur with a long shaft allows dissection of the niche until the round window membrane is directly seen. It is important to position the cochleostomy anterior and slightly inferior to the round window membrane as utilizing this position facilitates the angle of insertion of the electrode array (see Figure 28). If the round window is opened and the electrode array inserted through the round window, the angle of insertion is too acute and results in excessive pressure on the electrode array against the lateral wall of the cochlea during the attempted advancement of the electrode array. This excessive force applied to the electrode array can result in damage.

The design of the cochleostomy varies depending on the electrode array used. The smallest electrode array is associated with the Med-El Pulsar CI 100 electrode array and the diameter of the cochleostomy should only be 1.3 mm in diameter. For the Med-El Pulsar CI 100 or Sonata CI 100 with the standard array, the diameter of the electrode array increases from ≈ 0.5 × 0.6 mm at the apex (distal tip) to ≈ 1.3 mm at the proximal, thicker part of the array just before the marker ring. The marker ring is ≈ 1.5 mm in diameter. Thus, the cochleostomy can be as small as 1.3 mm and should be no larger than 1.5 mm to allow proper sealing of the cochleostomy with the marker ring. Small strips of fascia should be placed around the cochleostomy to seal the perilymphatic space from the middle ear (Figure 32). The cochleostomy required for placement of the Nucleus Freedom with the Contour Advance electrode is typically 1.5 to 2 mm. The electrode array itself has a diameter at the tip of ≈ 0.5 × 0.6 mm and the diameter at the basal portion of the array is 0.8 mm.

The present HiFocus 1j or Helix electrode utilizes a round cochleostomy, 1.6 mm in diameter, or an oval cochleostomy measuring 1.2 × 1.6 mm. The electrode array itself has a diameter at the tip of 0.6 mm, and the diameter at the basal contact is 0.8 mm (1j electrode) or 1.1 mm (Helix electrode).

With all 3 devices, once the cochleostomy has been created, it is important to irrigate the scala tympani via the cochleostomy to remove air bubbles and to wash bone debris from the

Med-El Pulsar CI100 and Sonata TI100. The Mef-

Med-El Pulsar CI100 and Sonata TI100 systems each have 6 separate electrode designs (see Figure 16) including a design used for common cavity applications, which is custom made for each individual patient (see Figure 17). Once the internal receiver is secured and the cochleostomy is complete, the electrode array is held in the nondominant hand. A claw-shaped instrument is used to help guide the tip of the electrode into the cochleostomy, and once this is retained at the edge of the cochleostomy, two claw-shaped instruments are used to advance the electrode array (see Figure 30). The advancement is facilitated if small segments of the electrode array are inserted with each subsequent movement, as close to the edge of the cochleostomy as possible. There is a circumferential ring that represents the limit of the electrode array to be inserted; and, for the standard array, this is located 31.5 mm from the distal tip. Once this is sealed at the cochleostomy, the manufacturer states that an adequate seal will be obtained if the cochleostomy is created at the optimal size. In addition, it is advisable to place strips of fascia around the electrode array within the cochleostomy site, and free fascia grafts are placed between the facial nerve and the electrode array as well as between the electrode array and the tympanic annulus.

Ossification of the Cochlea and Common Cavity Malformations

There is a range of ossification that can occur within the cochlea; and, depending on the extent of the ossification, there are different solutions that can be employed (Figure 33). Scala tympani or scala vestibuli insertions may be necessary, depending on the degree of ossification (see Figure 33B and C). During the opening of the cochleostomy, if some ossification of the cochlea is encountered, and once drilling past 1 to 4 mm of the basal cochlea, a normal scala tympani is encountered, the compressed electrode array may be the appropriate array for insertion. The Pulsar CI100S and the Pulsar CI100M are designed with the same number of electrode contacts (n = 12 pairs), but the total lengths of the electrode arrays are 13 or 21 mm, respectively, as compared to the standard electrode array of 31.5 mm. The ITD can be used to determine which array is the appropriate electrode to be inserted before opening an individual cochlear implant. With this, ITD

Freedom device has a second extracochlear electrode that is attached to the receiver-stimulator device.

Electrode Insertion

The electrode insertion is specific for each device and subsections describe the technique used for each electrode insertion. Several different detailed descriptions of electrode insertion techniques have been published recently.114 The standard electrodes are described below, and descriptions of special electrode designs are provided in the section dealing with ossification of the cochlea.

Securing the Receiver

Once the bone work has been completed and the cochleostomy opened, the internal device is secured in position with the retaining sutures. One to 3 nylon sutures are used for this purpose (see Figure 25). It is important during this process to be cognizant of the position of the electrode array so that excessive force or kinking is not encountered during the tightening of these sutures. It is also important that hemostats or other instruments not be used along any portion of the suture that will remain in the patient, as this weakens the material. Using a single throw in the first portion of the knot allows the second throw of the suture to slide along the monofilament nylon to achieve the appropriate level of tension and position of the internal device relative to the lateral aspect of the skull. It is also important that the knots be placed overlapping the bone and not overlying the internal device. A total of 8 knots are placed into each suture and a medium length tail to the suture is created when cutting the suture. After both of these retaining sutures are placed, the ground electrode is placed beneath the temporalis muscle for the Med-El Pulsar CI100 and Sonata TI100 and Nucleus Freedom devices. To accomplish this, a Freer elevator is used to elevate the periosseous and temporalis muscle, and the ground electrode is placed medial to the muscle. The Nucleus

Figure 32 Six-month-old infant undergoing right cochlear implantation. After full insertion of the 31 mm Med-El C40+ electrode array into the cochlea, the cochleostomy is sealed with multiple small strips of temporalis fascia or pericranium. This is an important step to reduce the risk of meningitis should otitis media develop. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)

Figure 33B and C). During the opening of the cochleostomy, there are different solutions that can be employed (Figure 33). Scala tympani or scala vestibuli insertions may be necessary, depending on the degree of ossification (see Figure 33B and C). During the opening of the cochleostomy, if some ossification of the cochlea is encountered, and once drilling past 1 to 4 mm of the basal cochlea, a normal scala tympani is encountered, the compressed electrode array may be the appropriate array for insertion. The Pulsar CI100S and the Pulsar CI100M are designed with the same number of electrode contacts (n = 12 pairs), but the total lengths of the electrode arrays are 13 or 21 mm, respectively, as compared to the standard electrode array of 31.5 mm. The ITD can be used to determine which array is the appropriate electrode to be inserted before opening an individual cochlear implant. With this, ITD

Figure 33B and C). During the opening of the cochleostomy, there are different solutions that can be employed (Figure 33). Scala tympani or scala vestibuli insertions may be necessary, depending on the degree of ossification (see Figure 33B and C). During the opening of the cochleostomy, if some ossification of the cochlea is encountered, and once drilling past 1 to 4 mm of the basal cochlea, a normal scala tympani is encountered, the compressed electrode array may be the appropriate array for insertion. The Pulsar CI100S and the Pulsar CI100M are designed with the same number of electrode contacts (n = 12 pairs), but the total lengths of the electrode arrays are 13 or 21 mm, respectively, as compared to the standard electrode array of 31.5 mm. The ITD can be used to determine which array is the appropriate electrode to be inserted before opening an individual cochlear implant. With this, ITD
Cochlear implantation in the ossified cochlea. (A) The cochlea is shown ghosted in deep to the middle ear. The internal carotid artery (CA) is anterior to the basal turn of the cochlea. The round window (RW), is the most posterior aspect of the cochlea within the middle ear, and it can be found 1.5 mm inferior to the stapedial tendon. The tensor tympani (TT) tendon enters the middle ear at the cochleiform process (CP), which represents the level of the pars ascendens of the cochlea. This landmark is the limit of the dissection, thereby, avoiding injury to the facial nerve. The anterior edge of the oval window (OW) is the posterior limit of drilling. (B) Ossification of the scala tympani without ossification of the scala vestibuli allows placement of the cochleostomy and full electrode insertion in the scala vestibuli. Note the more superior position of the cochleostomy. (C) With more severe ossification of the cochlea, use of a split electrode array allows placement of some electrode contacts into the ossified basal turn of the cochlea and other electrode contacts into the middle turn of the cochlea via a second cochleostomy. (Published with permission, copyright © 2007 P. A. Wackym, M. D.)

is advanced through the cochleostomy, and the depth of insertion is determined. If it is apparent that the standard electrode array would result in electrodes being extracochlear, the compressed electrode array should be used and fully inserted.

For more severely ossified cochleas, both the Cochlear Corporation and the Med-El Corporation manufacture split electrode arrays (see Figures 12 and 16). The Med-El split electrode design (PulsarCI100 GB) has 2 compressed electrode arrays with 5 and 7 pairs of electrode contacts, respectively. These electrode arrays are inserted via 2 cochleostomies (see Figure 33C).

Cochlear implantation with severe cochlear malformations, such as a common cavity, has been challenging. Among these problems are CSF gushers and a need for frequent reprogramming due to migrating electrodes. One solution that targets the migrating electrode problem is the sixth electrode design available with the PulsarCI100 device. For children with this malformation, the surgeon provides the dimensions of the common cavity to the manufacturer, and a PulsarCI100S electrode is custom made so that the distal end is lengthened with a nonactive segment of silicone ending with a small platinum ball at the tip (see Figure 16). Using the double posterior labyrinthotomy technique (see Figure 17C), the nonactive part of the implant is pushed into the superior labyrinthotomy until it is seen through the inferior labyrinthotomy. The small terminal ball is hooked through the inferior labyrinthotomy, and the terminal nonactive part of the array is pulled out, leaving a loop within the common cavity. Next the two arms are advanced together positioning the array along the inner wall of the cavity (see Figure 17D). Resistance is felt when the loop covers the internal circumference of the cavity. The surgical technique and early outcomes have been reported in a few small series of patients.119,120

Special Considerations Regarding Securing the Electrode Array

For all 3 devices manufactured for the United States marketplace, securing of the electrode array at the cochleostomy site and at the facial recess is important. The cochlear and facial recess are the same size at birth as they are throughout adulthood; and, therefore, it is important to secure the electrode array at the cochleostomy with the fascia graft, which will scar in place and bridge the surrounding promontory to the electrode array. Second sites of stabilization at the facial recess, with fascia grafts between the facial nerve and the electrode array as well as between the tympanic annulus and the electrode array, will further stabilize the relationship of the electrode array to the cochlea and facial recess. This is important in children because of their head growth. The sites of stabilization at the cochleostomy and facial recess will secure the distal electrode array anteriorly while the sutures and fibrous capsule that will form around the internal receiver as well as the electrode within the trough created at the time of the operation, will stabilize the proximal portion of the electrode array. The remainder of the electrode array is coiled within the mastoid and this air-filled space will allow the uncoiling of this electrode array during development as the child’s head grows. This mechanism allows the accomplishment of natural growth and development while maintaining the integrity and position of the cochlear implant and its electrode array within the cochlea.

Intraoperative Electrophysiologic Testing

Intraoperative testing of the cochlear implant is a critical portion of the operation. First, impedance measurements are conducted to determine if the electrode array has been damaged during insertion and that all of the available electrodes are functional. Intraoperative neural response telemetry (NRT) is available for the Nucleus Freedom device, and this allows direct recording from the eighth nerve distally following proximal stimulation. A similar system termed neural response imaging (NRI) is available for the HiRes 90K system. Med-El developed auditory response telemetry (ART); however, while it is available elsewhere in the world, it currently is not available in the United States pending FDA approval. NRT, NRI, and ART function in a similar manner.

For some of our patients, we perform intraoperative electrically evoked auditory brainstem response (EABR) testing. We do this with distal, intermediate and proximal electrodes and determine thresholds and maximum amplitudes of wave V. Beginning with the advent of perimodiolar electrodes, we performed this before placing the electrode array in the perimodiolar position and after placing the electrode array in the perimodiolar position.102,121 The details of the performance of this are described below; however, the utility of performing EABR testing is most apparent with the management of young children. While it is possible to determine behavioral thresholds in young children as young as 6 months old, we have found that it is valuable in the initial programming of these devices to have having objective information regarding the thresholds for 3 of the active electrodes. In addition, there is tremendous value to the families and to the patients receiving cochlear implants when we can state immediately postoperatively that not only is the electrode array fully inserted within the cochlea, but also that we have objective evidence of central auditory responses of the electrical stimulation delivered through these electrodes. This technique, together with NRT, NRI and ART, has obviated the need for intraoperative radiographic studies to confirm the position of the electrode array within the cochlea.

Procedures to record electrically evoked auditory potentials intraoperatively reliably from pediatric and adult patients are described in the following paragraphs. During the surgical preparation of the patient, subdermal needle electrodes are placed on the forehead, nape of the neck, vertex, and ear contralateral to the implant. Markers that identify the electrode location are placed on the electrode leads, which are then draped under the operating table until they are needed. A subdermal needle electrode is placed on the sterile table and is inserted in the ipsilateral...
The absolute level of current varies depending on the method of stimulation. Generally, lower current levels are used for the initial activation of the cochlear implant. The EABR threshold represents a stimulus current level that falls somewhere within the electrical dynamic range for a given electrode. This level corresponds to a current level that should be audible for the patient and can be approached from a minimum current level at the time of initial stimulation. The EABR threshold also provides prior knowledge of whether low, normal, or high current levels are expected at the initial stimulation, which can be quite helpful when presenting electrical stimuli to young children for the first time.

EABR tracings and threshold information for each tested electrode are provided to the programming audiologist for planning for the initial activation of the implant. In addition, the electrode position and any unusual circumstances that can affect performance, such as electrode misalignment, ossified cochlea, or unusual anatomy, are shared with the programming audiologist. This information assists in planning for the initial activation and avoids stimulation of electrodes that could generate unpleasant sensations, such as electrodes that may be outside the cochlea. Finally, as mentioned previously, the electrophysiologic test results are shared with the patient’s family and assure that the electrode is properly placed and that electrical stimulation will successfully activate the auditory system. The EABR results can also reflect the degree of central auditory system maturation as seen in children implanted as young as 6 months of age (see Figure 34).

**Closure and Postoperative Management**

The closure of the soft tissue varies depending on the initial soft tissue approach utilized. For young children, since the periosteum, scalp, and skin are all raised together in 1 layer, these are closed in 2 layers. The first layer is closed with inverted interrupted 4-0 Vicryl sutures (Johnson & Johnson Co., Ethicon Inc., Arlington, TX) and includes the periosteum, galea, and subcutaneous tissues. Once this layer has been closed, the skin is closed with a running locked 5-0 plain gut fast-absorbing suture (Johnson & Johnson Co., Ethicon Inc., Arlington, TX). The advantage of using all absorbable sutures in young children is that the skin sutures do not need to be removed.

For adult patients and children large enough to have the soft tissue approach completed in 2 layers, the periosteum is closed over the implant with simple interrupted 3-0 Vicryl or 3-0 Monocryl suture (Johnson & Johnson Co., Ethicon Inc., Arlington, TX). A noker important consideration, when thick scalp or unusually well-developed temporalis and scalp musculature is found, debulking of the muscle can be required. Also, defatting the scalp is possible; however, the vascular supply to the scalp runs with the galea and care should be taken to avoid compromising this. Maintaining a scalp, which is thin enough to allow the magnetic attraction of the transmitter coil to the internal cochlear stimulator device magnet, will allow the coil to the internal cochlear stimulator device magnet, will allow the coil to be secured to the scalp without falling off; however, if the scalp is too thick, this will not be possible. An alternate strategy is to thin the scalp flap. Surgical judgment in thinning the scalp is essential. The galea and subcutaneous layers are then closed with inverted interrupted 3-0 (adults) or 4-0 (children) Monocryl or Vicryl pop-off sutures and the skin is closed with a running locked 5-0 fast-absorbing gut suture or 4-0 nylon for the postauricular and scalp incisions.

For adults and children, care is taken to protect the incision with antibiotic ointment and strips of Teflon, and a pressure dressing is applied. A small sheet of cotton is trimmed to conform to the pinna, which helps protect the pinna from pressure-induced necrosis. Fluffs are placed

---

**Figure 34**

Intraoperative EABR growth functions from an older child aged 2 years 9 months (A) and the child’s younger sibling, aged 6 months (B). Both children were implanted with Med-El C40+ (Med-El Corporation) devices, and both sets of recordings are from stimulation of apical electrode 1. Stimulation levels for the older child were 379, 313, and 234 clinical units (top to bottom tracings, respectively), and 586, 474, and 309 clinical units for the young child (top to bottom tracings, respectively). Comparison of the high, medium, and low stimulation-level tracings indicate similar Wave V response amplitudes between children; however, differences are apparent in Wave V latency. The widths of the Wave V peaks are larger for the younger child. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)
over the scalp and elevated flaps, and one Kerlix (Kendall Healthcare Products Co., Mansfield, MA) and one Kling (Johnson & Johnson Co., Ethicon Inc., Arlington, TX) are wrapped around the patient’s head. Umbilical tape (Johnson & Johnson Co., Ethicon Inc., Arlington, TX) is used over the forehead to secure the dressing and to lift this dressing away from the patient’s eyes. The pressure dressing is left in place for the first postoperative night and is removed the following morning.

Virtually all cochlear implant operations are done on an outpatient basis with children being observed for less than 23 hours, principally to control postoperative pain. Adults are typically operated in an ambulatory manner unless their operation occurs late in the afternoon, as is the case when three cochlear implant operations are performed in one day.

Complications

The most common complications occurring after cochlear implantation are wound and flap related. Wound breakdown is most often associated with placement of the internal device too close to the pinna (see Figure 22) or at the site of the skin incision. Injury to the intratemporal internal carotid artery is extremely rare; however, as discussed earlier in this chapter, in young children in whom the round window niche is not clearly seen, it is possible to follow the hypotympanic air cell tract to the carotid artery. In such clinical situations, it is therefore important to maintain a high index of suspicion to identify the carotid artery prior to injury. Other risks of the cochlear implant procedure are similar to, and as rare as, those seen in operations for chronic ear otitis media: infection, facial paralysis, vertigo, CSF leakage, meningitis, and anesthesia-related complications.

Of these, the risk of meningitis most deserves further comment due to the recent heightened awareness of this complication. Early cases of meningitis are due to otitis media in the context of an unsealed cochleostomy. As discussed earlier, it is important to seal the cochleostomy with fascia. However, until the subsequent fibrosis has been completed, the inner ear is vulnerable to the passage of bacteria into the perilymphatic space and then the CSF space. Late cases of meningitis may be due to the higher risk of meningitis due to inner ear deformities or inadequate sealing of the cochleostomy. In any of these situations, the risk of meningitis can be further reduced by preoperative immunization with Prevnar (children under 2 years of age) and Pneumovax 23 (children 2 years of age and all other individuals). These vaccines recognize seven serotypes and 23 serotypes of Streptococcus pneumoniae, respectively. Children should also be vaccinated with Haemophilus influenzae type b conjugate (Hib) and quadrivalent A, C, Y, W-135 meningococcal polysaccharide (Menomune). Our cochlear implant program requires vaccination with the age appropriate vaccine prior to implantation.

Facial nerve stimulation can occur after cochlear implantation due to electrical activation of the nerve by the active electrodes. Placement of the fascia between the electrode array and the facial nerve as well as sealing the cochleostomy is designed to limit current spread. Certain primary bone diseases such as otosclerosis and Paget disease will increase the porosity of the bone, and this may allow extracochlear current spread and activation of the facial nerve. Similarly, placement of the electrode array within the IAC can result in facial nerve activation (see Figure 8). Programming the external speech processor can deactivate specific electrodes found to be stimulating the facial nerve, thereby eliminating this problem.

The final complication that should be mentioned is device failure. While this is uncommon, these failed devices are routinely removed, and the cochlea reimplanted. This is uncomplicated in most cases and results in comparable performance or even enhanced performance if the failed device is replaced with a later generation device.

Special Considerations Regarding Bilateral Cochlear Implantation

For patients who have never received a cochlear implant and who choose to receive bilateral cochlear implants, the operation can be performed in a sequential or simultaneous manner. For young children, the operations should be performed sequentially, primarily due to the small head size and because of the desire to avoid a longer anesthetic time. For older children and adults, the operations can be performed safely simultaneously.

Future Considerations

Multiple institutions and corporations are actively pursuing the development of a fully implantable cochlear implant. Reduced power requirements, improved battery life, and the ability to recharge the internal battery via a transcutaneous route are engineering issues that are being addressed. Likewise, the development of a microphone/transducer placed on the ossicular chain within the middle ear remains a technical challenge, which must be resolved before a fully implantable cochlear auditory prosthesis can be created. It is anticipated that additional surgical steps will be necessary to implant this type of device. In addition, work focused on tissue engineering is targeting strategies to reduce fibrosis and neo-ossification as well as increase primary afferent dendrite growth and spiral ganglion cell survival.

AUDITORY BRAINSTEM IMPLANTATION

The restoration of hearing in individuals with hearing loss of a wide range of causes has made dramatic strides over the past decades. At present, surgical intervention in the form of cochlear implants can provide useful auditory perception in individuals deriving little or no benefit from hearing aids; however, these auditory prostheses require an intact auditory nerve to conduct electrical signals to the brainstem. The restoration of auditory perception in individuals deafened by loss of the vestibulocochlear nerves is currently being provided by auditory brainstem implants (ABI).

The ABI is a device consisting of several electrodes placed on the brainstem surface to stimulate the cochlear nuclei directly. Externally, it is coupled with a digital speech processor similar to that of a cochlear implant. Current studies have shown that such stimulation can provide individuals with NF2 useful perception of environmental sounds and even open-set speech comprehension. However, there is also evidence that non-NF2 patients receiving an ABI, such as temporal bone fracture patients without a functional cochlear nerve, perform at a much higher level as measured by open-set speech discrimination testing.

There are only in ABI available in the United States, and the Cochlear Americas’ (Englewood, CO) ABI is approved by the FDA for use in individuals 17 years or older with NF2 undergoing resection of a vestibular schwannoma or in patients undergoing resection of a vestibular schwannoma in an only-hearing ear. Patients with NF2 are often left with complete sensorineural deafness due to the sacrifice of both auditory nerves during resection of bilateral tumors. Cochlear Americas’ array is a 21-electrode device with the electrodes embedded in a silastic paddle backed with Dacron mesh. This device is also used intraoperatively as a stimulating electrode for the EABR to help identify optimal positioning of the electrode paddle. The recommended protocol with this device utilizes a translabyrinthine approach to the tumor and subsequent implantation of the ABI. An FDA clinical trial of a new electrode array utilizing a penetrating electrode is underway, and several patients have received this device to date.

Optimal placement of the electrode paddle onto the cochlear nucleus is difficult because it is not possible to visualize this complex directly with the operating microscope via the surgical approaches used to reach these tumors. However, the use of the endoscope in placement of an ABI electrode array has been explored to accomplish this goal. Our team has taken a multidisciplinary approach in ABI electrode placement utilizing endoscopic guidance and electrophysiologic mapping to optimize electrode placement. This has resulted in increased numbers of active electrodes, as well as reduced numbers of electrodes producing side effects and nonactive electrodes.

Surgical Approaches

Translabyrinthine Approach. The translabyrinthine dissection should be performed in the standard fashion with an operating microscope and basic otologic instruments. In brief, a complete mastoidectomy is performed, and the facial
nerve and semicircular canals are identified. The vestibular labyrinth is removed, and the posterior and middle fossa dura is exposed. Working from the superior canal ampulla, the IAC is skeletonized. The jugular bulb is identified and should be thoroughly decompressed to provide direct visualization of the rostral fibers of the glossopharyngeal nerve. This allows identification of the implant site in a grossly distorted cerebellopontine angle.

A 0° endoscope is advanced into the operative field and used to identify the flocculus, vestibulocochlear, and glossopharyngeal nerves (Figure 35). In some individuals, the choroid plexus may be visible over or just inferior to the flocculus. The vestibulocochlear and glossopharyngeal nerves will appear to converge behind the flocculus with the imaginary point of convergence near the dorsal cochlear nucleus. A 30° or 45° endoscope can now be passed over, that is, lateral to the flocculus allowing visualization of the choroid plexus which can be traced medially to the rhomboid lip and foramen of Luschka. Use of the angled endoscope allows this to be accomplished with minimal retraction on the flocculus and thus helps to preserve the taenia chordae. The McCabe flap knife can now be used under endoscopic visualization to retract the choroid gently and expose the surface of the brainstem and lateral recess of the fourth ventricle. The surface of the brainstem within the recess has a characteristic glistening appearance due to the overlying ependyma.

The endoscope should be stabilized at the periphery of the operative field to allow introduction and manipulation of the electrode and instruments. It can be positioned superiorly against the tegmen or inferiorly against the bony ridge remaining over the tympanic and mastoid facial nerve. Decompression of the jugular bulb will allow adequate space for the distal aspect of the endoscope to be maneuvered. Positioning of the endoscope will be determined by the side of the patient being operated upon and the handedness of the surgeon. There is a tendency for the temperature of the distal endoscope to increase, which can cause neural stimulation and potentially neural damage. Care must be taken in positioning the endoscope near the facial nerve, and attention, must be paid to intraoperative neurophysiologic monitoring.

The implant is introduced into the site with a Rosen needle or a number 11 Rhoton dissector, and the paddle is directed into the foramen of Luschka. The angled endoscope allows visualization of the entire length of the electrode array insuring full contact with the brainstem. In addition, the position of the implant can be recorded with digital image capture and digital video. This can help to correlate anatomy with the results of electrophysiologic testing.

The distal portion of the electrode extends through the surgical defect to the receiver/stimulator. This is similar to that of a cochlear implant and is implanted identically. The defect is closed in standard translabyrinthine fashion, and routine postoperative management is followed.

**Retrosigmoid Approach.** The retrosigmoid or suboccipital approach is performed in the standard manner and should be of a size adequate for safe tumor extirpation or smaller when performing ABI placement for non-NF2 applications. The use of the endoscope actually allows for a smaller craniotomy than would be needed with the operating microscope, but the optical modality used for tumor removal should take precedence and determine the surgical approach. The dura is incised and reflected to expose the cerebellum. A cerebellar retractor is placed to provide access to the cerebellopontine angle. It is assumed here that decompression by opening the lateral medullary cistern and drilling of bone over the IAC is done in the course of exposing the tumor.

The principal criticism of the retrosigmoid approach for ABI placement is the perceived need for extensive cerebellar retraction to expose the implant site. However, for endoscopic
visualization of the lateral recess of the fourth ventricle, less retraction is actually necessary relative to the translabyrinthine approach. The 30° or 45° endoscope can be passed along the cerebellar retractor and “look” medially into the implant site even though it may not be directly visible through the craniotomy.

The landmarks for the dorsal cochlear nucleus in the retrosigmoid approach are identical to those used in the translabyrinthine approach. The perspective is shifted in a slightly caudal direction; however, and visualization of the surface of the brainstem within the recess is less oblique and consequently easier to identify the ABI electrode contact site (Figure 36). As in the translabyrinthine approach, the operating microscope is introduced first to identify the flocculus and vestibulocochlear and glossopharyngeal nerves. The root entry zone of the eighth nerve will be hidden behind the flocculus, but the entry of the glossopharyngeal rootlets may be apparent.

Once the gross anatomy is identified, the 30° or 45° endoscope can be introduced to look “around” the flocculus. The root entry zones should be clearly visible as will the choroidplexus emerging from the foramen of Luschka. The flocculus can now be retracted with the Mccabe flap knife exposing the rhomboid lip, lateral recess, and glistening brainstem surface overlying the dorsal cochlear nucleus. A small amount of tenia choroidea may be visualized helping to define the cochlear nuclear complex further.

The endoscope should be stabilized against the cerebellar retractor at either the superior or inferior aspect of the field. Side of operation and handedness of the surgeon will determine this. The ABI is advanced to the implant site with a Rosen needle and maneuvered into the foramen of Luschka. We found that this instrument combined with the less oblique approach to the brainstem makes placement of the implant relatively easy. The position of the implant can be confirmed with the endoscope.

**Auditory Brainstem Implantation Highlights.** A systematic approach to finding the dorsal cochlear nucleus is necessary to position the ABI appropriately on the brainstem surface. This is particularly important in situations in which tumor or surgical extirpation has altered the normal appearance of the cerebellopontine angle. The 0° and 30° endoscopes provide high-resolution views of these landmarks and allow examination of the cerebellopontine angle with minimal retraction or manipulation. This examination enables preservation of delicate structures, which can further delineate the dorsal cochlear nucleus.

In the translabyrinthine and retrosigmoid approaches identical landmarks are used and followed to localize the implant site:

- the flocculus and eighth and ninth cranial nerves are identified;
- the region between the root entry zones of these nerves and rostral to the flocculus will contain the choroid plexus;
- the choroid plexus can be followed into the foramen of Luschka and thus the lateral recess of the fourth ventricle;
- the fold of the tela choroidea forming the rhomboid lip further delineates the foramen of Luschka;
- the root entry zone of the eighth nerve will “point” to the region of the cochlear nuclear complex;
- the tenia choroidea, if preserved, attach at the junction of the dorsal and inferior ventral cochlear nuclei;
- the brainstem surface in the recess over the cochlear nuclear complex has a glistening ependymal layer; and
- the brainstem overlying the dorsal cochlear nucleus may demonstrate a slight bulge.

After initial placement using endoscopic guidance, electrophysiologic testing using EABR is performed. Repositioning the electrode array using endoscopic-control and retesting the EABR allow optimization of electrode placement. This process typically takes between 30 and 60 minutes; however, in one patient this process required 3 hours.

**Clinical Experience and Discussion**

To date our team has placed 7 ABIs in 6 patients, 5 with NF2 and 1 with a nonfunctional auditory nerve following temporal bone fracture (Figure 37). The same multidisciplinary approach to ABI electrode placement has been used in all patients. Intraoperative endoscopic placement of the electrode paddle was performed by the same surgeon (PAW) as we have described previously. In addition, intraoperative EABR was performed using the paradigm suggested by Cochlear Americas, with the exception that repeated mapping was not completed until optimal placement, as defined by maximum number of active auditory electrodes using EABR, was achieved.

It has been stated that localization of the brainstem surface overlying the dorsal cochlear nucleus is difficult. Brackmann and colleagues noted that the dorsal nucleus in lower mammals forms a characteristic “bulge” on the brainstem surface which they have not observed in humans. We have intermittently seen this surface bulge in both cadaveric specimens and our

Right retrosigmoid approach and ABI placement December 2006 using 45° endoscope and electrically EABR guidance. (A) View of cochlear nucleus before placement of ABI. The rhomboid lip can be seen (short arrow) in relationship to the lateral recess and the vestibulocochlear nerve (VIII). Flocculus, bottom center. (B) ABI in position over the cochlear nucleus. The Dacron mesh wings are bowed around the inside of the rhomboid lip. A loop of the anterior inferior cerebellar artery (AICA) can be seen between the electrode array and cranial nerve VIII (long arrow). (C) CSF can be seen welling up through the foramen of Luschka, center. Cranial nerves IX, X, and XI are seen in relationship to the ABI electrode paddle. The extent of the AICA loop can be seen (long arrow). (D) Polytetrafluoroethylene (Teflon) felt placed between the vestibulocochlear nerve and the loop of AICA as well as within the lateral recess. (Published with permission, copyright © 2007 P.A. Wackym, M.D.)
patients undergoing endoscopic placement of an A BI which may reflect the fact that such a landmark is, at best, inconsistent. Further complicating localization of the dorsal cochlear nucleus is its position within the lateral recess of the fourth ventricle, an area reported to be not directly visible within the standard trans-labyrinthine surgical field. A dditional reports have likewise noted that the site of implanta-tion may be obscured in a trans-labyrinthine dis-section. As such, this region is difficult to locate in a clinical setting, and the importance of surgical landmarks to guide the surgeon has been stressed. We have found that the ret-rosigmoid approach provides a better view of the cochlear nucleus complex via the operating microscope.

While others have also utilized EABR to facilitate optimal placement of the electrode array, we have typically spent 30 to 60 minutes in mapping out this ideal location. However, we have taken up to 3 hours to accomplish this task. This multidisciplinary approach has resulted in excellent outcomes as measured by number of active electrodes and number of electrodes that are nonresponsive or produce side effects. As this series expands, generalization of these principles may be possible.

**SUMMARY AND CONCLUSIONS**

Cochlear implants and ABIs have advanced dramat-ically over half of a century. These auditory prosthesis now are available in a wide range of transduction strategies and electrode designs allowing focused and effective solutions to the clinical problems of patients with hearing impairment who cannot be rehabilitated with hearing aids. These applications and outcomes will no doubt continue to expand and improve as the results of clinical trials and new innovations are incorporated into clinical practice.

Cochlear Implant Coding Strategies and Device Programming

Kaibao Nie, PhD
Ward Drennan, PhD
Jay Rubinstein, MD, PhD

Cochlear implants are designed to stimulate surviving auditory neurons with weak electric currents, generating neural spikes that the brain can interpret as sounds. To achieve this function, sounds are converted to safe electric currents. In most cochlear implant devices, this conversion is implemented with a sound processor running various coding strategies that take acoustic inputs, extract acoustic features, and then generate patterned electric outputs. Over 40 years of cochlear implant research and development, a variety of coding strategies have been developed. Associated with them are some fitting parameters, such as electric threshold level, electric most comfortable level, stimulation rate, pulse width, stimulation mode, and filter table. After the operation of implantation, each coding strategy is customized to take into account differences among patients such as the cause of the hearing loss, neural survival, electrode placement, and loudness perception. To optimally fit a patient with a specific coding strategy and its associated parameter set, it is necessary to understand thoroughly how each strategy processes sounds and converts them into electric stimulation signals. Throughout this chapter, a number of abbreviations are used and these have been summarized in Table 1.

Clinical programming of a cochlear implant with various coding strategies is not a simple task, given that it involves basic engineering concepts of digital signal processing (DSP), speech processing, electronics, and psychoacoustics. This chapter aims at facilitating the task by assisting in the understanding of the engineering structure of a cochlear implant, the history of implant coding strategies, the mechanisms of current sound coding strategies, as well as the practical procedures in clinical fittings.

ENGINEERING STRUCTURE OF A COCHLEAR IMPLANT

To build a cochlear implant, 1 major issue encountered is the safe transmission of electrical currents to the implanted electrodes through human skin. Earlier cochlear implants used a percutaneous link (wires directly pass through the human skin) between an external processor and an internal electrode array. The percutaneous link can efficiently send currents directly to the electrodes, but it has drawbacks. Patients with this type of implant have an exposed socket close to the implanted ear. Such exposure can cause infection, and it is therefore less desirable. Modern commercial cochlear implants abandon this design, except for research purposes.

Currently, all 3 cochlear implant manufacturers (Cochlear Corporation, Advanced Bionics Corporation, and Med-El Corporation) utilize the transcutaneous wireless link, with one magnet coil placed underneath the skin and another matched externally on top of the implanted coil. Instead of delivering currents through a plug socket in the case of a percutaneous connection, the wireless link conveys binary codes of stimulating currents over a high frequency radio wave, and real stimulation currents are produced internally by one or more current generators.

Figure 1 presents the schematic diagram of a contemporary cochlear implant. The 5 essential components of a transcutaneous implant are:

1. A microphone. Normally, it is omnidirectional, picking up sounds from all directions. To improve the wearer’s speech understanding in background noise, some devices now make use of a directional microphone, selectively picking up sounds from the front while attenuating others. Additionally, sound sources, such as TV, MP3 player, and FM (frequency modulation) assistive listening device, can also be directly connected as audio inputs.

2. A sound processor. It is responsible for digitizing the microphone’s analog output, splitting the digital sound into frequency bands, extracting acoustic features, and generating current-related binary codes for transmission. Speech coding strategies run on the processor’s digital signal processor chip, which is capable of performing millions of instructions per second.

3. A wireless communication link. A pair of magnet coils sitting on each side of the skin establishes a wireless communication link between the external sound processor and the internal implant. In the case of a transcutaneous link, stimulation currents are produced by controlled current sources inside an implantable electronic package without batteries. This requires that both control binary codes and electric power should be sent to the implant via the link. Most devices transmit both with a high voltage (eg, 5 to 10 V) and high frequency (eg, >10 MHz) radio wave as the carrier. The alternating carrier is transformed to a DC voltage for providing power to the internal electronic circuits. The wireless transmission can be bidirectional, from the external sound processor to the internal implant or vice versa. The inaudible data path is referred to as forward telemetry (FT). Reversely, an outward path, termed backward telemetry (BT), can also be

The frequency selectivity of the basilar membrane is 20,000 Hz (base) on a logarithmic scale. The audible frequency range of 20 Hz (apex) to 20,000 Hz is tonotopically represented in the inner ear. The snail-like cochlea functions as a tonotopic frequency analyzer, evenly spanning the frequency band. The function of BT is to send back to the speech processor some neural encoding mechanisms by normal ears in in cochlear implant coding strategy development.

The Past: Exploring the Nature of Electrical Stimulation

The idea of curing deafness with electrical stimulation was inspired by the discovery of eighteenth-century Italian scientist Alessandro Volta, the inventor of the electric battery. Out of curiosity, he inserted 2 metal rods into each of his ears and connected them to a circuit of roughly 50 V. Immediately he perceived a boiling sound. Volta’s experiment on his own ears eventually led to the modern cochlear implants’ worldwide use by over 100,000 deaf people to regain hearing.

The first trial of direct auditory nerve stimulation in a human was reported in the 1950s by two French investigators, André Djourno and Charles Eyriès. During an operation for cholesteatoma, they placed wires in the modiolus and then applied currents. The patient heard a sound like “a roulette wheel” and could even discern a few words.

In hopes of reproducing hearing with an artificial apparatus, Dr. William House and his colleagues in the early 1970s built an experimental single-channel cochlear implant (House/3M). In 1984, it became the world’s first US Food and Drug Administration (FDA) approved device for implantation in adults. The device had a speech processor, a transcutaneous link, and a single electrode. The sound processor amplified the stimulation signal and sent it through a band-pass filter from 340 to 2,700 Hz. For the purpose of wireless transmission, the filtered speech signal was amplitude modulated with a carrier of 16 kHz. A pair of coils coupled the speech-carrying radio wave to the implanted single electrode. In this way, the stimulation current on the House/3M electrode was analog, and it varied at a rate of 16 kHz. Patients who received the House/3M implants were able to recognize some environmental sounds and discern some vowels but not all.

At the time when the single-channel implants were under clinical trials, the design of experimental cochlear implants that can stimulate multiple cochlear sites was being conducted at other locations. One remarkable device was the four-channel Ineraid implant manufactured by the Symbion, Inc. (University of Utah) in 1980s. The Ineraid implant increased the number of electrodes to 4, using the compressed analog (CA) speech processor. In the CA strategy, an automatic gain controller (AGC) compressed a sound’s dynamic range. The compressed sound was then parsed into 4 subbands: 100 to 700 Hz, 700 to 1,400 Hz, 1,400 to 2,300 Hz, and 2,300 to 5,000 Hz. At the last stage, the 4 narrow-band analog signals were equalized in gain and directly delivered to the 4 intracochlear electrodes via a percutaneous connection. In assigning the stimulating electrodes, the higher frequency bands were toward the basal electrodes while the lower bands toward the apical electrodes, to mimic the place coding of speech. Experimental results showed that Ineraid patients benefited from the improvement in coding strategy, since they could achieve better open-set speech recognition than those using the single-channel device. Although the CA strategy provided patients with fine temporal and course spectral cues in speech, analog current stimulation of multiple sites could excite a large group of neurons simultaneously resulting in channel-to-channel interaction and loudness summation. These side effects could be detrimental to speech understanding.

The University of Melbourne group led by Dr. Graeme Clark and the Cochlear Corporation in Australia were also among the pioneers in cochlear implant coding strategy development. A series of specific coding strategies have been successfully designed for the Cochlear Corporation’s Nucleus implants, and they are described in the following section.

The Present: Restoring Speech Perception

Continuous Interleaved Sampling (CIS). To address the channel interaction and loudness summation issues, Blake Wilson and colleagues at the Research Triangle Institute in North Carolina proposed in 1991 to use interleaved pulses instead of analog currents. The CIS strategy is presented as a functional block diagram in Figure 2: a sound picked up by a microphone is preemphasized with a high-pass filter at 1,200 Hz to equalize its spectrum. A bank of band-pass filters then splits the sound into several narrowband signals. Unlike the CA strategy, each subband signal further goes through an envelope detector, consisting of a rectifier and a low-pass filter typically at a 400 Hz cut-off frequency. The

turning from simultaneous analog to inter-
leaved pulsatile stimulation yielded remarkable
progress in open-set speech perception. In a
letter published in Nature in 1995, Wilson and col-
leagues reported that after being fitted with the
new CIS strategy all 7 patients who had excel-
ent performance with the CA processors showed
significant improvement in speech recognition
scores.5

The breakthrough in cochlear implant coding
strategies brought cochlear implants into a new
era, as DSP chips and integrated circuits became
smaller and more powerful. All 3 commercial
cochlear implant devices implement the CIS
strategy or its variants. For example, the Nucleus
implants by Cochlear Corporation can be pro-
grammed with a standard 4-, 6-, or 8-channel
CIS. The Med-El implants implement the CIS+
strategy, at a higher stimulation pulse rate and
CIS. The Med-El implants implement the CIS+
grammed with a standard 4-, 6-, or 8-channel
implants by Cochlear Corporation can be pro-
grammed for most cochlear implant users.

The Claron devices by Advanced Bionics implement strategies with completely
nonsimultaneous or partially simultaneous stimu-
lution, such as the paired pulsatile sampler (PPS)
or quadruple pulsatile sampler (QPS) strategies.

In comparison with the CISs sequential stimula-
tion (“Solo,” eg, channel 1-2-3-4-5-6-7-8…),
the PPS activates 1 pair of channels at the same
time (“Duo,” eg, [1, 5]-[2, 6]-[3, 7]-[4, 8] …),
while the QPS enables 4 channels simultane-
ously (“Quartet,” for example [1, 5, 9, 13]-[2, 6,
10, 14]-[3, 7, 11, 15]-[4, 8, 12, 16] …). Even
though simultaneous stimulation exists in PPS
and QPS, the chance of channel interaction is
reduced by activating widely separated chan-
nels in Advanced Bionics’ Clarion devices. Stud-
ies showed that some patients can benefit from
the PPS and QPS strategies on consonant and
word recognition.5

Spectral PEAK (SPEAK) and Advanced
Combined Encoder (ACE). The Nucleus implants
can be programmed with two proprietary cod-
ing strategies SPEAK and ACE. Both strategies
are evolved from the earlier F0/F2 (fundamen-
tal frequency/second formant), F0/F1/F2, and
the multiple spectral peaks or multi-PEAK
(MPEAK) strategies.7,8

At the time when the first-generation Nucleus
implants were designed in 1980s, the objec-
tive was initially to restore speech understand-
ing ability. Formants or resonating frequencies
were known to be important for vowel identifi-
cation. In the source-filter model of speech pro-
duction from the 1960s, a voiced sound like a
vowel was generated as periodic glottal pulses
passing through a vocal tract filter at the rate of
F0, whereas unvoiced sound like a consonant
was produced with random glottal pulses as the
excitation source. Energy peaks in the vocal
tract filter corresponded to formant frequen-
cies. Possibly influenced by this model, the first
Nucleus implant coding strategy F0/F2 attempted
to encode the second formant F2, and the funda-
mental frequency F0 in a similar way. Dur-
ing stimulation, 1 of 20 electrodes in a Nucleus
implant was stimulated with 1 pulse at a time
according to the frequency of F2. The amplitude
of the pulse was proportional to the energy height
of F2 and the pulse’s repetition rate was either
proportional to F0 for periodic sounds or random
for aperiodic sounds. A subsequent F0/F1/F2
strategy added the first formant F1 to the F0/F2
strategy. The basal 15 electrodes were assigned
to F2 and the apical 5 electrodes were allocated
to F1. The F0/F1/F2 strategy provided superior
open-set speech recognition.

Frequencies being encoded in F0/F2 or
F0/F1/F2 are highly limited to 2,500 Hz and
below, because the frequency ranges of F1 and
F2 are 300 to 1,000 Hz and 1,000 to 2,500 Hz,
respectively, for English vowels. This might be
sufficient for vowel identification, but it is insuf-
cient for identifying consonants, the energies

The MPEAK strategy was developed in the
late 1980s to transmit more high frequency
information. In MPEAK, the coding of F1 and
F2 remained the same and 3 additional envelope
detectors, that is, 2 to 2.8 kHz, 2.8 to 4 kHz, and
4 to 6 kHz, were added to the speech proces-
sor. During vowel-like sounds, not only 2 elec-
trons were stimulated in a way similar to F0/F1/
F2, but 2 additional apical electrodes were also
stimulated according to the outputs of the first 2
envelope detectors. All 4 electrodes being stimu-
lated had a pulse rate at F0; during consonant-
like sounds, F1 was not considered. In addition
to the electrode being stimulated by F2, 3 basal
electrodes were activated by the outputs of all 3
envelope detectors. The pulse rate was set ran-
domly for consonants. The MPEAK strategy
was shown to produce better speech recognition
than the previous strategies encoding the first and
the second formants only.9

The SPEAK strategy was introduced in the
1990s to overcome problems of inaccurately
extracting formants and fundamental frequency
in realistic listening environments. In SPEAK,
a sound was divided into 20 bands followed by
20 envelope detectors. Rather than sending
all envelopes to 20 electrodes, only 5 to 10 maxima
among them were selected for activating corre-
sponding electrodes from 1 cycle to another. The
average stimulation cycle was 4 ms, or a pulse
rate of 250pps, which was lower than a typical
CIS strategy. An advanced version that combines
the SPEAK and the CIS strategies is the currently
used ACE strategy with a stimulation rate of 900
pps up to 3,500 pps per channel. ACE represents
the more general class of the “n of m” strategies,
which select n maxima from a total of m process-
ing bands for stimulation.

Simultaneous Analog Stimulator (SAS). The
presence of channel interaction and loudness
summation prevents the CA strategy from being
programmed for most cochlear implant users.
A analog stimulation preserves good temporal
cues, which could potentially provide benefits
to patients who can be fitted with the simultaneous
settings. One strategy that can be programmed
is the SAS strategy, used in Claron devices by
Advanced Bionics. The SAS uses high rate
monophasic pulses to sample the analog wave-
form. This strategy has been successfully used
by a small number of patients who have little or
no issues with simultaneous stimulation. Good
performance has been reported, particularly for
music perception.10

Figure 2 The block diagram of a 6-channel continuous interleaved sampling (CIS) coding strategy. The spectrum of
input speech is first equalized with a preemphasis high-pass filter. A filter bank then splits the speech into 6 subband
signals, vibrating around carrier frequencies from low to high, respectively. Each signal’s slowly varying envelope is
extracted with a rectifier followed by a low-pass filter whereas its fast-changing fine structure is discarded. The acoustic
envelope is further compressed nonlinearly to match the narrow electric dynamic range. Finally, all six envelopes are
sampled and modulated with interleaved biphasic pulses that are sent to stimulation electrodes (E1–E6).
**Hi-Resolution Strategy.** The standard CIS strategy offers 6-channel stimulation at a rate of 833 pps, which is capable of encoding temporal information below 400 Hz (roughly half of the stimulation rate). To deliver more spectral and temporal information, Advanced Bionics developed the high resolution (HiRes) strategy that stimulates 16 channels at a rate of up to 5,156 pps per channel.

In clinical fitting, the HiRes strategy can be either set as sequential stimulation (HiRes-S) or paired stimulation (HiRes-P), similar to the CIS or the PPS strategy described above. When the pulse width is 10.8 μs, for instance, the HiRes-S sequentially sends pulses to 16 monopolar channels at a maximum rate of 2,900 pps per channel. At the same setting, the HiRes-P can perform a duo of stimulation with 1 pair of channels being activated simultaneously, increasing the stimulation rate up to 5,156 pps. The HiRes strategy is now available in Advanced Bionics’ HiRes90K and CII implants.

For comparison, Figure 3 shows a set of stimulation patterns illustrating the CA, SAS CIS, PPS, and ACE strategy’s outputs in response to a short segment of speech stimuli. The CA strategy sends each individual channel the raw analog currents, oscillating around a specific center frequency. However, the SAS strategy samples each analog waveform, creating a series of stair waves. In contrast, discrete biphasic pulse trains are being used in the CIS, PPS, and ACE strategies. The black bars on top of panel (C), (D), and (E) indicate 1 stimulation cycle, respectively. Within 1 cycle, the CIS strategy sequentially stimulates each electrode. Instead, the PPS strategy simultaneously stimulates one pair of electrodes. In ACE, 6 of 20 electrodes are activated in this example within 1 cycle. Similar patterns can be found in the n of m and the SPEAK strategy.

**The Future: Combination for Better Speech Understanding and Music Appreciation**

Although only crude spectral and temporal cues are being encoded in all speech coding strategies, cochlear implants have been successful in restoring speech understanding abilities to deaf patients. Adults and children with monaural cochlear implants can achieve high levels of phoneme and sentence recognition under relatively quiet listening conditions. Nonetheless, problems still remain under adverse listening conditions: multitalker speech or speech in background noise poses challenges to implant users; most implantees are unable to appreciate music normally; they may understand what is being said but not who says it; and tone and pitch perception are poor compared to normal hearing listeners.

One major cause for these existing problems is that current auditory prosthetic technologies are limited in their representation of sounds with high spectral and temporal resolutions. For the speech resolution, even though 12 to 22 channels are being stimulated in implants, the number of functional channel is from 4 to 8 as demonstrated by a variety of psychoacoustic experiments. For the temporal resolution, only the temporal envelope cues are being coded in most strategies, and the fine structure cues are mostly discarded as a result of envelope extraction. Implant users can only detect temporal pitch change below 300 to 500 Hz (maximum 1,000 Hz). Higher stimulation rate and analog strategies may provide more temporal cues, but to what extent a patient can utilize them remains a debatable issue.

Several novel technologies of improving coding strategies are under investigation or in clinical trial. One approach for patients with residual hearing is the combination of electric and acoustic stimulation (EAS) by inserting a short electrode array that provides high frequency information while preserving the residual low frequency hearing in the same ear, or by combining a cochlear implant with a hearing aid in the opposite ear.

In addition, a hybrid coding strategy that combines the analog or digitized waveform stimulation at lower frequency bands with envelope stimulation at higher frequency bands could provide sufficient cues for tone, music and pitch perceptions. A more promising strategy is the utilization of “virtual channel” stimulation to improve spectral resolution. Balancing the weights of 2 adjacent simultaneously active electrodes can create intermediate channels. To improve temporal resolution further, a conditioning stimulation strategy is also under study. In this experimental strategy, high rate pulse trains barely below the electric threshold levels are running in addition to a specific speech coding strategy. The conditioners can randomize the firing of auditory neurons to mimic the stochastic neural firing characteristics found in normal hearing. All these emerging new technologies
hold the hope of restoring speech and music perception closer to normal hearing.19

PROGRAMMING A COCHLEAR IMPLANT
